Causal Reasoning with Ancestral Graphs

Editor: Gregory F. Cooper

Abstract

Causal reasoning is primarily concerned with what would happen to a system under external interventions. In particular, we are often interested in predicting the probability distribution of some random variables that would result if some other variables were *forced* to take certain values. One prominent approach to tackling this problem is based on causal Bayesian networks, using directed acyclic graphs as *causal* diagrams to relate post-intervention probabilities to pre-intervention probabilities that are estimable from observational data. However, such causal diagrams are seldom fully testable given observational data. In consequence, many causal discovery algorithms based on data-mining can only output an equivalence class of causal diagrams (rather than a single one). This paper is concerned with causal reasoning given an equivalence class of causal diagrams, represented by a (partial) *ancestral graph*. We present two main results. The first result extends Pearl (1995)'s celebrated *do-calculus* to the context of ancestral graphs. In the second result, we focus on a key component of Pearl's calculus—the property of *invariance under interventions*, and give stronger graphical conditions for this property than those implied by the first result. The second result also improves the earlier, similar results due to Spirtes et al. (1993).

Keywords: ancestral graphs, causal Bayesian network, do-calculus, intervention

1. Introduction

Intellectual curiosity aside, an important reason for people to care about causality or causal explanation is the need—for example, in policy assessment or decision making—to predict consequences of actions or interventions before actually carrying them out. Sometimes we can base that prediction on similar past interventions or experiments, in which case the inference is but an instance of the classical inductive generalization. Other times, however, we do not have access to sufficient controlled experimental studies for various reasons, and can only make passive observations before interventions take place. Under the latter circumstances, we need to reason from pre-intervention or observational data to a post-intervention setting.

A prominent machinery for causal reasoning of this kind is known as *causal Bayesian network* (Spirtes et al., 1993; Pearl, 2000), which we will describe in more detail in the next section. In this framework, once the causal structure—represented by a directed acyclic graph (DAG) over a set of attributes or random variables—is fully given, every query about post-intervention probability can be answered in terms of pre-intervention probabilities. So, if every variable in the causal structure is (passively) observed, the observational data can be used to estimate the post-intervention probability of interest.

Complications come in at least two ways. First, some variables in the causal DAG may be unobserved, or worse, unobservable. So even if the causal DAG (with latent variables) is fully known, we may not be able to predict certain intervention effects because we only have data from the marginal distribution over the observed variables instead of the joint distribution over all causally relevant variables. The question is what post-intervention probability is or is not identifiable given a causal DAG with latent variables. Much of Pearl's work (Pearl, 1995, 1998, 2000), and more recently Tian and Pearl (2004) are paradigmatic attempts to address this problem.

Second, the causal structure is seldom, if ever, fully known. In the situation we are concerned with in this paper, where no substantial background knowledge or controlled study is available, we have to rely upon observational data to inform us about causal structure. The familiar curse is that very rarely can observational data determine a unique causal structure, and many causal discovery algorithms in the literature output an equivalence class of causal structures based on observational data (Spirtes et al., 1993; Meek, 1995a; Spirtes et al., 1999; Chickering, 2002).[1] Different causal structures in the class may or may not give the same answer to a query about post-intervention probability. For a simple illustration, consider two causal Bayesian networks (see Section 2 below), $X \rightarrow Y \rightarrow Z$ and $X \leftarrow Y \rightarrow Z$, over three variables X, Y and Z. The two causal structures are indistinguishable (without strong parametric assumptions) by observational data. Suppose we are interested in the post-intervention probability distribution of Y given that X is manipulated to take some fixed value x. The structure $X \rightarrow Y \rightarrow Z$ entails that the post-intervention distribution of Y is identical to the pre-intervention distribution of Y *conditional on* $X = x$, whereas the structure $X \leftarrow Y \rightarrow Z$ entails that the post-intervention distribution of Y is identical to the pre-intervention marginal distribution of Y. So the two structures give different answers to this particular query. By contrast, if we are interested in the post-intervention distribution of Z under an intervention on Y, the two structures give the same answer.

The matter becomes formidably involved when both complications are present. Suppose we observe a set of random variables $\mathbf{O}$, but for all we know, the underlying causal structure may involve extra latent variables. We will not worry about the estimation of the pre-intervention distribution of $\mathbf{O}$ in this paper, so we may well assume for simplicity that the pre-intervention distribution of $\mathbf{O}$ is known. But we are interested in queries about post-intervention probability, such as the probability of $\mathbf{Y}$ conditional on $\mathbf{Z}$ that would result under an intervention on $\mathbf{X}$ (where $\mathbf{X}, \mathbf{Y}, \mathbf{Z} \subseteq \mathbf{O}$). The question is whether and how we can answer such queries from the given pre-intervention distribution of $\mathbf{O}$.

This problem is naturally divided into two parts. The first part is what some causal discovery algorithms attempt to achieve, namely, to learn something about the causal structure—usually features shared by all causal structures in an equivalence class—from the pre-intervention distribution of $\mathbf{O}$. The second part is to figure out, given the learned causal information, whether a post-intervention probability is identifiable in terms of pre-intervention probabilities.

This paper provides some results concerning the second part, assuming the available causal information is summarized in a (partial) *ancestral graph*. Ancestral graphical models (Richardson and Spirtes, 2002, 2003) have proved to be an elegant and useful surrogate for DAG models with latent variables (more details follow in Section 3), not the least because provably correct algorithms are available for learning an equivalence class of ancestral graphs represented by a partial ancestral graph from the pre-intervention distribution of the observed variables—in particular, from the

1. The recent work on linear non-Gaussian structural equation models (Shimizu et al., 2006) is an exception. However, we do not make parametric assumptions in this paper.

conditional independence and dependence relations implied by the distribution (Spirtes et al., 1999; Zhang, forthcoming).

We have two main results. First, we extend the *do*-calculus of Pearl (1995) to the context of ancestral graphs (Section 4), so that the resulting calculus is based on an equivalence class of causal DAGs with latent variables rather than a single one. Second, we focus on a key component of Pearl's calculus—the property of *invariance under interventions* studied by Spirtes et al. (1993), and give stronger graphical conditions for this property than those implied by the first result (Section 5). Our result improves upon the Spirtes-Glymour-Scheines conditions for invariance formulated with respect to the so-called *inducing path graphs*, whose relationship with ancestral graphs is discussed in Appendix A.

2. Causal Bayesian Network

A Bayesian network for a set of random variables $\mathbf{V}$ consists of a pair $\langle \mathcal{G}, P \rangle$, where $\mathcal{G}$ is a directed acyclic graph (DAG) with $\mathbf{V}$ as the set of vertices, and P is the joint probability function of $\mathbf{V}$, such that P factorizes according to $\mathcal{G}$ as follows:

$$P(\mathbf{V}) = \prod_{Y \in \mathbf{V}} P(Y | \mathbf{Pa}_{\mathcal{G}}(Y))$$

where $\mathbf{Pa}_{\mathcal{G}}(Y)$ denotes the set of parents of Y in $\mathcal{G}$. In a causal Bayesian network, the DAG $\mathcal{G}$ is interpreted causally, as a representation of the causal structure over $\mathbf{V}$. That is, for $X, Y \in \mathbf{V}$, an arrow from X to Y ($X \to Y$) in $\mathcal{G}$ means that X has a *direct* causal influence on Y relative to $\mathbf{V}$. We refer to a causally interpreted DAG as a **causal DAG**. The postulate that the (pre-intervention) joint distribution P factorizes according to the causal DAG $\mathcal{G}$ is known as the **causal Markov condition**.

What about interventions? For simplicity, let us focus on what Pearl (2000) calls *atomic* interventions—interventions that fix the values of the target variables—though the results in Section 5 also apply to more general types of interventions (such as interventions that confer a non-degenerate probability distribution on the target variables). In the framework of causal Bayesian network, an intervention on $\mathbf{X} \subseteq \mathbf{V}$ is supposed to be *effective* in the sense that the value of $\mathbf{X}$ is completely determined by the intervention, and *local* in the sense that the conditional distributions of other variables (variables not in $\mathbf{X}$) given their respective parents in the causal DAG are not affected by the intervention. Graphically, such an intervention amounts to erasing all arrows into $\mathbf{X}$ in the causal DAG (because variables in $\mathbf{X}$ do not depend on their original parents any more), but otherwise keeping the graph as it is. Call this modified graph the **post-intervention causal graph**.

Based on this understanding of interventions, the following postulate has been proposed by several authors in various forms (Robins, 1986; Spirtes et al., 1993; Pearl, 2000):

> **Intervention Principle** Given a causal DAG $\mathcal{G}$ over $\mathbf{V}$ and a (pre-intervention) joint distribution P that factorizes according to $\mathcal{G}$, the post-intervention distribution $P_{\mathbf{X}:=\mathbf{x}}(\mathbf{V})$—that is, the joint distribution of $\mathbf{V}$ after $\mathbf{X} \subseteq \mathbf{V}$ are manipulated to values $\mathbf{x}$ by an intervention—takes a similar, truncated form of factorization, as follows:
>
> $$P_{\mathbf{X}:=\mathbf{x}}(\mathbf{V}) = \begin{cases} \prod_{Y \in \mathbf{V} \setminus \mathbf{X}} P(Y | \mathbf{Pa}_{\mathcal{G}}(Y)) & \text{for values of } \mathbf{V} \text{ consistent with } \mathbf{X} = \mathbf{x}, \\ 0 & \text{otherwise.} \end{cases}$$

Note that in the case of a null intervention (when $\mathbf{X} = \emptyset$), the intervention principle implies the factorization of the pre-intervention distribution P according to $\mathcal{G}$, which is just the causal Markov

condition. So the intervention principle generalizes the causal Markov condition: it assumes that the post-intervention distribution also satisfies the causal Markov condition with the post-intervention causal graph.

By the intervention principle, once the causal DAG is given, the post-intervention joint distribution can be calculated in terms of pre-intervention probabilities.[2] So if every variable is observed, and hence those pre-intervention probabilities can be estimated, any post-intervention probability is estimable as well.

It is time to recall the two complications mentioned in the last section. First, the intervention principle is only plausible when the given set of variables is *causally sufficient*. Here is what causal sufficiency means. Given a set of variables $\mathbf{V}$, and two variables $A, B \in \mathbf{V}$, a variable C (not necessarily included in $\mathbf{V}$) is called a *common direct cause* of A and B relative to $\mathbf{V}$ if C has a direct causal influence on A and also a direct causal influence on B relative to $\mathbf{V} \cup \{C\}$. $\mathbf{V}$ is said to be *causally sufficient* if for every pair of variables $V_1, V_2 \in \mathbf{V}$, every common direct cause of V_1 and V_2 relative to $\mathbf{V}$ is also a member of $\mathbf{V}$. It is well known that the causal Markov condition tends to fail for a causally insufficient set of variables (Spirtes et al., 1993), and even more so with the intervention principle. But in most real situations, there is no reason to assume that the set of observed variables is causally sufficient, so the causal Bayesian network may well involve latent variables.

Second, the causal DAG is not fully learnable with observational, pre-intervention data. The causal discovery algorithms in the literature—some of which are provably correct in the large sample limit assuming the causal Markov condition and its converse, causal Faithfulness condition—typically return an equivalence class of DAGs that imply the same conditional independence relations among the observed variables (according to the Markov condition), with some causal features in common that constitute the learned causal information. Given such limited causal information, a post-intervention probability may or may not be uniquely identifiable.

Taking both complications into account, the interesting question is this: what causal reasoning is warranted given the causal information learnable by algorithms that do not assume causal sufficiency for the set of observed variables, such as the FCI algorithm presented in Spirtes et al. (1999)? Before we explore the question, let us make it a little more precise with the formalism of ancestral graphs.

3. Ancestral Graphical Models

Ancestral graphical models are motivated by the need to represent data generating processes that may involve latent confounders and/or selection bias,[3] without explicitly modelling the unobserved variables (Richardson and Spirtes, 2002). We do not deal with selection bias in this paper, so we use only part of the machinery.

A (directed) *mixed graph* is a vertex-edge graph that may contain two kinds of edges: directed edges ($\rightarrow$) and bi-directed edges ($\leftrightarrow$). Between any two vertices there is at most one edge. The two ends of an edge we call *marks*. Obviously there are two kinds of marks: *arrowhead* ($>$) and *tail* ($-$). The marks of a bi-directed edge are both arrowheads, and a directed edge has one arrowhead

2. A technical issue is that some conditional probabilities may be undefined in the pre-intervention distribution. In this paper we ignore that issue by assuming that the pre-intervention distribution is strictly positive. Otherwise we just need to add the proviso "when all the conditional probabilities involved are defined" to all our results.
3. Roughly speaking, there is selection bias if the probability of a unit being sampled depends on certain properties of the unit. The kind of selection bias that is especially troublesome for causal inference is when two or more properties of interest affect the probability of being sampled, giving rise to "misleading" associations in the sample.

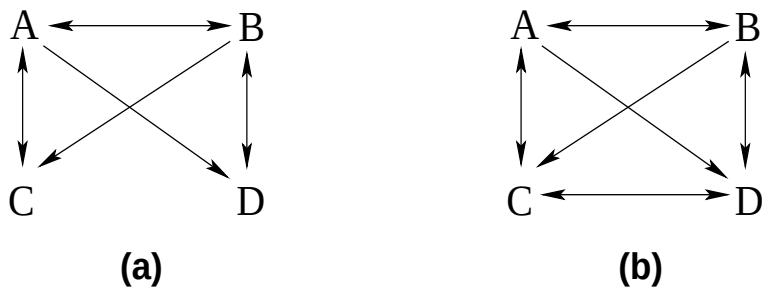

Figure 1: (a) an ancestral graph that is not maximal; (b) a maximal ancestral graph.

and one tail. We say an edge is *into* (or *out of*) a vertex if the mark of the edge at the vertex is an arrowhead (or tail).

Two vertices are said to be *adjacent* in a graph if there is an edge (of any kind) between them. Given a mixed graph $\mathcal{G}$ and two adjacent vertices X, Y therein, X is called a *parent* of Y and Y a *child* of X if $X \rightarrow Y$ is in $\mathcal{G}$; X is called a *spouse* of Y (and Y a spouse of X) if $X \leftrightarrow Y$ is in $\mathcal{G}$. A *path* in $\mathcal{G}$ is a sequence of distinct vertices $\langle V_0, ..., V_n \rangle$ such that for all $0 \leq i \leq n-1$, V_i and V_{i+1} are adjacent in $\mathcal{G}$. A *directed path from V_0 to V_n* in $\mathcal{G}$ is a sequence of distinct vertices $\langle V_0, ..., V_n \rangle$ such that for all $0 \leq i \leq n-1$, V_i is a parent of V_{i+1} in $\mathcal{G}$. X is called an *ancestor* of Y and Y a *descendant* of X if $X = Y$ or there is a directed path from X to Y. We use $\mathbf{Pa}_{\mathcal{G}}, \mathbf{Ch}_{\mathcal{G}}, \mathbf{Sp}_{\mathcal{G}}, \mathbf{An}_{\mathcal{G}}, \mathbf{De}_{\mathcal{G}}$ to denote the set of parents, children, spouses, ancestors, and descendants of a vertex in $\mathcal{G}$, respectively. A *directed cycle* occurs in $\mathcal{G}$ when $Y \rightarrow X$ is in $\mathcal{G}$ and $X \in \mathbf{An}_{\mathcal{G}}(Y)$. An *almost directed cycle* occurs when $Y \leftrightarrow X$ is in $\mathcal{G}$ and $X \in \mathbf{An}_{\mathcal{G}}(Y)$.[4]

Given a path $p = \langle V_0, ..., V_n \rangle$ with $n > 1$, V_i ($1 \leq i \leq n-1$) is a *collider* on p if the two edges incident to V_i are both into V_i, that is, have an arrowhead at V_i; otherwise it is called a *noncollider* on p. In Figure 1(a), for example, B is a collider on the path $\langle A, B, D \rangle$, but is a non-collider on the path $\langle C, B, D \rangle$. A *collider path* is a path on which every vertex except for the endpoints is a collider. For example, in Figure 1(a), the path $\langle C, A, B, D \rangle$ is a collider path because both A and B are colliders on the path. Let $\mathbf{L}$ be any subset of vertices in the graph. An *inducing path relative to* $\mathbf{L}$ is a path on which every vertex not in $\mathbf{L}$ (except for the endpoints) is a collider on the path and every collider is an ancestor of an endpoint of the path. For example, any single-edge path is trivially an inducing path relative to any set of vertices (because the definition does not constrain the endpoints of the path). In Figure 1(a), the path $\langle C, B, D \rangle$ is an inducing path relative to $\{B\}$, but not an inducing path relative to the empty set (because B is not a collider). However, the path $\langle C, A, B, D \rangle$ is an inducing path relative to the empty set, because both A and B are colliders on the path, A is an ancestor of D, and B is an ancestor of C. To simplify terminology, we will henceforth refer to inducing paths relative to the empty set simply as inducing paths.[5]

Definition 1 (MAG) *A mixed graph is called a maximal ancestral graph (MAG) if*

i. the graph does not contain any directed or almost directed cycles (ancestral); and

4. The terminology of "almost directed cycle" is motivated by the fact that removing the arrowhead at Y on $Y \leftrightarrow X$ results in a directed cycle.
5. They are called *primitive inducing paths* by Richardson and Spirtes (2002).

ii. there is no inducing path between any two non-adjacent vertices (maximal).

The first condition is obviously an extension of the defining condition for DAGs. It follows that in an ancestral graph an arrowhead, whether on a directed edge or a bi-directed edge, implies non-ancestorship. The second condition is a technical one, but the original motivation is the familiar pairwise Markov property of DAGs: if two vertices are not adjacent, then they are d-separated by some set of other vertices. The notion of d-separation carries over to mixed graphs in a straightforward way, as we will see shortly. But in general an ancestral graph does not need to satisfy the pairwise Markov property, or what is called maximality here. A sufficient and necessary condition for maximality turns out to be precisely the second clause in the above definition, as proved by Richardson and Spirtes (2002). So although the graph in Figure 1(a) is ancestral, it is not maximal because there is an inducing path between C and D (i.e., $\langle C, A, B, D \rangle$), but C and D are not adjacent. However, each non-maximal ancestral graph has a unique supergraph that is ancestral and maximal. For example, Figure 1(b) is the unique MAG that is also a supergraph of Figure 1(a); the former has an extra bi-directed edge between C and D.

It is worth noting that both conditions in Definition 1 are obviously met by a DAG. Hence, syntactically a DAG is also a MAG, one without bi-directed edges.

An important notion in directed graphical models is that of d-separation, which captures exactly the conditional independence relations entailed by a DAG according to the Markov condition. It is straightforward to extend the notion to mixed graphs, which, following Richardson and Spirtes (2002), we call *m-separation*.

Definition 2 (m-separation) *In a mixed graph, a path p between vertices X and Y is active (or m-connecting) relative to a (possibly empty) set of vertices $\mathbf{Z}$ ($X, Y \notin \mathbf{Z}$) if*

i. every non-collider on p is not a member of $\mathbf{Z}$;

ii. every collider on p is an ancestor of some member of $\mathbf{Z}$.

X and Y are said to be m-separated by $\mathbf{Z}$ if there is no active path between X and Y relative to $\mathbf{Z}$.

Two disjoint sets of variables $\mathbf{X}$ and $\mathbf{Y}$ are m-separated by $\mathbf{Z}$ if every variable in $\mathbf{X}$ is m-separated from every variable in $\mathbf{Y}$ by $\mathbf{Z}$.

In DAGs, obviously, m-separation reduces to d-separation. The (global) Markov property of ancestral graphical models is defined by m-separation.

A nice property of MAGs is that they can represent the marginal independence models of DAGs in the following sense: given any DAG $\mathcal{G}$ over $\mathbf{V} = \mathbf{O} \cup \mathbf{L}$—where $\mathbf{O}$ denotes the set of observed variables, and $\mathbf{L}$ denotes the set of latent variables—there is a MAG over $\mathbf{O}$ alone such that for any disjoint $\mathbf{X}, \mathbf{Y}, \mathbf{Z} \subseteq \mathbf{O}$, $\mathbf{X}$ and $\mathbf{Y}$ are d-separated by $\mathbf{Z}$ in $\mathcal{G}$ (and hence entailed by $\mathcal{G}$ to be independent conditional on $\mathbf{Z}$) if and only if they are m-separated by $\mathbf{Z}$ in the MAG (and hence entailed by the MAG to be independent conditional on $\mathbf{Z}$). The following construction gives us such a MAG:

Input: a DAG $\mathcal{G}$ over $\langle \mathbf{O}, \mathbf{L} \rangle$
Output: a MAG $\mathcal{M}_{\mathcal{G}}$ over $\mathbf{O}$

1. for each pair of variables $A, B \in \mathbf{O}$, A and B are adjacent in $\mathcal{M}_{\mathcal{G}}$ if and only if there is an inducing path between them relative to $\mathbf{L}$ in $\mathcal{G}$;

2. for each pair of adjacent variables A, B in $\mathcal{M}_\mathcal{G}$, orient the edge as $A \rightarrow B$ in $\mathcal{M}_\mathcal{G}$ if A is an ancestor of B in $\mathcal{G}$; orient it as $A \leftarrow B$ in $\mathcal{M}_\mathcal{G}$ if B is an ancestor of A in $\mathcal{G}$; orient it as $A \leftrightarrow B$ in $\mathcal{M}_\mathcal{G}$ otherwise.

It can be shown that $\mathcal{M}_\mathcal{G}$ is indeed a MAG and represents the marginal independence model over $\mathbf{O}$ (Richardson and Spirtes, 2002; also see Lemma 20 below). More importantly, $\mathcal{M}_\mathcal{G}$ also retains the ancestral relationships—and hence causal relationships under the standard interpretation—among $\mathbf{O}$. So, if $\mathcal{G}$ is the causal DAG for $\langle \mathbf{O}, \mathbf{L} \rangle$, it is fair to call $\mathcal{M}_\mathcal{G}$ the **causal MAG** for $\mathbf{O}$. Henceforth when we speak of a MAG over $\mathbf{O}$ *representing* a DAG over $\langle \mathbf{O}, \mathbf{L} \rangle$, we mean that the MAG is the output of the above construction procedure applied to the DAG.

Different causal DAGs may correspond to the same causal MAG. So essentially a MAG represents a set of DAGs that have the exact same d-separation structures and ancestral relationships among the observed variables. A causal MAG thus carries uncertainty about what the true causal DAG is, but also reveals features that must be satisfied by the underlying causal DAG.

There is then a natural causal interpretation of the edges in MAGs, derivative from the causal interpretation of DAGs. A directed edge from A to B in a MAG means that A is a cause of B (which is a shorthand way of saying that there is a causal pathway from A to B in the underlying DAG); a bi-directed edge between A and B means that A is not a cause of B and B is not a cause of A, which implies that there is a latent common cause of A and B (i.e., there is a latent variable L in the underlying DAG such that there is a directed path from L to A and a directed path from L to B[6]).

We borrow a simple example from Spirtes et al. (1993) to illustrate various concepts and results in this paper. Suppose we are able to observe the following variables: *Income* (I), *Parents' smoking habits* (PSH), *Smoking* (S), *Genotype* (G) and *Lung cancer* (L). The data, for all we know, are generated according to an underlying mechanism which might involve unobserved common causes. Suppose, unknown to us, the structure of the causal mechanism is the one in Figure 2, where *Profession* is an unmeasured common cause of *Income* and *Smoking*.[7]

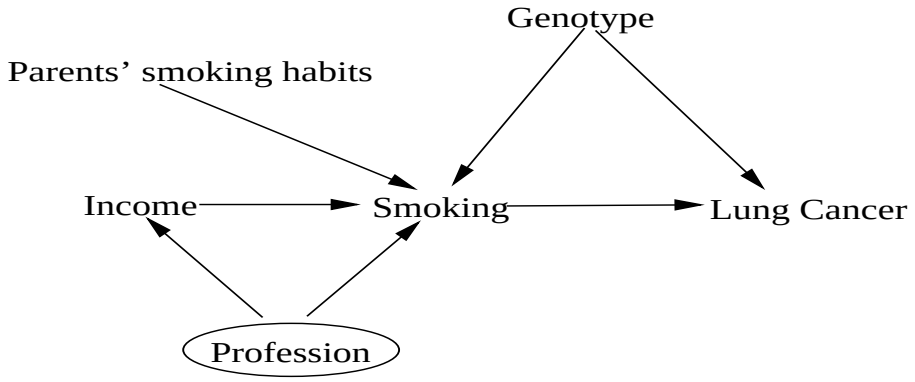

Figure 2: A causal DAG with a latent variable.

6. Note that a latent common cause is not necessarily a common *direct* cause as defined on page 4. The path from L to A, for example, may include other observed variables.
7. This example is used purely for illustrative purposes, so we will not worry why Profession is not observed but Genotype is. The exact domains of the variables do not matter either.

The causal MAG that corresponds to the causal DAG is depicted in Figure 3(a)—which *syntactically* happens to be a DAG in this case. This MAG can represent some other DAGs as well. For example, it can also represent the DAG with an extra latent common cause of *PSH* and *S*.

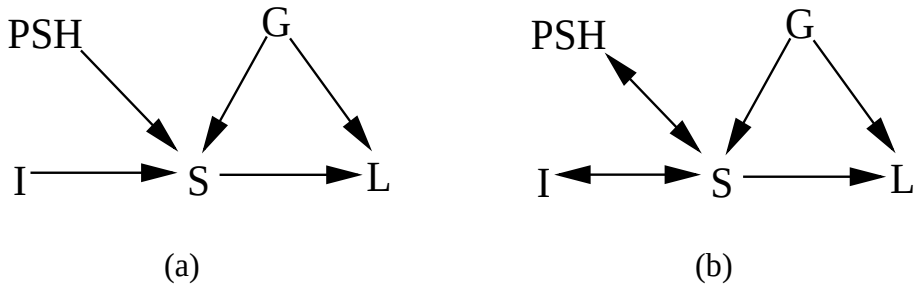

Figure 3: Two Markov Equivalent MAGs.

In general a MAG is still not fully testable with observational data. Just as different DAGs can share the exact same d-separation features and hence entail the exact same conditional independence constraints, different MAGs can entail the exact same constraints by the m-separation criterion. This is known as *Markov equivalence*. Several characterizations of the Markov equivalence between MAGs are available (Spirtes and Richardson, 1996; Ali et al., 2004; Zhang and Spirtes, 2005; Zhao et al., 2005). For the purpose of the present paper, it suffices to note that, as is the case with DAGs, all Markov equivalent MAGs have the same adjacencies and usually some common edge orientations as well. For example, the two MAGs in Figure 3 are Markov equivalent.

This motivates the following representation of equivalence classes of MAGs. Let *partial mixed graphs* denote the class of graphs that can contain four kinds of edges: $\rightarrow$, $\leftrightarrow$, $\circ\!\!-\!\!\circ$ and $\circ\!\!\rightarrow$, and hence three kinds of end marks for edges: arrowhead ($>$), tail ($-$) and circle ($\circ$).

Definition 3 (PAG) *Let $[\mathcal{M}]$ be the Markov equivalence class of an arbitrary MAG $\mathcal{M}$. The partial ancestral graph (PAG) for $[\mathcal{M}]$, $\mathcal{P}_{[\mathcal{M}]}$, is a partial mixed graph such that*

i. $\mathcal{P}_{[\mathcal{M}]}$ has the same adjacencies as $\mathcal{M}$ (and any member of $[\mathcal{M}]$) does;

ii. A mark of arrowhead is in $\mathcal{P}_{[\mathcal{M}]}$ if and only if it is shared by all MAGs in $[\mathcal{M}]$; and

iii. A mark of tail is in $\mathcal{P}_{[\mathcal{M}]}$ if and only if it is shared by all MAGs in $[\mathcal{M}]$.[8]

Basically a PAG represents an equivalence class of MAGs by displaying all common edge marks shared by all members in the class and displaying circles for those marks that are not common, much in the same way that a so-called Pattern (a.k.a. a PDAG or an essential graph) represents an equivalence class of DAGs (see, e.g., Spirtes et al., 1993, chap. 5; Chickering, 1995; Andersson et al., 1997). For instance, the PAG for our running example is drawn in Figure 4, which displays all the commonalities among MAGs that are Markov equivalent to the MAGs in Figure 3.

8. This defines what Zhang (2006, pp. 71) calls *complete* or *maximally oriented* PAGs. In this paper, we do not consider PAGs that fail to display all common edge marks in an equivalence class of MAGs (as, e.g., allowed in Spirtes et al., 1999), so we will simply use 'PAG' to mean 'maximally oriented PAG'.

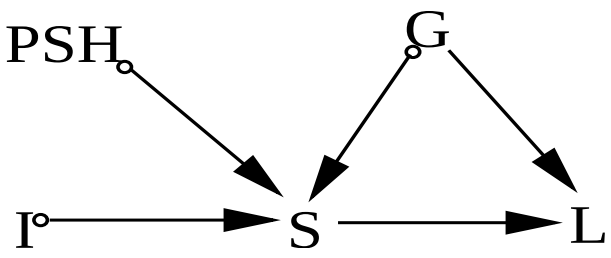

Figure 4: The PAG in our five-variable example.

Different PAGs, representing different equivalence classes of MAGs, entail different sets of conditional independence constraints. Hence a PAG is in principle fully testable by the conditional independence relations among the observed variables. Assuming the causal Markov condition and its converse, the causal Faithfulness condition,[9] there is a provably correct independence-constraint-based algorithm to learn a PAG from an oracle of conditional independence relations (Spirtes et al., 1999; Zhang, 2006, chap. 3).[10] Score-based algorithms for learning PAGs are also under investigation.

Directed paths and ancestors/descendants in a PAG are defined in the same way as in a MAG. In addition, a path between X and Y, $\langle X = V_0, ..., V_n = Y \rangle$, is called a *possibly directed path* from X to Y[11] if for every $0 < i \leq n$, the edge between V_{i-1} and V_i is not into V_{i-1}. Call X a *possible ancestor* of Y (and Y a *possible descendant* of X) if $X = Y$ or there is a possibly directed path from X to Y in the PAG.[12] For example, in Figure 4, the path $\langle I, S, L \rangle$ is a possibly directed path, and I is a possible ancestor of L. We use $\mathbf{PossibleAn}_{\mathcal{P}}(Y)$ to denote the set of possible ancestors of Y in $\mathcal{P}$.

In partial mixed graphs two analogues of m-connecting paths will play a role later. Let p be any path in a partial mixed graph, and W be any (non-endpoint) vertex on p. Let U and V be the two vertices adjacent to W on p. W is a *collider* on p if, as before, both the edge between U and W and the edge between V and W are into W (i.e., have an arrowhead at W, $U *\!\!\rightarrow W \leftarrow\!\!* V$). W is called a *definite non-collider* on p if the edge between U and W or the edge between V and W is out of W

9. We have introduced the causal Markov condition in its factorization form. In terms of d-separation, the causal Markov condition says that d-separation in a causal DAG implies conditional independence in the (pre-intervention) population distribution. The causal Faithfulness condition says that d-connection in a causal DAG implies conditional dependence in the (pre-intervention) population distribution. Given the exact correspondence between d-separation relations among the observed variables in the causal DAG and m-separation relations in the causal MAG, the two conditions imply that conditional independence relations among the observed variables correspond exactly to m-separation in the causal MAG, which forms the basis of constraint-based learning algorithms.
10. It is essentially the FCI algorithm (Spirtes et al., 1999), but with slight modifications (Zhang, 2006, chap. 3). The implemented FCI algorithm in the Tetrad IV package (http://www.phil.cmu.edu/projects/tetrad/tetrad4.html) is the modified version. By the way, if we also take into account the possibility of selection bias, then we need to consider a broader class of MAGs which can contain undirected edges, and the FCI algorithm needs to be augmented with additional edge inference rules (Zhang, 2006, chap. 4; forthcoming).
11. It is named a *potentially directed path* in Zhang (2006, pp. 99). The present terminology is more consistent with the names for other related notions, such as possible ancestor, possibly m-connecting path, etc.
12. The qualifier 'possible/possibly' is used to indicate that there is some MAG represented by the PAG in which the corresponding path is directed, and X is an ancestor of Y. This is not hard to establish given the valid procedure for constructing representative MAGs from a PAG presented in Lemma 4.3.6 of Zhang (2006) or Theorem 2 of Zhang (forthcoming).

(i.e., has a tail at W, $U \leftarrow W *\!\!-\!\!* V$ or $U *\!\!-\!\!* W \rightarrow V$), or both edges have a circle mark at W and there is no edge between U and V (i.e., $U *\!\!-\!\!\circ W \circ\!\!-\!\!* V$, where U and V are not adjacent).[13] The first analogue of m-connecting path is the following:

Definition 4 (Definite m-connecting path) *In a partial mixed graph, a path p between two vertices X and Y is a definite m-connecting path relative to a (possibly empty) set of vertices $\mathbf{Z}$ ($X, Y \notin \mathbf{Z}$) if every non-endpoint vertex on p is either a definite non-collider or a collider and*

i. every definite non-collider on p is not a member of $\mathbf{Z}$;

ii. every collider on p is an ancestor of some member of $\mathbf{Z}$.

It is not hard to see that if there is a definite m-connecting path between X and Y given $\mathbf{Z}$ in a PAG, then in every MAG represented by the PAG, the corresponding path is an m-connecting path between X and Y given $\mathbf{Z}$. For example, in Figure 4 the path $\langle I, S, G\rangle$ is definitely m-connecting given L, and this path is m-connecting given L in every member of the equivalence class. A quite surprising result is that if there is an m-connecting path between X and Y given $\mathbf{Z}$ in a MAG, then there must be a definite m-connecting path (not necessarily the same path) between X and Y given $\mathbf{Z}$ in its PAG, which we will use in Section 5.

Another analogue of m-connecting path is the following:

Definition 5 (Possibly m-connecting path) *In a partial mixed graph, a path p between vertices X and Y is possibly m-connecting relative to a (possibly empty) set of vertices $\mathbf{Z}$ ($X, Y \notin \mathbf{Z}$) if*

i. every definite non-collider on p is not a member of $\mathbf{Z}$;

ii. every collider on p is a possible ancestor of some member of $\mathbf{Z}$.

Obviously a definite m-connecting path is also a possibly m-connecting path, but not necessarily vice versa. In particular, on a possibly m-connecting path it is not required that every (non-endpoint) vertex be of a "definite" status. Figure 5 provides an illustration. The graph on the right is the PAG for the equivalence class that contains the MAG on the left (in this case, unfortunately, no informative edge mark is revealed in the PAG). In the PAG, the path $\langle X, Y, Z, W\rangle$ is a possibly m-connecting path but not a definite m-connecting path relative to $\{Y, Z\}$, because Y and Z are neither colliders nor definite non-colliders on the path. Note that in the MAG, $\langle X, Y, Z, W\rangle$ is not m-connecting relative to $\{Y, Z\}$. In fact, X and W are m-separated by $\{Y, Z\}$ in the MAG. So unlike a definite m-connecting path, a mere possibly m-connecting path in a PAG does not necessarily correspond to a m-connecting path (or imply the existence of a m-connecting path) in a representative MAG in the equivalence class.[14]

As we will see, the main result in Section 4 is formulated in terms of absence of possibly m-connecting paths (what we will call, for want of a better term, definite m-separation), whereas the

13. '*' is used as wildcard that denotes any of the three possible marks: circle, arrowhead, and tail. When the graph is a PAG for some equivalence class of MAGs, the qualifier 'definite' is used to indicate that the vertex is a non-collider on the path in each and every MAG represented by the PAG, even though the circles may correspond to different marks in different MAGs. The reason why $U *\!\!-\!\!\circ W \circ\!\!-\!\!* V$ is a definite non-collider when U and V are not adjacent is because if it were a collider, it would be shared by all Markov equivalent MAGs, and hence would be manifest in the PAG.

14. This case is even more extreme in that in *every* MAG that belongs to the equivalence class, X and W are m-separated by Y and Z. So this example can be used to show that the *do*-calculus developed in Section 4 is not yet complete, though it is not clear how serious the incompleteness is.

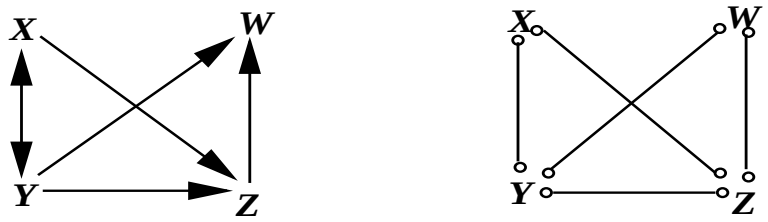

Figure 5: Difference between possible and definite m-connecting paths: in the PAG on the right, $\langle X, Y, Z, W \rangle$ is a possibly m-connecting path relative to $\{Y, Z\}$ but *not* a definite m-connecting path relative to $\{Y, Z\}$. Also note that $\langle X, Y, Z, W \rangle$ is *not* m-connecting relative to $\{Y, Z\}$ in the MAG on the left, even though the MAG is a member of the equivalence class represented by the PAG.

main result in Section 5 is formulated in terms of absence of definite m-connecting paths. This is one important aspect in which the result in Section 5 is better than that in Section 4 (and than the analogous results presented in Spirtes et al., 1993) regarding the property of invariance under interventions. We will come back to this point after we present the PAG-based *do*-calculus.

4. Do-Calculus

Pearl (1995) developed an elegant *do*-calculus for identifying post-intervention probabilities given a single causal DAG with (or without) latent variables. To honor the name of the calculus, in this section we will use Pearl's *'do' operator* to denote post-intervention probabilities. Basically, the notation we used for the post-intervention probability function under an intervention on $\mathbf{X}$, $P_{\mathbf{X}:=\mathbf{x}}(\bullet)$, will be written as $P(\bullet|do(\mathbf{X} = \mathbf{x}))$.

The calculus contains three inference rules whose antecedents make reference to surgeries on the given causal DAG. There are two types of graph manipulations:

Definition 6 (Manipulations of DAGs) *Given a DAG $\mathcal{G}$ and a set of variables $\mathbf{X}$ therein,*

- *the* **X-lower-manipulation** *of $\mathcal{G}$ deletes all edges in $\mathcal{G}$ that are out of variables in $\mathbf{X}$, and otherwise keeps $\mathcal{G}$ as it is. The resulting graph is denoted as $\mathcal{G}_{\underline{\mathbf{X}}}$.*
- *the* **X-upper-manipulation** *of $\mathcal{G}$ deletes all edges in $\mathcal{G}$ that are into variables in $\mathbf{X}$, and otherwise keeps $\mathcal{G}$ as it is. The resulting graph is denoted as $\mathcal{G}_{\overline{\mathbf{X}}}$.*

The following proposition summarizes Pearl's *do*-calculus. (Following Pearl, we use lower case letters to denote generic value settings for the sets of variables denoted by the corresponding upper case letters. So for simplicity we write $P(\mathbf{x})$ to mean $P(\mathbf{X} = \mathbf{x})$, and $do(\mathbf{x})$ to mean $do(\mathbf{X} = \mathbf{x})$.)

Proposition 7 (Pearl) *Let $\mathcal{G}$ be the causal DAG for $\mathbf{V}$, and $\mathbf{U}, \mathbf{X}, \mathbf{Y}, \mathbf{W}$ be disjoint subsets of $\mathbf{V}$. The following rules are sound:*

1. *if $\mathbf{Y}$ and $\mathbf{X}$ are d-separated by $\mathbf{U} \cup \mathbf{W}$ in $\mathcal{G}_{\overline{\mathbf{U}}}$, then*

$$P(\mathbf{y}|do(\mathbf{u}), \mathbf{x}, \mathbf{w}) = P(\mathbf{y}|do(\mathbf{u}), \mathbf{w}).$$

2. *if* $\mathbf{Y}$ *and* $\mathbf{X}$ *are d-separated by* $\mathbf{U} \cup \mathbf{W}$ *in* $\mathcal{G}_{\underline{\mathbf{X}}\overline{\mathbf{U}}}$*, then*

$$P(\mathbf{y}|do(\mathbf{u}), do(\mathbf{x}), \mathbf{w}) = P(\mathbf{y}|do(\mathbf{u}), \mathbf{x}, \mathbf{w}).$$

3. *if* $\mathbf{Y}$ *and* $\mathbf{X}$ *are d-separated by* $\mathbf{U} \cup \mathbf{W}$ *in* $\mathcal{G}_{\overline{\mathbf{U}\mathbf{X}'}}$*, then*

$$P(\mathbf{y}|do(\mathbf{u}), do(\mathbf{x}), \mathbf{w}) = P(\mathbf{y}|do(\mathbf{u}), \mathbf{w})$$

where $\mathbf{X}' = \mathbf{X} \backslash \mathbf{An}_{\mathcal{G}_{\overline{\mathbf{U}}}}(\mathbf{W}) = \mathbf{X} \backslash (\cup_{W \in \mathbf{W}} \mathbf{An}_{\mathcal{G}_{\overline{\mathbf{U}}}}(W))$.

The proposition follows from the intervention principle (Pearl, 1995). The first rule is actually not independent—it can be derived from the other two rules (Huang and Valtorta, 2006), but it has long been an official part of the calculus. The soundness of the calculus ensures that any post-intervention probability that can be reduced via the calculus to an expression that only involves pre-intervention probabilities of observed variables is identifiable. Recently, the completeness of the calculus was also established, in the sense that any identifiable post-intervention probability can be so reduced using the calculus (Huang and Valtorta, 2006; Shpister and Pearl, 2006).

Our goal is to develop a similar calculus when the available causal information is given in a PAG. A natural idea is to formulate analogous inference rules in terms of (manipulated) PAGs, to the effect that if a certain rule is applicable given a PAG, the corresponding rule in Pearl's calculus will be applicable given the (unknown) true causal DAG. How to guarantee that? Recall that a PAG represents an equivalence class of MAGs; each MAG, in turn, represents a set of causal DAGs. The union of all these sets is the set of DAGs represented by the PAG—one of them is the true causal DAG. So a sure way to get what we want is to formulate analogous rules in terms of PAGs such that if the rule is applicable given a PAG, then for every DAG represented by the PAG, the corresponding rule in Pearl's calculus is applicable.

For this purpose, it is natural to develop the desired calculus in two steps. First, we derive an analogous *do*-calculus based on MAGs, such that if a rule is applicable given a MAG, then for every DAG represented by the MAG, the corresponding rule in Pearl's calculus is applicable. Second, we extend that to a *do*-calculus based on PAGs, such that if a rule is applicable given a PAG, then for every MAG in the equivalence class represented by the PAG, the corresponding rule in the MAG-based calculus is applicable.

Before we define appropriate analogues of graph manipulations on MAGs, it is necessary to distinguish two kinds of directed edges in a MAG, according to the following criterion.

Definition 8 (Visibility) *Given a MAG* $\mathcal{M}$*, a directed edge* $A \to B$ *in* $\mathcal{M}$ *is* **visible** *if there is a vertex* C *not adjacent to* B*, such that either there is an edge between* C *and* A *that is into* A*, or there is a collider path between* C *and* A *that is into* A *and every vertex on the path is a parent of* B*. Otherwise* $A \to B$ *is said to be* **invisible**.

Figure 6 gives the possible configurations that make a directed edge $A \to B$ visible. The distinction between visible and invisible directed edges is important because of the following two facts.

Lemma 9 *Let* $\mathcal{G}$ *be a DAG over* $\mathbf{O} \cup \mathbf{L}$*, and* $\mathcal{M}$ *be the MAG over* $\mathbf{O}$ *that represents the DAG. For any* $A, B \in \mathbf{O}$*, if* $A \in \mathbf{An}_{\mathcal{G}}(B)$*, and there is an inducing path relative to* $\mathbf{L}$ *between* A *and* B *that is into* A *in* $\mathcal{G}$*, then there is a directed edge* $A \to B$ *in* $\mathcal{M}$ *that is invisible.*

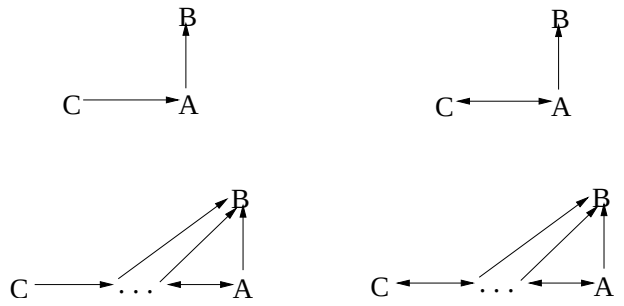

Figure 6: Possible configurations of visibility for $A \rightarrow B$.

Proof See Appendix B. ■

Taking the contrapositive of Lemma 9 gives us the fact that if $A \rightarrow B$ is visible in a MAG, then in *every* DAG represented by the MAG, there is no inducing path between A and B relative to the set of latent variables that is also into A. This implies that for every such DAG G, $G_{\underline{A}}$—the graph resulting from eliminating edges out of A in G—will not contain any inducing path between A and B relative to the set of latent variables, which means that the MAG that represents $G_{\underline{A}}$ will not contain any edge between A and B. So intuitively, deleting edges out of A in the underlying DAG corresponds to deleting visible arrows out of A in the MAG.

How about invisible arrows? Here is the relevant fact.

Lemma 10 *Let $\mathcal{M}$ be any MAG over a set of variables* **O**, *and $A \rightarrow B$ be any directed edge in $\mathcal{M}$. If $A \rightarrow B$ is invisible in $\mathcal{M}$, then there is a DAG whose MAG is $\mathcal{M}$ in which A and B share a latent parent, that is, there is a latent variable L_{AB} in the DAG such that $A \leftarrow L_{AB} \rightarrow B$ is a subgraph of the DAG.*

Proof See Appendix B. ■

Obviously $A \leftarrow L_{AB} \rightarrow B$ is an inducing path between A and B relative to the set of latent variables. So if $A \rightarrow B$ in a MAG is invisible, at least for *some* DAG G represented by the MAG—and for all we know, this DAG may well be the true causal DAG—$G_{\underline{A}}$ contains $A \leftarrow L_{AB} \rightarrow B$, and hence corresponds to a MAG in which $A \leftrightarrow B$ appears.

Finally, for either $A \leftrightarrow B$ or $A \rightarrow B$ in a MAG, it is not hard to show that for *every* DAG represented by the MAG, there is no inducing path in the DAG between A and B relative to the set of latent variables that is also out of B (since otherwise B would be an ancestor of A, violating the definition of ancestral graphs). So deleting edges into B in the underlying DAG corresponds to deleting edges into B in the MAG. These considerations motivate the following definition.

Definition 11 (Manipulations of MAGs) *Given a MAG $\mathcal{M}$ and a set of variables* **X** *therein,*

- *the* **X-lower-manipulation** *of $\mathcal{M}$ deletes all those edges that are visible in $\mathcal{M}$ and are out of variables in* **X**, *replaces all those edges that are out of variables in* **X** *but are invisible in $\mathcal{M}$ with bi-directed edges, and otherwise keeps $\mathcal{M}$ as it is. The resulting graph is denoted as $\mathcal{M}_{\underline{\mathbf{X}}}$.*

- *the* **X-upper-manipulation** *of $\mathcal{M}$ deletes all those edges in $\mathcal{M}$ that are into variables in* **X**, *and otherwise keeps $\mathcal{M}$ as it is. The resulting graph is denoted as $\mathcal{M}_{\overline{\mathbf{X}}}$.*

We stipulate that lower-manipulation has a higher priority than upper-manipulation, so that $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ (or $\mathcal{M}_{\overline{\mathbf{X}}\underline{\mathbf{Y}}}$) denotes the graph resulting from applying the **X***-upper-manipulation to the* **Y***-lower-manipulated graph of $\mathcal{M}$.*

A couple of comments are in order. First, unlike the case of DAGs, the lower-manipulation for MAGs may introduce new edges, that is, replacing invisible directed edges with bi-directed edges. Again, the reason we do this is that an invisible directed edge from A to B allows the possibility of a latent common parent of A and B in the underlying DAG. If so, the A-lower-manipulated DAG will correspond to a MAG in which there is a bi-directed edge between A and B. Second, because of the possibility of introducing new bi-directed edges, we need the priority stipulation that lower-manipulation is to be done before upper-manipulation. The stipulation is not necessary for DAGs, because no new edges would be introduced in the lower-manipulation of DAGs, and hence the order does not matter.

Ideally, if $\mathcal{M}$ is the MAG of a DAG $\mathcal{G}$, we would like $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ to be the MAG of $\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. But this is not always possible, as two DAGs represented by the same MAG before a manipulation may correspond to different MAGs after the manipulation. But we still have the following fact:

Lemma 12 *Let $\mathcal{G}$ be a DAG over $\mathbf{O} \cup \mathbf{L}$, and $\mathcal{M}$ be the MAG of $\mathcal{G}$ over* **O**. *Let* **X** *and* **Y** *be two possibly empty subsets of* **O**, *and $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$ be the MAG of $\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. For any $A, B \in \mathbf{O}$ and $\mathbf{C} \subseteq \mathbf{O}$ that does not contain A or B, if there is an m-connecting path between A and B given* **C** *in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$, then there is an m-connecting path between A and B given* **C** *in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$.*

Proof See Appendix B. ■

Recall that a graphical model is called an *independence map* of another if any independence implied by the former is also implied by the latter (Chickering, 2002). So another way of putting Lemma 12 is that $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ is an independence map of $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$, which we write as $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}} \leq \mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. The diagram in Figure 7 visualizes what is going on.

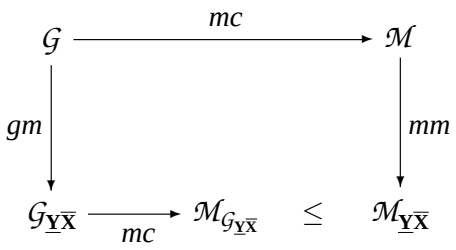

Figure 7: Illustration of Lemma 12: *mc* refers to MAG construction introduced in Section 3; *gm* refers to DAG manipulation; and *mm* refers to MAG manipulation.

Corollary 13 *Let $\mathcal{M}$ be a MAG over* **O**, *and* **X** *and* **Y** *be two subsets of* **O**. *For any $A, B \in$* **O** *and* **C** $\subseteq$ **O** *that does not contain A or B, if A and B are m-separated by* **C** *in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, then A and B are d-separated by* **C** *in $\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ for every $\mathcal{G}$ represented by $\mathcal{M}$.*

Proof By Lemma 12, if A and B are m-separated by **C** in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, they are also m-separated by **C** in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$, for every $\mathcal{G}$ represented by $\mathcal{M}$, which in turn implies that A and B are d-separated by **C** in $\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ for every $\mathcal{G}$ represented by $\mathcal{M}$, because d-separation relations among **O** in a DAG correspond exactly to m-separation relations in its MAG. ■

The converse of Corollary 13, however, is not true in general. To give the simplest example, consider the MAG $\mathcal{M}$ in Figure 8(a): $X \leftarrow Y \rightarrow Z$ (which happens to be a DAG syntactically). The two DAGs, $\mathcal{G}1$ in 8(b) and $\mathcal{G}2$ in 8(c), are both represented by $\mathcal{M}$. By the definition of lower-manipulation, $\mathcal{M}_{\underline{Y}}$ is the graph $X \leftrightarrow Y \leftrightarrow Z$. On the other hand, $\mathcal{G}1_{\underline{Y}}$ is $X \leftarrow L1 \rightarrow Y \quad Z$; and $\mathcal{G}2_{\underline{Y}}$ is $X \quad Y \leftarrow L2 \rightarrow Z$. Obviously, the MAG of $\mathcal{G}1_{\underline{Y}}$ is $X \leftrightarrow Y \quad Z$, and the MAG of $\mathcal{G}2_{\underline{Y}}$ is $X \quad Y \leftrightarrow Z$, both of which are *proper* subgraphs of $\mathcal{M}_{\underline{Y}}$. So an m-separation relation in $\mathcal{M}_{\underline{Y}}$—for example, X and Z are m-separated by the empty set—corresponds to a d-separation relation in both $\mathcal{G}1_{\underline{Y}}$ and $\mathcal{G}2_{\underline{Y}}$, in accord with Corollary 13.

By contrast, the converse of Corollary 13 fails for $\mathcal{M}$. It can be checked that for every $\mathcal{G}$ represented by $\mathcal{M}$, X and Z are d-separated by Y in $\mathcal{G}_{\underline{Y}}$, as evidenced by $\mathcal{G}1_{\underline{Y}}$ and $\mathcal{G}2_{\underline{Y}}$. But X and Z are not m-separated by Y in $\mathcal{M}_{\underline{Y}}$.

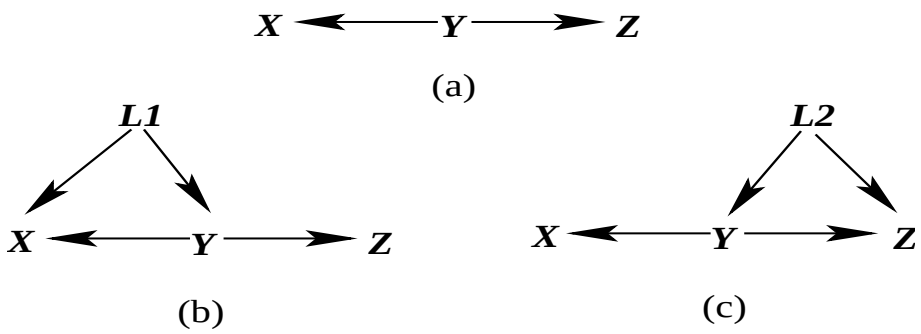

Figure 8: A counterexample to the converse of Corollary 13.

However, Definition 11 is not to be blamed for this limitation. In this simple example, one can easily enumerate all possible directed mixed graphs over X, Y, Z and see that for none of them do both Corollary 13 and its converse hold. Intuitively, this is because the MAG in Figure 8(a) implies that either $\langle X, Y \rangle$ does not have a common latent parent or $\langle Y, Z \rangle$ does not have a common latent parent in the underlying DAG. So under the Y-lower-manipulation of the underlying DAG, for all we know, either $\langle X, Y \rangle$ or $\langle Y, Z \rangle$ will become unconnected. But this disjunctive information cannot be precisely represented by a single graph.

More generally, no matter how we define $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, as long as it is a single graph, the converse of Corollary 13 will not hold in general, unless Corollary 13 itself fails. $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, as a single graph, can only aim to be a supergraph (up to Markov equivalence) of $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$ for every $\mathcal{G}$ represented by $\mathcal{M}$ (which makes Corollary 13 true). To this end, Definition 11 is 'minimal' in the following sense: two

variables are adjacent in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ if and only if there exists a DAG $\mathcal{G}$ represented by $\mathcal{M}$ such that the two variables are adjacent in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$. In this regard, $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ does not have more edges than necessary. One can, for example, check this fact for the simple case in Figure 8.

We are now ready to state the intermediate theorem on MAG-based *do*-calculus.

Theorem 14 (*do*-calculus given a MAG) *Let $\mathcal{M}$ be the causal MAG over $\mathbf{O}$, and $\mathbf{U}, \mathbf{X}$, $\mathbf{Y}$, $\mathbf{W}$ be disjoint subsets of $\mathbf{O}$. The following rules are valid, in the sense that if the antecedent of the rule holds, then the consequent holds no matter which DAG represented by $\mathcal{M}$ is the true causal DAG.*

1. *if $\mathbf{Y}$ and $\mathbf{X}$ are m-separated by $\mathbf{U} \cup \mathbf{W}$ in $\mathcal{M}_{\overline{\mathbf{U}}}$, then*

$$P(\mathbf{y}|do(\mathbf{u}), \mathbf{x}, \mathbf{w}) = P(\mathbf{y}|do(\mathbf{u}), \mathbf{w}).$$

2. *if $\mathbf{Y}$ and $\mathbf{X}$ are m-separated by $\mathbf{U} \cup \mathbf{W}$ in $\mathcal{M}_{\underline{\mathbf{X}}\overline{\mathbf{U}}}$, then*

$$P(\mathbf{y}|do(\mathbf{u}), do(\mathbf{x}), \mathbf{w}) = P(\mathbf{y}|do(\mathbf{u}), \mathbf{x}, \mathbf{w}).$$

3. *if $\mathbf{Y}$ and $\mathbf{X}$ are m-separated by $\mathbf{U} \cup \mathbf{W}$ in $\mathcal{M}_{\overline{\mathbf{U}\mathbf{X}'}}$, then*

$$P(\mathbf{y}|do(\mathbf{u}), do(\mathbf{x}), \mathbf{w}) = P(\mathbf{y}|do(\mathbf{u}), \mathbf{w})$$

where $\mathbf{X}' = \mathbf{X} \backslash \mathbf{An}_{\mathcal{M}_{\overline{\mathbf{U}}}}(\mathbf{W})$.

Proof This readily follows from Proposition 7, Corollary 13, and the fact that for every $\mathcal{G}$ represented by $\mathcal{M}$, $\mathbf{An}_{\mathcal{G}_{\overline{\mathbf{U}}}}(\mathbf{W}) \cap \mathbf{O} = \mathbf{An}_{\mathcal{M}_{\overline{\mathbf{U}}}}(\mathbf{W})$. ■

As already noted, the true causal MAG is not uniquely recoverable from the pre-intervention distribution, thanks to Markov equivalence. So the main value of Theorem 14 is to facilitate the development of a PAG-based *do*-calculus. However, it is worth noting that when supplemented with some background causal knowledge, such as knowledge of the form that some variable is not a cause of another variable, it is in principle possible to determine that the true causal MAG belongs to a proper subset of the full equivalence class represented by the PAG. Depending on how strong the background knowledge is, the subset could be as big as the full equivalence class or as small as a singleton. In this sense, Theorem 14 and Theorem 17 below may be viewed as two extreme cases of a more general *do*-calculus based on a subset of Markov equivalent MAGs.

To extend the calculus to PAGs, we need to define manipulations on PAGs. They are essentially the same as the manipulations of MAGs. The definition of visibility still makes sense in PAGs, except that we will call a directed edge in a PAG *definitely visible* if it satisfies the condition for visibility in Definition 8, in order to emphasize that this edge is visible in all MAGs in the equivalence class. Despite the extreme similarity to manipulations on MAGs, let us still write down the definition of PAG manipulations for easy reference.

Definition 15 (Manipulations of PAGs) *Given a PAG $\mathcal{P}$ and a set of variables $\mathbf{X}$ therein,*

- *the* **X-lower-manipulation** *of $\mathcal{P}$ deletes all those edges that are definitely visible in $\mathcal{P}$ and are out of variables in $\mathbf{X}$, replaces all those edges that are out of variables in $\mathbf{X}$ but are not definitely visible in $\mathcal{P}$ with bi-directed edges, and otherwise keeps $\mathcal{P}$ as it is. The resulting graph is denoted as $\mathcal{P}_{\underline{\mathbf{X}}}$.*

- *the* **X-upper-manipulation** *of $\mathcal{P}$ deletes all those edges in $\mathcal{P}$ that are into variables in* **X**, *and otherwise keeps $\mathcal{P}$ as it is. The resulting graph is denoted as $\mathcal{P}_{\overline{\mathbf{X}}}$.*

We stipulate that lower-manipulation has a higher priority than upper-manipulation, so that $\mathcal{P}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ (or $\mathcal{P}_{\overline{\mathbf{X}}\underline{\mathbf{Y}}}$) denotes the graph resulting from applying the **X***-upper-manipulation to the* **Y***-lower-manipulated graph of $\mathcal{P}$.*

We should emphasize that except in rare situations, $\mathcal{P}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ is not a PAG any more (i.e., not a PAG for any Markov equivalence class of MAGs). But from $\mathcal{P}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ we still gain information about m-separation in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, where $\mathcal{M}$ is a MAG that belongs to the Markov equivalence class represented by $\mathcal{P}$. Here is a simple connection. Given a MAG $\mathcal{M}$ and the PAG $\mathcal{P}$ that represents $[\mathcal{M}]$, a trivial fact is that a m-connecting path in $\mathcal{M}$ is also a possibly m-connecting path in $\mathcal{P}$. This is also true for $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ and $\mathcal{P}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$.

Lemma 16 *Let $\mathcal{M}$ be a MAG over* **O**, *and $\mathcal{P}$ be the PAG for $[\mathcal{M}]$. Let* **X** *and* **Y** *be two subsets of* **O**. *For any $A, B \in \mathbf{O}$ and $\mathbf{C} \subseteq \mathbf{O}$ that does not contain A or B, if a path p between A and B is m-connecting given* **C** *in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, then p, the same sequence of variables, forms a possibly m-connecting path between A and B given* **C** *in $\mathcal{P}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$.*[15]

Proof See Appendix B. ■

If there is no possibly m-connecting path between *A* and *B* given **C** in a partial mixed graph, we say that *A* and *B* are *definitely m-separated* by **C** in the graph. A *do*-calculus follows:

Theorem 17 (*do*-calculus given a PAG) *Let $\mathcal{P}$ be the causal PAG for* **O**, *and* $\mathbf{U}, \mathbf{X}, \mathbf{Y}, \mathbf{W}$ *be disjoint subsets of* **O**. *The following rules are valid:*

1. *if* **Y** *and* **X** *are definitely m-separated by $\mathbf{U} \cup \mathbf{W}$ in $\mathcal{P}_{\overline{\mathbf{U}}}$, then*

$$P(\mathbf{y}|do(\mathbf{u}), \mathbf{x}, \mathbf{w}) = P(\mathbf{y}|do(\mathbf{u}), \mathbf{w}).$$

2. *if* **Y** *and* **X** *are definitely m-separated by $\mathbf{U} \cup \mathbf{W}$ in $\mathcal{P}_{\underline{\mathbf{X}}\overline{\mathbf{U}}}$, then*

$$P(\mathbf{y}|do(\mathbf{u}), do(\mathbf{x}), \mathbf{w}) = P(\mathbf{y}|do(\mathbf{u}), \mathbf{x}, \mathbf{w}).$$

3. *if* **Y** *and* **X** *are definitely m-separated by $\mathbf{U} \cup \mathbf{W}$ in $\mathcal{P}_{\overline{\mathbf{U}\mathbf{X}'}}$, then*

$$P(\mathbf{y}|do(\mathbf{u}), do(\mathbf{x}), \mathbf{w}) = P(\mathbf{y}|do(\mathbf{u}), \mathbf{w})$$

where $\mathbf{X}' = \mathbf{X} \backslash \mathbf{PossibleAn}_{\mathcal{P}_{\overline{\mathbf{U}}}}(\mathbf{W})$.

15. For our purpose, what we need is the obvious consequence of the lemma that if there is an m-connecting path in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, then there is a possibly m-connecting path in $\mathcal{P}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. We suspect that a stronger result might hold as well: if there is an m-connecting path in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, then there is a definite m-connecting path in $\mathcal{P}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. We can't prove or disprove the stronger result at the moment.

Proof It follows from Lemma 16 and Theorem 14. The only caveat is that in general $\mathbf{An}_{\mathcal{M}_{\overline{\mathbf{U}}}}(\mathbf{W}) \neq \mathbf{PossibleAn}_{\mathcal{P}_{\overline{\mathbf{U}}}}(\mathbf{W})$ for an arbitrary $\mathcal{M}$ represented by $\mathcal{P}$. But it is always the case that $\mathbf{An}_{\mathcal{M}_{\overline{\mathbf{U}}}}(\mathbf{W}) \subseteq \mathbf{PossibleAn}_{\mathcal{P}_{\overline{\mathbf{U}}}}(\mathbf{W})$, which means that $\mathbf{X}\backslash\mathbf{An}_{\mathcal{M}_{\overline{\mathbf{U}}}}(\mathbf{W}) \supseteq \mathbf{X}\backslash\mathbf{PossibleAn}_{\mathcal{P}_{\overline{\mathbf{U}}}}(\mathbf{W})$ for every $\mathcal{M}$ represented by $\mathcal{P}$. So it is possible that for rule (3), $\mathcal{P}_{\overline{\mathbf{UX}'}}$ leaves more edges in than necessary, but it does not affect the validity of rule (3). ■

The possibility that $\mathcal{P}_{\overline{\mathbf{UX}'}}$ leaves more edges in than necessary is one of three aspects in which our *do*-calculus may be "incomplete" in the following sense: it is possible that a rule in the PAG-based *do*-calculus is not applicable, but for every DAG compatible with the given PAG, the corresponding rule in Pearl's DAG-based calculus is applicable. The other two aspects are already noted: (1) the calculus is formulated in terms of the absence of possibly m-connecting paths (cf. Footnote 14, and more on this in the next section); and (2) the MAG-based *do*-calculus is based on Corollary 13 whose converse does not hold. Therefore, the PAG-based *do*-calculus as currently formulated may be further improved.

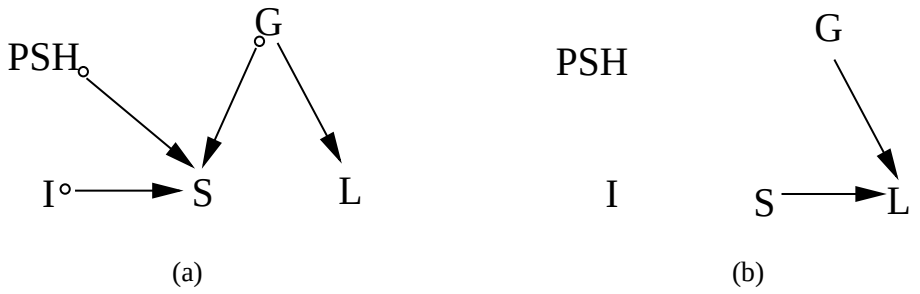

Figure 9: PAG Surgery: $\mathcal{P}_{\underline{S}}$ and $\mathcal{P}_{\overline{S}}$.

That said, let us illustrate the utility of the *do*-calculus with the simple example used in Section 3. Given the PAG in Figure 4 we can infer that $P(L|do(S),G) = P(L|S,G)$ by rule 2, because L and S are definitely m-separated by $\{G\}$ in $\mathcal{P}_{\underline{S}}$ (Figure 9(a)); and $P(G|do(S)) = P(G)$ by rule 3, because G and S are definitely m-separated in $\mathcal{P}_{\overline{S}}$ (Figure 9(b)). It follows that

$$\begin{aligned} P(L|do(S)) &= \sum_G P(L,G|do(S)) \\ &= \sum_G P(L|do(S),G)P(G|do(S)) \\ &= \sum_G P(L|S,G)P(G). \end{aligned}$$

By contrast, it is not valid in the *do*-calculus that $P(L|do(G),S) = P(L|G,S)$ because L and G are not definitely m-separated by $\{S\}$ in $\mathcal{P}_{\underline{G}}$, which is depicted in Figure 10. (Notice the bi-directed edge between L and G.)

5. Invariance Under Interventions

We now develop stronger results for a key component of *do*-calculus, the property of *invariance under interventions*, first systematically studied in Spirtes et al. (1993). The idea is simple. A

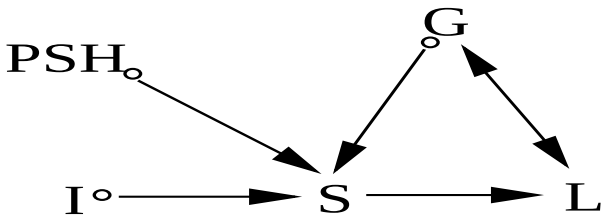

Figure 10: PAG Surgery: $\mathcal{P}_{\underline{G}}$.

conditional probability $P(\mathbf{Y} = \mathbf{y}|\mathbf{Z} = \mathbf{z})$ is said to be *invariant* under an intervention $\mathbf{X} := \mathbf{x}$—or $do(\mathbf{X} = \mathbf{x})$—if $P_{\mathbf{X}:=\mathbf{x}}(\mathbf{y}|\mathbf{z}) = P(\mathbf{y}|\mathbf{z})$.[16] This concept (under the name of 'observability') plays an important role in some interesting theoretical work on observational studies (e.g., Pratt and Schlaifer, 1988; for a good review see Winship and Morgan, 1999), and also forms the basis of the prediction algorithm presented in Spirtes et al. (1993), which seeks to identify a post-intervention probability by searching for an expression in terms of invariant probabilities.

It is also the corner stone of Pearl's *do*-calculus. To see this, let us take a closer look at the second and third rules in the *do*-calculus. The second rule of the calculus gives a graphical condition for when we can conclude

$$P(\mathbf{y}|do(\mathbf{u}), do(\mathbf{x}), \mathbf{w}) = P(\mathbf{y}|do(\mathbf{u}), \mathbf{x}, \mathbf{w}).$$

If we take $\mathbf{U}$ to be the empty set and write the above equation in the subscript notation, we get

$$P_{\mathbf{X}:=\mathbf{x}}(\mathbf{y}|\mathbf{w}) = P(\mathbf{y}|\mathbf{x}, \mathbf{w}).$$

Since $P_{\mathbf{X}:=\mathbf{x}}(\mathbf{X} = \mathbf{x}) = 1$, thanks to the supposed effectiveness of the intervention, we have

$$P_{\mathbf{X}:=\mathbf{x}}(\mathbf{y}|\mathbf{w}) = P_{\mathbf{X}:=\mathbf{x}}(\mathbf{y}|\mathbf{x}, \mathbf{w}).$$

So a special case of the second rule is a condition for $P_{\mathbf{X}:=\mathbf{x}}(\mathbf{y}|\mathbf{x}, \mathbf{w}) = P(\mathbf{y}|\mathbf{x}, \mathbf{w})$, that is, for when $P(\mathbf{y}|\mathbf{x}, \mathbf{w})$ is invariant under the intervention $\mathbf{X} := \mathbf{x}$. In fact, the second rule is nothing but a generalization of this condition to tell when a post-intervention probability $P_{\mathbf{u}}(\mathbf{y}|\mathbf{x}, \mathbf{w})$ would be invariant under a *further* intervention $\mathbf{X} := \mathbf{x}$.

The third rule is more obviously about invariance. It is a generalization of the condition for $P_{\mathbf{X}:=\mathbf{x}}(\mathbf{y}|\mathbf{w}) = P(\mathbf{y}|\mathbf{w})$, that is, for when $P(\mathbf{y}|\mathbf{w})$ is invariant under the intervention $\mathbf{X} := \mathbf{x}$. The difference between rule 2 and rule 3 is that rule 2 is about invariance of $P(\mathbf{y}|\mathbf{z})$ under an intervention on $\mathbf{X}$ in case $\mathbf{X} \subseteq \mathbf{Z}$ $(= \mathbf{X} \cup \mathbf{W})$, whereas rule 3 is about invariance of $P(\mathbf{y}|\mathbf{z})$ under an intervention on $\mathbf{X}$ in case $\mathbf{X}$ and $\mathbf{Z}$ $(= \mathbf{W})$ are disjoint. As we mentioned earlier, the first rule is not essential, so the *do*-calculus is in effect a generalization of conditions for invariance.

We now focus on this key component of *do*-calculus, and present better graphical conditions for judging invariance given a PAG than those that are implied by the PAG-based *do*-calculus presented in the last section. The conditions for invariance implied by Pearl's (DAG-based) *do*-calculus can

16. Here we allow that $\mathbf{X}$ and $\mathbf{Z}$ have a non-empty intersection, and assume that the conditioning operation is applied to the post-intervention population (i.e., intervening comes before conditioning). As a result, when we speak of $P_{\mathbf{X}:=\mathbf{x}}(\mathbf{y}|\mathbf{z})$, we implicitly assume that $\mathbf{x}$ and $\mathbf{z}$ are consistent regarding the values for variables in $\mathbf{X} \cap \mathbf{Z}$, for otherwise the quantity is undefined.

be equivalently formulated without referring to manipulated graphs, as given in Spirtes et al. (1993, Theorem 7.1) before the *do*-calculus was invented. In this section we develop corresponding conditions in terms of PAGs. The conditions will be not only sufficient in the sense that if the conditions are satisfied, then every DAG compatible with the given PAG entails invariance, but also necessary in the sense that if the conditions fail, then there is at least one DAG compatible with the given PAG that does not entail invariance. In this aspect, the conditions are also superior to earlier results on invariance given an equivalence class of DAGs due to Spirtes et al. (1993, Theorems 7.3 and 7.4).

We first state the conditions for judging invariance given a DAG, originally presented in Spirtes et al. (1993, Theorem 7.1).

Proposition 18 (Spirtes, Glymour, Scheines) *Let $\mathcal{G}$ be the causal DAG for $\mathbf{O}\cup\mathbf{L}$, and $\mathbf{X},\mathbf{Y},\mathbf{Z}\subseteq\mathbf{O}$ be three sets of variables such that $\mathbf{X}\cap\mathbf{Y}=\mathbf{Y}\cap\mathbf{Z}=\emptyset$ (but $\mathbf{X}$ and $\mathbf{Z}$ can overlap). $P(\mathbf{y}|\mathbf{z})$ is invariant under an intervention on $\mathbf{X}$ if*

(1) for every $X\in\mathbf{X}\cap\mathbf{Z}$, there is no d-connecting path between X and any member of $\mathbf{Y}$ given $\mathbf{Z}\backslash\{X\}$ that is into X;

(2) for every $X\in\mathbf{X}\cap(\mathbf{An}_{\mathcal{G}}(\mathbf{Z})\backslash\mathbf{Z})$, there is no d-connecting path between X and any member of $\mathbf{Y}$ given $\mathbf{Z}$; and

(3) for every $X\in\mathbf{X}\backslash\mathbf{An}_{\mathcal{G}}(\mathbf{Z})$, there is no d-connecting path between X and any member of $\mathbf{Y}$ given $\mathbf{Z}$ that is out of X.[17]

Remark: Because $\mathbf{Z}\subseteq\mathbf{An}_{\mathcal{G}}(\mathbf{Z})$, $\mathbf{X}\cap\mathbf{Z},\mathbf{X}\cap(\mathbf{An}_{\mathcal{G}}(\mathbf{Z})\backslash\mathbf{Z})$ and $\mathbf{X}\backslash\mathbf{An}_{\mathcal{G}}(\mathbf{Z})$ form a partition of $\mathbf{X}$. So for each member of $\mathbf{X}$, only one of the conditions is relevant.

The proposition is an equivalent formulation of Theorem 7.1 in Spirtes et al. (1993). It is not hard to check that the proposition follows from rules 2 and 3 in the DAG-based *do*-calculus (Proposition 7); the talk of d-separation in manipulated graphs is replaced by the talk of absence of d-connecting paths of certain orientations in the original graph. Conversely, the proposition implies the special case of rules 2 and 3 where the background intervention $do(\mathbf{U})$ is empty. Specifically, clause (1) in the proposition corresponds to rule 2 in the *do*-calculus; clauses (2) and (3) correspond to rule 3 in the *do*-calculus.

Spirtes et al. (1993, pp. 164-5) argued that these conditions are also "almost necessary" for invariance. What they meant is that if the conditions are not satisfied, then the causal structure does not *entail* the invariance, although there may exist some particular distribution compatible with the causal structure such that $P(\mathbf{y}|\mathbf{z})$ is invariant under some particular intervention on $\mathbf{X}$. From now on when we speak of invariance entailed by the causal DAG, we mean that the conditions in Proposition 18 are satisfied—or equivalently, that the invariance follows from an application of rule 2 or rule 3 in the DAG-based *do*-calculus.[18] Our purpose is to demonstrate that there are corresponding graphical

17. It is not hard to see that (3) is equivalent to saying that for every $X\in\mathbf{X}\backslash\mathbf{An}_{\mathcal{G}}(\mathbf{Z})$, there is no directed path from X to any member of $\mathbf{Y}$. Lemma 23 below is an immediate corollary of this equivalent formulation.

18. This stipulation is of course not intended to be a definition of the notion of *structurally entailed invariance*. A proper definition would be to the effect that for every distribution compatible with the causal structure, $P(\mathbf{y}|\mathbf{z})$ is invariant under any intervention of $\mathbf{X}$. The argument given by Spirtes et al. (1993, pp. 164-5) for (their equivalent formulation of) Proposition 18 suggests that the conditions are sufficient and necessary for structurally entailed invariance. Their argument uses the device of what they call policy variables, extra variables introduced into the

conditions relative to a PAG that are sufficient and necessary for the conditions in Proposition 18 to hold for each and every DAG compatible with the PAG.

Once again, we develop the conditions in two steps: first to MAGs and then to PAGs. In the first step, our goal is to find sufficient and necessary conditions for invariance entailed by a MAG, as defined below:

Definition 19 (Invariance entailed by a MAG) *Let $\mathcal{M}$ be a causal MAG over $\mathbf{O}$, and $\mathbf{X}$, $\mathbf{Y}$, $\mathbf{Z} \subseteq \mathbf{O}$ be three sets of variables such that $\mathbf{X} \cap \mathbf{Y} = \mathbf{Y} \cap \mathbf{Z} = \emptyset$, $P(\mathbf{y}|\mathbf{z})$ is* **entailed to be invariant under interventions on X given** *$\mathcal{M}$ if for every DAG $\mathcal{G}(\mathbf{O}, \mathbf{L})$ represented by $\mathcal{M}$, $P(\mathbf{y}|\mathbf{z})$ is entailed to be invariant under interventions on $\mathbf{X}$ given $\mathcal{G}$ (i.e., the conditions in Proposition 18 are satisfied).*

The question is how to judge invariance entailed by a MAG without doing the intractable job of checking the conditions in Proposition 18 for each and every compatible DAG. The next few lemmas, Lemmas 20-23, state useful connections between d-connecting paths in a DAG and m-connecting paths in the corresponding MAG. Lemma 20 records the important result due to Richardson and Spirtes (2002) that d-separation relations among observed variables in a DAG with latent variables correspond exactly to m-separation relations in its MAG.

Lemma 20 *Let $\mathcal{G}$ be any DAG over $\mathbf{O} \cup \mathbf{L}$, and $\mathcal{M}$ be the MAG of $\mathcal{G}$ over $\mathbf{O}$. For any $A, B \in \mathbf{O}$ and $\mathbf{C} \subseteq \mathbf{O}$ that does not contain A or B, there is a path d-connecting A and B given $\mathbf{C}$ in $\mathcal{G}$ if and only if there is a path m-connecting A and B given $\mathbf{C}$ in $\mathcal{M}$.*

Proof This is a special case of Lemma 17 and Lemma 18 in Spirtes and Richardson (1996), and also a special case of Theorem 4.18 in Richardson and Spirtes (2002). ■

Given Lemma 20, we know how to tell whether clause (2) of Proposition 18 holds in all DAGs compatible with a given MAG. For the other two conditions in Proposition 18, we need to take into account the orientations of d-connecting paths.

Lemma 21 *Let $\mathcal{G}$ be any DAG over $\mathbf{O} \cup \mathbf{L}$, and $\mathcal{M}$ be the MAG of $\mathcal{G}$ over $\mathbf{O}$. For any $A, B \in \mathbf{O}$ and $\mathbf{C} \subseteq \mathbf{O}$ that does not contain A or B, if there is a path d-connecting A and B given $\mathbf{C}$ in $\mathcal{G}$ that is into A, then there is a path m-connecting A and B given $\mathbf{C}$ in $\mathcal{M}$ that is either into A or contains an invisible edge out of A.*

Proof See Appendix B. ■

Lemma 22 *Let $\mathcal{M}$ be any MAG over $\mathbf{O}$. For any $A, B \in \mathbf{O}$ and $\mathbf{C} \subseteq \mathbf{O}$ that does not contain A or B, if there is a path m-connecting A and B given $\mathbf{C}$ in $\mathcal{M}$ that is either into A or contains an invisible edge out of A, then there exists a DAG $\mathcal{G}$ over $\mathbf{O} \cup \mathbf{L}$ (for some extra variables $\mathbf{L}$) whose MAG is $\mathcal{M}$, such that in $\mathcal{G}$ there is a path d-connecting A and B given $\mathbf{C}$ that is into A.*

causal DAG to represent interventions. Given the causal DAG $\mathcal{G}$, a policy variable for a variable X is an (extra) parent of X but otherwise not adjacent to any other variables in $\mathcal{G}$. Interventions can then be simulated by conditioning on the intervention variables, and invariance can be reformulated as conditional independence involving intervention variables. The conditions in Proposition 18 are equivalent to saying that the variables in $\mathbf{Y}$ are d-separated from the policy variables for $\mathbf{X}$ by $\mathbf{Z}$ (in the graph augmented by the policy variables). It thus seems plausible that these conditions are sufficient and necessary for structurally entailed invariance, given that d-separation is a sufficient and necessary condition for structurally entailed conditional independence (Geiger et al., 1990; Meek, 1995b). But Spirtes et al. did not give a rigorous proof for necessity. As an anonymous reviewer points out, the rigorous proof, if any, would need to be carefully made, and in particular, one should be careful in treating policy variables as random variables. We will not take on this task here.

Proof See Appendix B. ■

Obviously these two lemmas are related to adapting clause (1) in Proposition 18 to MAGs. The next lemma is related to clause (3).

Lemma 23 *Let $\mathcal{G}$ be any DAG over $\mathbf{O} \cup \mathbf{L}$, and $\mathcal{M}$ be the MAG of $\mathcal{G}$ over $\mathbf{O}$. For any $A, B \in \mathbf{O}$ and $\mathbf{C} \subseteq \mathbf{O}$ that does not contain B or any descendant of A in $\mathcal{G}$ (or in $\mathcal{M}$, since $\mathcal{G}$ and $\mathcal{M}$ have the same ancestral relations among variables in $\mathbf{O}$), there is a path d-connecting A and B given $\mathbf{C}$ in $\mathcal{G}$ that is out of A if and only if there is a path m-connecting A and B given $\mathbf{C}$ in $\mathcal{M}$ that is out of A.*

Proof See Appendix B. ■

Given these lemmas, the conditions in Proposition 18 are readily translated into the following conditions for invariance given a MAG.

Theorem 24 *Suppose $\mathcal{M}$ is the causal MAG over a set of variables $\mathbf{O}$. For any $\mathbf{X}, \mathbf{Y}, \mathbf{Z} \subseteq \mathbf{O}$, $\mathbf{X} \cap \mathbf{Y} = \mathbf{Y} \cap \mathbf{Z} = \emptyset$, $P(\mathbf{y}|\mathbf{z})$ is entailed to be invariant under interventions on $\mathbf{X}$ given $\mathcal{M}$ if and only if*

(1) for every $X \in \mathbf{X} \cap \mathbf{Z}$, there is no m-connecting path between X and any member of $\mathbf{Y}$ given $\mathbf{Z} \backslash \{X\}$ that is into X or contains an invisible edge out of X;

(2) for every $X \in \mathbf{X} \cap (\mathbf{An}_{\mathcal{M}}(\mathbf{Z}) \backslash \mathbf{Z})$, there is no m-connecting path between X and any member of $\mathbf{Y}$ given $\mathbf{Z}$; and

(3) for every $X \in \mathbf{X} \backslash \mathbf{An}_{\mathcal{M}}(\mathbf{Z})$, there is no m-connecting path between X and any member of $\mathbf{Y}$ given $\mathbf{Z}$ that is out of X.

Proof Given Lemma 21, if (1) holds, then for every DAG represented by $\mathcal{M}$, the first condition in Proposition 18 holds. Given Lemma 20 and the fact that $\mathcal{M}$ and all DAGs represented by $\mathcal{M}$ have the exact same ancestral relations among $\mathbf{O}$, if (2) holds, the second condition in Proposition 18 holds for every DAG represented by $\mathcal{M}$. Moreover, given Lemma 23, if (3) holds, the third condition in Proposition 18 holds for every DAG represented by $\mathcal{M}$. So (1), (2) and (3) together imply that $P(\mathbf{y}|\mathbf{z})$ is invariant under interventions on $\mathbf{X}$ given $\mathcal{M}$.

Conversely, if (1) fails, then by Lemma 22, there is a DAG represented by $\mathcal{M}$ in which the first condition in Proposition 18 fails. Likewise with conditions (2) and (3), in light of Lemmas 20 and 23 and the fact that $\mathcal{M}$ and a DAG represented by $\mathcal{M}$ have the exact same ancestral relations among $\mathbf{O}$. So (1), (2) and (3) are also necessary for $P(\mathbf{y}|\mathbf{z})$ to be entailed to be invariant under interventions on $\mathbf{X}$ given $\mathcal{M}$. ■

For example, given the MAG in Figure 3(a), $P(L|G,S)$ is invariant under interventions on S, because the only m-connecting path between L and S given G is $\langle L, S \rangle$, which contains a visible directed edge out of L, and so the relevant clause in Theorem 24, clause (1), is satisfied. By contrast, $P(L|G,S)$ is not entailed to be invariant under interventions on G given the MAG—in the sense that there exists a causal DAG compatible with the MAG given which $P(L|G,S)$ is not entailed to be invariant under interventions on G—because clause (1) is not satisfied.

In a similar fashion, we can extend the result to invariance entailed by a PAG. Definition first:

Definition 25 (Invariance entailed by a PAG) *Let $\mathcal{P}$ be a PAG over* $\mathbf{O}$*, and* $\mathbf{X},\mathbf{Y},\mathbf{Z} \subseteq \mathbf{O}$ *be three sets of variables such that* $\mathbf{X} \cap \mathbf{Y} = \mathbf{Y} \cap \mathbf{Z} = \emptyset$*, $P(\mathbf{y}|\mathbf{z})$ is* **entailed to be invariant under interventions on X given** *$\mathcal{P}$ if for every MAG $\mathcal{M}$ in the Markov equivalence class represented by $\mathcal{P}$, $P(\mathbf{y}|\mathbf{z})$ is entailed to be invariant under interventions on* $\mathbf{X}$ *given $\mathcal{M}$.*

We need a few lemmas that state connections between m-connecting paths in a MAG and definite m-connecting paths (as opposed to mere possibly m-connecting paths) in its PAG. By the definition of definite m-connecting paths (Definition 4), definite m-connection in a PAG implies m-connection in every MAG represented by the PAG. It is not obvious, however, that m-connection in a MAG will always be revealed as definite m-connection in its PAG. Fortunately, this turns out to be true. However, the proof is highly involved, and relies on many results about the properties of PAGs and the transformation between PAGs and MAGs presented in Zhang (2006, chapters 3-4), which would take up too much space and might distract readers from the main points of the present paper. So we will simply state the fact here, and refer interested readers to Zhang (2006, chap. 5, Lemma 5.1.7) for the proof.

Lemma 26 *Let $\mathcal{M}$ be a MAG over* $\mathbf{O}$*, and $\mathcal{P}$ be the PAG that represents $[\mathcal{M}]$. For any $A,B \in \mathbf{O}$ and $\mathbf{C} \subseteq \mathbf{O}$ that does not contain A or B, if there is a path m-connecting A and B given* $\mathbf{C}$ *in $\mathcal{M}$, then there is a path definitely m-connecting A and B given* $\mathbf{C}$ *in $\mathcal{P}$. Furthermore, if there is an m-connecting path in $\mathcal{M}$ that is either into A or out of A with an invisible directed edge, then there is a definite m-connecting path in $\mathcal{P}$ that does not start with a definitely visible edge out of A.*

Proof See the proof of Lemma 5.1.7 in Zhang (2006, pp. 207). ■

The converse to the second part of Lemma 26 is also true.

Lemma 27 *Let $\mathcal{P}$ be a PAG over* $\mathbf{O}$*. For any $A,B \in \mathbf{O}$ and $\mathbf{C} \subseteq \mathbf{O}$ that does not contain A or B, if there is a path definitely m-connecting A and B given* $\mathbf{C}$ *in $\mathcal{P}$ that does not start with a definitely visible edge out of A, then there exists a MAG $\mathcal{M}$ in the equivalence class represented by $\mathcal{P}$ in which there is a path m-connecting A and B given* $\mathbf{C}$ *that is either into A or includes an invisible directed edge out of A.*

Proof See Appendix B. ■

Lemmas 26 and 27 are useful for establishing conditions analogous to clauses (1) and (2) in Theorem 24. For clause (3), we need two more lemmas.

Lemma 28 *Let $\mathcal{M}$ be a MAG over* $\mathbf{O}$*, and $\mathcal{P}$ be the PAG that represents $[\mathcal{M}]$. For any $A,B \in \mathbf{O}$ and $\mathbf{C} \subseteq \mathbf{O}$ that does not contain B or any descendant of A in $\mathcal{M}$, if there is a path m-connecting A and B given* $\mathbf{C}$ *in $\mathcal{M}$ that is out of A, then there is a path definitely m-connecting A and B given* $\mathbf{C}$ *in $\mathcal{P}$ that is not into A (i.e., the edge incident to A on the path is either $A \circ\!\!-\!\!\circ$, or $A \circ\!\!\rightarrow$, or $A \rightarrow$).*

Proof See Appendix B. ■

Lemma 29 *Let $\mathcal{P}$ be a PAG over* $\mathbf{O}$*. For any $A,B \in \mathbf{O}$ and $\mathbf{C} \subseteq \mathbf{O}$ that does not contain A or B, if there is a path definitely m-connecting A and B given* $\mathbf{C}$ *in $\mathcal{P}$ that is not into A, then there exists a MAG $\mathcal{M}$ represented by $\mathcal{P}$ in which there is a path m-connecting A and B given* $\mathbf{C}$ *that is out of A.*

Proof See Appendix B. ■

The main theorem follows.

Theorem 30 *Suppose $\mathcal{P}$ is the causal PAG over a set of variables $\mathbf{O}$. For any $\mathbf{X}, \mathbf{Y}, \mathbf{Z} \subseteq \mathbf{O}$ such that $\mathbf{X} \cap \mathbf{Y} = \mathbf{Y} \cap \mathbf{Z} = \emptyset$, $P(\mathbf{y}|\mathbf{z})$ is entailed to be invariant under interventions on $\mathbf{X}$ given $\mathcal{P}$ if and only if*

(1) for every $X \in \mathbf{X} \cap \mathbf{Z}$, every definite m-connecting path, if any, between X and any member of $\mathbf{Y}$ given $\mathbf{Z} \backslash \{X\}$ is out of X with a definitely visible edge;

(2) for every $X \in \mathbf{X} \cap (\mathbf{PossibleAn}_{\mathcal{P}}(\mathbf{Z}) \backslash \mathbf{Z})$, there is no definite m-connecting path between X and any member of $\mathbf{Y}$ given $\mathbf{Z}$; and

(3) for every $X \in \mathbf{X} \backslash \mathbf{PossibleAn}_{\mathcal{P}}(\mathbf{Z})$, every definite m-connecting path, if any, between X and any member of $\mathbf{Y}$ given $\mathbf{Z}$ is into X.

Proof We show that (1), (2) and (3) are sufficient and necessary for the corresponding conditions in Theorem 24 to hold for all MAGs represented by $\mathcal{P}$. It follows from Lemma 26 that if (1) holds, then the first condition in Theorem 24 holds for all MAGs represented by $\mathcal{P}$. Note moreover that for every MAG $\mathcal{M}$ represented by $\mathcal{P}$, $\mathbf{An}_{\mathcal{M}}(\mathbf{Z}) \subseteq \mathbf{PossibleAn}_{\mathcal{P}}(\mathbf{Z})$. It again follows from Lemma 26 that if (2) holds, then the second condition in Theorem 24 holds for all MAGs represented by $\mathcal{P}$. Finally, it follows from Lemma 28 (and Lemma 26) that if (3) holds, the third condition in Theorem 24 holds for all MAGs represented by $\mathcal{P}$. Hence (1), (2) and (3) are sufficient.

Conversely, if (1) fails, then by Lemma 27, there exists a MAG represented by $\mathcal{P}$ for which the first condition in Theorem 24 fails.

To show the necessity of (2), we need the fact mentioned in Footnote 11 that if X is a possible ancestor of a vertex $Z \in \mathbf{Z}$ in $\mathcal{P}$, then there exists a MAG represented by $\mathcal{P}$, in which X is an ancestor of Z. So if (2) fails, that is, there is a definite m-connecting path between a variable $X \in \mathbf{X} \cap (\mathbf{PossibleAn}_{\mathcal{P}}(\mathbf{Z}) \backslash \mathbf{Z})$ and a member of $\mathbf{Y}$ given $\mathbf{Z}$ in $\mathcal{P}$, then there exists a MAG $\mathcal{M}$ represented by $\mathcal{P}$ in which $X \in \mathbf{X} \cap (\mathbf{An}_{\mathcal{M}}(\mathbf{Z}) \backslash \mathbf{Z})$, and there is an m-connecting path between X and a member of $\mathbf{Y}$ given $\mathbf{Z}$, which violates clause (2) of Theorem 24.

Lastly, if (3) fails, that is, there is a definite m-connecting path between a variable $X \in \mathbf{X} \backslash \mathbf{PossibleAn}_{\mathcal{P}}(\mathbf{Z})$ and a member of $\mathbf{Y}$ given $\mathbf{Z}$ that is *not* into X, then it follows from Lemma 29 that there exists a MAG $\mathcal{M}$ represented by $\mathcal{P}$ in which there is an m-connecting path between X and a member of $\mathbf{Y}$ given $\mathbf{Z}$ that is out of X. Moreover, since $X \in \mathbf{X} \backslash \mathbf{PossibleAn}_{\mathcal{P}}(\mathbf{Z})$, X cannot be an ancestor of $\mathbf{Z}$ in $\mathcal{M}$, that is, $X \in \mathbf{X} \backslash \mathbf{An}_{\mathcal{M}}(\mathbf{Z})$. So $\mathcal{M}$ fails clause (3) of Theorem 24. Therefore, the conditions are also necessary. ■

For a simple illustration, consider again the PAG in Figure 4. Given the PAG, it can be inferred that $P(L|G,S)$ is invariant under interventions on I, because there is no definite m-connecting path between L and I given $\{G,S\}$, satisfying the relevant clause—clause (2)—in Theorem 30. $P(L|G,S)$ is also invariant under interventions on S because the only definitely m-connecting path between L and S given $\{G\}$ is $S \rightarrow L$ which contains a definitely visible edge out of S, satisfying the relevant clause—clause (1)—in Theorem 30.

On the other hand, for example, $P(S)$ is not entailed to be invariant under interventions on I. Note that given the MAG of Figure 3(b), $P(S)$ is indeed entailed to be invariant under interventions on I, but this invariance is not unanimously implied in the equivalence class. Given some other MAGs in the class, such as the one in Figure 3(a), $P(S)$ is not entailed to be invariant under interventions on I.

As briefly noted in the last section, the PAG-based *do*-calculus in its current form is not complete. We mentioned three issues that might be responsible for this (cf. the comments right after Theorem 17), but only one of them we are sure leads to counterexamples—examples in which a rule in the DAG-based calculus is applicable for all DAGs compatible with the given PAG, but the corresponding rule in the PAG-based calculus is not applicable. It is the fact that the calculus is formulated in terms of absence of possibly m-connecting paths. Consider the example we used to illustrate the difference between definite and possibly m-connecting paths in Section 3. Given the PAG in Figure 5, we cannot apply rule 2 of the PAG-based *do*-calculus to conclude that $P(W|do(X),Y,Z) = P(W|Y,Z)$, because there is a possibly m-connecting path between X and W relative to $\{Y,Z\}$ in the PAG (note that since $X \in \mathbf{PossibleAn}(\{Y,Z\})$, the rule does not require manipulating the graph). However, it can be shown that for every DAG compatible with the PAG, X and W are d-separated by $\{Y,Z\}$ in either the X-upper-manipulation of the DAG or in the DAG itself. So rule 2 of the DAG-based *do*-calculus is actually applicable given any DAG compatible with the PAG.

Although we suspect that such counterexamples may not be encountered often in practice, it is at least theoretically interesting to handle them. Our results in this section provide an improvement in regard to the important special case of invariance. That is, the conditions given in Theorem 30 are complete for deriving statements of invariance, in the following sense: if the conditions therein fail relative to a PAG, then there exists a DAG represented by the PAG given which the conditions in Proposition 18 do not hold. The example in Figure 5 is not a counterexample to the completeness of Theorem 30. Unlike the *do*-calculus presented in Theorem 17, Theorem 30 implies that $P(W|Y,Z)$ is entailed to be invariant under interventions on X given the PAG (and hence we can conclude that $P(W|do(X),Y,Z) = P(W|Y,Z)$), because there is no definite m-connecting path between X and W relative to $\{Y,Z\}$ in the PAG. Whether it is valid to formulate the PAG-based *do*-calculus in terms of definite m-connecting paths is an open question at this point (cf. Footnote 15).[19]

Theorem 30 is in style very similar to Theorems 7.3 and 7.4 in Spirtes et al. (1993). The latter are formulated with respect to a *partially oriented inducing path graph* (POIPG). We include in Appendix A a description of the inducing path graphs (IPGs) as well as their relationship to ancestral graphs. As shown there, syntactically the class of ancestral graphs is a proper subclass of the class of inducing path graphs. In consequence a PAG in general reveals more qualitative causal information than a POIPG. In addition, it seems MAGs are easier to parameterize than IPGs. (For a linear parametrization of MAGs, see Richardson and Spirtes, 2002.)

Apart from the advantages of working with MAGs and PAGs over IPGs and POIPGs, our Theorem 30 is superior to Spirtes et al.'s theorems in that our theorem is formulated in terms of definite m-connecting paths, whereas theirs, like the results in the last section, are formulated in terms of

19. Here is another way to view the open problem. As explained earlier, *do*-calculus is essentially a generalization of the invariance conditions. Not only does it address the question of when $(\mathbf{y}|\mathbf{z})$ is invariant under an intervention $\mathbf{X} := \mathbf{x}$, it also addresses the more general question of when a post-intervention probability $P_{\mathbf{u}}(\mathbf{y}|\mathbf{z})$ would be invariant under a *further* intervention $\mathbf{X} := \mathbf{x}$. Our results in this section do not cover the latter question. To generalize the results in terms of definite m-connecting paths to address the latter question is parallel to improving the *do*-calculus.

possibly m-connecting paths. As a result, their conditions are only sufficient but not necessary. Regarding the case in Figure 5, for example, their theorems do not imply that $P(W|Y,Z)$ is entailed to be invariant under interventions on X, due to the presence of the possibly m-connecting path in the graph (which in this case is also the POIPG). Furthermore, since definite m-connecting paths are special cases of possibly m-connecting paths, there are more possibly m-connecting paths than definite m-connecting paths to check in a PAG. This may turn out to be a computational advantage for our theorem.

6. Conclusion

Causal reasoning about consequences of interventions has received rigorous and interesting treatments in the framework of causal Bayesian networks. Much of the work assumes that the structure of the causal Bayesian network, represented by a directed acyclic graph, is fully given. In this paper we have provided some results about causal reasoning under weaker causal assumptions, represented by a maximal ancestral graph or a partial ancestral graph, the latter of which is fully testable with observational data (assuming the causal Faithfulness condition).

Theorem 17 in Section 4 gives us a *do*-calculus under testable causal assumptions, represented by a PAG. The idea is that when any rule in the calculus is applicable given the PAG, the corresponding rule in Pearl's original *do*-calculus is applicable relative to each and every DAG compatible with the PAG. The converse, however, is not true; it is not the case that whenever all DAGs compatible with the PAG sanction the application of a certain rule in the *do*-calculus, the corresponding rule in the PAG-based calculus is also applicable. An interesting project is to either improve the calculus, or to investigate more closely the extent to which the current version is not complete.

As a first step towards improvement, we examined in Section 5 an important special case of the *do*-calculus—the graphical conditions for invariance under interventions—and presented sufficient and necessary conditions for invariance given a PAG. These conditions are very similar but also superior to the analogous results proved by Spirtes et al. (1993). In the latter work, there is also an algorithm (named Prediction Algorithm) for identifying post-intervention probabilities based on the conditions for invariance. The results in this paper can certainly be used to improve that algorithm.

The search for a syntactic derivation in the *do*-calculus to identify a post-intervention probability is no minor computational task. For this reason, it is worth deriving handy graphical criteria for identifiability from the *do*-calculus. Since invariant quantities are the most basic identifiable quantities, the condition for invariance is the most basic among such graphical criteria. Other graphical criteria in the literature, including the well known "back door criterion" and "front door criterion", should be extendible to PAGs in the same way as we did for invariance. On the other hand, a novel approach to identification has been developed recently by Tian and Pearl (2004), which proves computationally attractive. To adapt that approach to ancestral graphs is probably a worthy project.

Acknowledgments

I am grateful to Clark Glymour, Thomas Richardson, and Peter Spirtes for their helpful comments on the part of my dissertation this paper is based on. Thanks also to three anonymous referees for helping improve the paper significantly. One of them, especially, made extremely detailed and helpful suggestions.

Appendix A. Inducing Path Graphs

The theory of invariance under interventions developed in this paper is largely parallel to that developed in Spirtes et al. (1993). Their theory is based on a graphical representation called inducing path graphs. This graphical object is not given an independent syntactic definition, but defined via a construction relative to a DAG (with latent variables). It is clear from the construction that this representation is closely related to MAGs. In this appendix we specify the exact relationship between them. In particular, we justify an independent syntactic definition of inducing path graphs, which makes it clear that syntactically the class of MAGs is a subclass of inducing path graphs.

An *inducing path graph (IPG)* is a directed mixed graph, defined relative to a DAG, through the following construction:

Input: a DAG $\mathcal{G}$ over $\langle \mathbf{O}, \mathbf{L} \rangle$
Output: an IPG $I_{\mathcal{G}}$ over $\mathbf{O}$

1. for each pair of variables $A, B \in \mathbf{O}$, A and B are adjacent in $I_{\mathcal{G}}$ if and only if there is an inducing path between them relative to $\mathbf{L}$ in $\mathcal{G}$;

2. for each pair of adjacent vertices A, B in $I_{\mathcal{G}}$, mark the A-end of the edge as an arrowhead if there is an inducing path between A and B that is into A, otherwise mark the A-end of the edge as a tail.

It can be shown that the construction outputs a mixed graph $I_{\mathcal{G}}$ in which the set of m-separation relations matches exactly the set of d-separation relations among $\mathbf{O}$ in the original DAG $\mathcal{G}$ (Spirtes and Verma, 1992). Furthermore, $I_{\mathcal{G}}$ encodes information about inducing paths in the original graph, which in turn implies features of the original DAG that bear causal significance. Specifically, we have two useful facts: (i) if there is an inducing path between A and B relative to $\mathbf{L}$ that is out of A, then A is an ancestor of B in $\mathcal{G}$; (ii) if there is an inducing path between A and B relative to $\mathbf{L}$ that is into both A and B, then A and B have a common ancestor in $\mathbf{L}$ unmediated by any other observed variable.[20] So $I_{\mathcal{G}}$, just like the MAG for $\mathcal{G}$, represents both the conditional independence relations and (features of) the causal structure among the observed variables $\mathbf{O}$. Since the above construction produces a unique graph given a DAG $\mathcal{G}$, it is fair to call $I_{\mathcal{G}}$ the IPG for $\mathcal{G}$.

Therefore a directed mixed graph over a set of variables is an IPG if it is the IPG for some DAG. We now show that a directed mixed graph is an IPG if and only if it is maximal and does not contain a directed cycle.

Theorem 31 *For any directed mixed graph I over a set of variables $\mathbf{O}$, there exists a DAG $\mathcal{G}$ over $\mathbf{O}$ and possibly some extra variables $\mathbf{L}$ such that $I = I_{\mathcal{G}}$—that is, I is the IPG for $\mathcal{G}$—if and only if*

(i1) There is no directed cycle in I; and

(i2) I is maximal (i.e., there is no inducing path between two non-adjacent variables).

Proof We first show that the conditions are necessary (**only if**). Suppose there exists a DAG $\mathcal{G}(\mathbf{O}, \mathbf{L})$ whose IPG is I. In other words, I is the output of the IPG construction procedure given $\mathcal{G}$. If there is any directed cycle in I, say $c = \langle O_1, \ldots, O_n, O_1 \rangle$, then between any pair of adjacent nodes in the cycle, O_i and O_{i+1} ($1 \leq i \leq n$ and $O_{n+1} = O_1$), there is an inducing path between them in $\mathcal{G}$ relative

20. For more details of the causal interpretation of IPGs, see Spirtes et al. (1993, pp. 130-138).

to **L**, which, by one of the facts mentioned earlier, implies that O_i is an ancestor of O_{i+1} in $\mathcal{G}$. Thus there would be a directed cycle in $\mathcal{G}$ as well, a contradiction. Therefore there is no directed cycle in I. To show that it is also maximal, consider any two non-adjacent nodes A and B in I. We show that there is no inducing path in I between A and B. Otherwise let $p = \langle A, O_1, \ldots, O_n, B \rangle$ be an inducing path. By the construction, there is an inducing path relative to **L** in $\mathcal{G}$ between A and O_1 that is into O_1, and an inducing path relative to **L** in $\mathcal{G}$ between B and O_n that is into O_n, and for every $1 \leq i \leq i-1$, there is an inducing path relative to **L** in $\mathcal{G}$ between O_i and O_{i+1} that is into both. By Lemma 32 in Appendix B, it follows that there is an inducing path between A and B relative to **L** in $\mathcal{G}$, and so A and B should be adjacent in I, a contradiction. Therefore I is also maximal.

Next we demonstrate sufficiency (**if**). If the two conditions hold, construct a DAG $\mathcal{G}$ as follows: retain all the directed edges in I, and for each bi-directed edge $A \leftrightarrow B$ in I, introduce a latent variable L_{AB} in $\mathcal{G}$ and replace $A \leftrightarrow B$ with $A \leftarrow L_{AB} \rightarrow B$.[21] It is easy to see that the resulting graph $\mathcal{G}$ is a DAG, as in I there is no directed cycle. We show that $I = I_{\mathcal{G}}$, the IPG for $\mathcal{G}$. For any pair of variables A and B in I, there are four cases to consider:

Case 1: $A \rightarrow B$ is in I. Then $A \rightarrow B$ is also in $\mathcal{G}$, so A and B are adjacent in $I_{\mathcal{G}}$. In $I_{\mathcal{G}}$, the edge between A and B is not $A \leftarrow B$, because otherwise B would have to be an ancestor of A in $\mathcal{G}$, a contradiction. The edge is not $A \leftrightarrow B$ either, because otherwise there would have to be a latent variable that is a parent of both A and B, which by the construction of $\mathcal{G}$ is not the case. So $A \rightarrow B$ is also in $I_{\mathcal{G}}$.

Case 2: $A \leftarrow B$ is in I. By the same argument as in *Case 1*, $A \leftarrow B$ is also in $I_{\mathcal{G}}$.

Case 3: $A \leftrightarrow B$ is in I. Then there is a L_{AB} such that $A \leftarrow L_{AB} \rightarrow B$ is in $\mathcal{G}$. Then obviously $\langle A, L_{AB}, B \rangle$ is an inducing path relative to **L** in $\mathcal{G}$ that is into both A and B, and hence $A \leftrightarrow B$ is also in $I_{\mathcal{G}}$.

Case 4: A and B are not adjacent in I. We show that they are not adjacent in $I_{\mathcal{G}}$ either. For this, we only need to show that there is no inducing path between A and B relative to **L** in $\mathcal{G}$. Suppose otherwise that there is such an inducing path p between A and B in $\mathcal{G}$. Let $\langle A, O_1, \ldots, O_n, B \rangle$ be the sub-sequence of p consisting of all observed variables on p. By the definition of inducing path, all O_i's ($1 \leq i \leq n$) are colliders on p and are ancestors of either A or B. By the construction of $\mathcal{G}$, it is easy to see that O_i's are also ancestors of either A or B in I. It is also easy to see that either $A \rightarrow O_1$ or $A \leftarrow L_{AO_1} \rightarrow O_1$ appears in $\mathcal{G}$, which implies that there is an edge between A and O_1 that is into O_1 in I. Likewise, there is an edge between O_n and B that is into O_n in I, and there is an edge between O_i and O_{i+1} that is into both in I for all $1 \leq i \leq n-1$. So $\langle A, O_1, \ldots, O_n, B \rangle$ constitutes an inducing path between A and B in I, which contradicts the assumption that I is maximal. So there is no inducing path between A and B relative to **L** in $\mathcal{G}$, which means that A and B are not adjacent in $I_{\mathcal{G}}$.

Therefore $I = I_{\mathcal{G}}$, the IPG for $\mathcal{G}$. ■

Given this theorem, it is clear that we can define IPGs in terms of $(i1)$ and $(i2)$. So a MAG is also an IPG, but an IPG is not necessarily a MAG, as the former may contain an almost directed cycle. The simplest IPG which is not a MAG is shown in Figure 11.

Spirtes et al. (1993) uses *partially oriented inducing path graphs (POIPGs)* to represent Markov equivalence classes of IPGs. The idea is exactly the same as PAGs. A (complete) POIPG displays (all) common marks in a Markov equivalence class of IPGs. An obvious fact is that given a set of conditional independence facts that admits a faithful representation by a MAG, the Markov equiva-

21. This is named *canonical DAG* in Richardson and Spirtes (2002).

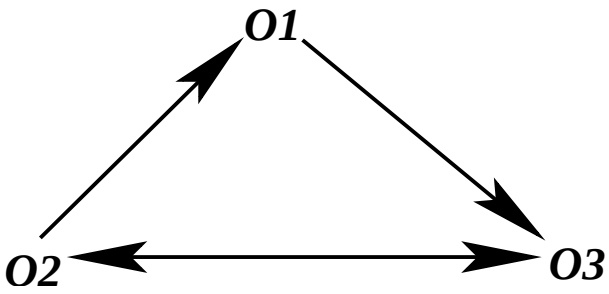

Figure 11: A simplest IPG that is not a MAG

lence class of MAGs is included in the Markov equivalence class of IPGs. It follows that the POIPG cannot contain more informative marks than the PAG, but may contain fewer. So a PAG usually reveals more qualitative causal information than a POIPG does.

Appendix B. Proofs of the Lemmas

In proving some of the lemmas, we will use the following fact, which was proved in, for example, Spirtes et al. (1999, pp. 243):

Lemma 32 *Let $\mathcal{G}(\mathbf{O},\mathbf{L})$ be a DAG, and $\langle V_0,\ldots,V_n\rangle$ be a sequence of distinct variables in $\mathbf{O}$. If (1) for all $0 \le i \le n-1$, there is an inducing path in $\mathcal{G}$ between V_i and V_{i+1} relative to $\mathbf{L}$ that is into V_i unless possibly $i = 0$ and is into V_{i+1} unless possibly $i = n-1$; and (2) for all $1 \le i \le n-1$, V_i is an ancestor of either V_0 or V_n in $\mathcal{G}$; then there is a subpath s of the concatenation of those inducing paths that is an inducing path between V_0 and V_n relative to $\mathbf{L}$ in $\mathcal{G}$. Furthermore, if the said inducing path between V_0 and V_1 is into V_0, then s is into V_0, and if the said inducing path between V_{n-1} and V_n is into V_n, then s is into V_n.*

Proof This is a special case of Lemma 10 in Spirtes et al. (1999, pp. 243). See their paper for a detailed proof. (One may think that the concatenation itself would be an inducing path between V_0 and V_n. This is almost correct, except that the concatenation may contain the same vertex multiple times. So in general it is a subsequence of the concatenation that constitutes an inducing path between V_0 and V_n.) ■

Lemma 32 gives a way to argue for the presence of an inducing path between two variables in a DAG, and hence is very useful for demonstrating that two variables are adjacent in the corresponding MAG. We will see several applications of this lemma in the subsequent proofs.

Proof of Lemma 9

Proof Since there is an inducing path between A and B relative to $\mathbf{L}$ in $\mathcal{G}$, A and B are adjacent in $\mathcal{M}$. Furthermore, since $A \in \mathbf{An}_{\mathcal{G}}(B)$, the edge between A and B in $\mathcal{M}$ is $A \to B$. We now show that it is invisible in $\mathcal{M}$. To show this, it suffices to show that for any C, if in $\mathcal{M}$ there is an edge between C and A that is into A or there is a collider path between C and A that is into A and every vertex on the path is a parent of B, then C is adjacent to B, which means that the condition for visibility cannot be met.

Let u be an inducing path between A and B relative to $\mathbf{L}$ in $\mathcal{G}$ that is into A. For any C, we consider the two possible cases separately:

Case 1: There is an edge between C and A in $\mathcal{M}$ that is into A. Then, by the way $\mathcal{M}$ is constructed from $\mathcal{G}$, there must be an inducing path u' in $\mathcal{G}$ between A and C relative to $\mathbf{L}$. Moreover, u' is into A, for otherwise A would be an ancestor of C, so that the edge between A and C in $\mathcal{M}$ would be out of A. Given u, u' and the fact that $A \in \mathbf{An}_{\mathcal{G}}(B)$, we can apply Lemma 32 to conclude that there is an inducing path between C and B relative to $\mathbf{L}$ in $\mathcal{G}$, which means C and B are adjacent in $\mathcal{M}$.

Case 2: There is a collider path p in $\mathcal{M}$ between C and A that is into A and every non-endpoint vertex on the path is a parent of B. For every pair of adjacent vertices $\langle V_i, V_{i+1}\rangle$ on p, the edge is $V_i \leftrightarrow V_{i+1}$ if $V_i \neq C$, and otherwise either $C \leftrightarrow V_{i+1}$ or $C \rightarrow V_{i+1}$. It follows that there is an inducing path in $\mathcal{G}$ between V_i and V_{i+1} relative to $\mathbf{L}$ such that the path is into V_{i+1}, and is into V_i unless possibly $V_i = C$. Given these inducing paths and the fact that every variable other than C on p is an ancestor of B, we can apply Lemma 32 to conclude that there is an inducing path between C and B relative to $\mathbf{L}$ in $\mathcal{G}$, which means C and B are adjacent in $\mathcal{M}$.

Therefore, the edge $A \rightarrow B$ is invisible in $\mathcal{M}$. ■

Proof of Lemma 10

Proof Construct a DAG from $\mathcal{M}$ as follows:

1. Leave every directed edge in $\mathcal{M}$ as it is. Introduce a latent variable L_{AB} and add $A \leftarrow L_{AB} \rightarrow B$ to the graph.

2. for every bi-directed edge $Z \leftrightarrow W$ in $\mathcal{M}$, delete the bi-directed edge. Introduce a latent variable L_{ZW} and add $Z \leftarrow L_{ZW} \rightarrow W$ to the graph.

The resulting graph we denote by $\mathcal{G}$, a DAG over $(\mathbf{O}, \mathbf{L})$, where $\mathbf{L} = \{L_{AB}\} \cup \{L_{ZW} | Z \leftrightarrow W \text{ is in } \mathcal{M}\}$. Obviously $\mathcal{G}$ is a DAG in which A and B share a latent parent. We need to show that $\mathcal{M} = \mathcal{M}_{\mathcal{G}}$, that is, $\mathcal{M}$ is the MAG of $\mathcal{G}$. For any pair of variables X and Y, there are four cases to consider:

Case 1: $X \rightarrow Y$ is in $\mathcal{M}$. Since $\mathcal{G}$ retains all directed edges in $\mathcal{M}$, $X \rightarrow Y$ is also in $\mathcal{G}$, and hence is also in $\mathcal{M}_{\mathcal{G}}$.

Case 2: $X \leftarrow Y$ is in $\mathcal{M}$. Same as *Case 1*.

Case 3: $X \leftrightarrow Y$ is in $\mathcal{M}$. Then there is a latent variable L_{XY} in $\mathcal{G}$ such that $X \leftarrow L_{XY} \rightarrow Y$ appears in $\mathcal{G}$. Since $X \leftarrow L_{XY} \rightarrow Y$ is an inducing path between X and Y relative to $\mathbf{L}$ in $\mathcal{G}$, X and Y are adjacent in $\mathcal{M}_{\mathcal{G}}$. Furthermore, it is easy to see that the construction of $\mathcal{G}$ does not create any directed path from X to Y or from Y to X. So X is not an ancestor of Y and Y is not an ancestor of X in $\mathcal{G}$. It follows that in $\mathcal{M}_{\mathcal{G}}$ the edge between X and Y is $X \leftrightarrow Y$.

Case 4: X and Y are not adjacent in $\mathcal{M}$. We show that in $\mathcal{G}$ there is no inducing path between X and Y relative to $\mathbf{L}$. Suppose otherwise that there is one. Let p be an inducing path between X and Y relative to $\mathbf{L}$ in $\mathcal{G}$ that includes a minimal number of observed variables. Let $\langle X, O_1, \ldots, O_n, Y\rangle$ be the sub-sequence of p consisting of all observed variables on p. By the definition of inducing path, all O_i's ($1 \leq i \leq n$) are colliders on p and are ancestors of either X or Y in $\mathcal{G}$. Since the construction of $\mathcal{G}$ does not create any new directed path from an observed variable to another observed variable, O_i's are also ancestors of either X or Y in $\mathcal{M}$. Since O_1 is a collider on p, either $X \rightarrow O_1$ or $X \leftarrow L_{XO_1} \rightarrow O_1$ appears in $\mathcal{G}$. Either way there is an edge between X and O_1 that is into O_1 in $\mathcal{M}$. Likewise, there is an edge between O_n and Y that is into O_n in $\mathcal{M}$.

Moreover, for all $1 \leq i \leq n-1$, the path p in $\mathcal{G}$ contains $O_i \leftarrow L_{O_iO_{i+1}} \rightarrow O_{i+1}$, because all O_i's are colliders on p. Thus in $\mathcal{M}$ there is an edge between O_i and O_{i+1}. Regarding these edges, by construction of the MAG, either all of them are bi-directed, or one of them is $A \rightarrow B$ and others are bi-directed. In the former case, $\langle X, O_1, \ldots, O_n, Y \rangle$ constitutes an inducing path between X and Y in $\mathcal{M}$, which contradicts the maximality of $\mathcal{M}$. In the latter case, without loss of generality, suppose $\langle A, B \rangle = \langle O_k, O_{k+1} \rangle$. Then $\langle X, O_1, ..., O_k = A \rangle$ is a collider path into A in $\mathcal{M}$. We now show by induction that for all $1 \leq i \leq k-1$, O_i is a parent of B in $\mathcal{M}$.

Consider O_{k-1} in the base case. O_{k-1} is adjacent to B, for otherwise $A \rightarrow B$ would be visible in $\mathcal{M}$ because there is an edge between O_{k-1} and A that is into A. The edge between O_{k-1} and B is not $O_{k-1} \leftarrow B$, for otherwise there would be $A \rightarrow B \rightarrow O_{k-1}$ and yet an edge between O_{k-1} and A that is into A in $\mathcal{M}$, which contradicts the fact that $\mathcal{M}$ is ancestral. The edge between them is not $O_{k-1} \leftrightarrow B$, for otherwise there would be an inducing path between X and Y relative to $\mathbf{L}$ in $\mathcal{G}$ that includes fewer observed variables than p does, which contradicts our choice of p. So O_{k-1} is a parent of B in $\mathcal{M}$.

In the inductive step, suppose for all $1 < m+1 \leq j \leq k-1$, O_j is a parent of B in $\mathcal{M}$, and we need to show that O_m is also a parent of B in $\mathcal{M}$. The argument is essentially the same as in the base case. Specifically, O_m and B are adjacent because otherwise it follows from the inductive hypothesis that $A \rightarrow B$ is visible. The edge is not $O_m \leftarrow B$ on pain of making $\mathcal{M}$ non-ancestral; and the edge is not $O_m \leftrightarrow B$ on pain of creating an inducing path that includes fewer observed variables than p does. So O_m is also a parent of B.

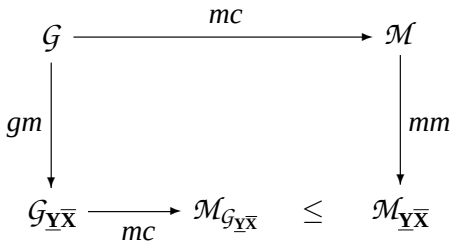
Now we have shown that for all $1 \leq i \leq k-1$, O_i is a parent of B in $\mathcal{M}$. It follows that X is adjacent to B, for otherwise $A \rightarrow B$ would be visible. Again, the edge is not $X \leftarrow B$ on pain of making $\mathcal{M}$ non-ancestral. So the edge between X and B in $\mathcal{M}$ is into B, but then there is an inducing path between X and Y relative to $\mathbf{L}$ in $\mathcal{G}$ that includes fewer observed variables than p does, which is a contradiction with our choice of p.

So our initial supposition is false. There is no inducing path between X and Y relative to $\mathbf{L}$ in $\mathcal{G}$, and hence X and Y are not adjacent in $\mathcal{M}_{\mathcal{G}}$.

Therefore $\mathcal{M} = \mathcal{M}_{\mathcal{G}}$. ■

Proof of Lemma 12

Proof Recall the diagram in Figure 7:



What we need to show is that $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ is an I-map of $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$, or in other words, whatever m-separation relation is true in the former is also true in the latter. To show this, it suffices to show that $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ is Markov equivalent to a supergraph of $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$.

For that purpose, we first establish two facts: (1) every directed edge in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$ is also in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$; and (2) for every bi-directed edge $S \leftrightarrow T$ in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$, S and T are also adjacent in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$; and the edge between S and T is either a bi-directed edge or an invisible directed edge in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$.

(1) is relatively easy to show. Note that for any $P \to Q$ in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$, $P \notin \mathbf{Y}$, for otherwise P would not be an ancestor of Q in $\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, and hence would not be a parent of Q in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$; and likewise $Q \notin \mathbf{X}$, for otherwise Q would not be a descendant of P in $\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, and hence would not be a child of P in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$. Furthermore, because $\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ is a subgraph of $\mathcal{G}$, any inducing path between P and Q relative to $\mathbf{L}$ in $\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ is also present in $\mathcal{G}$, and any directed path from P to Q in the former is also present in the latter. This entails that $P \to Q$ is also in $\mathcal{M}$, the MAG of $\mathcal{G}$. Since $P \notin \mathbf{Y}$ and $Q \notin \mathbf{X}$, $P \to Q$ is also present in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. So (1) is true.

(2) is less obvious. First of all, note that if $S \leftrightarrow T$ is in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$, then there is an inducing path between S and T relative to $\mathbf{L}$ in $\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ that is into both S and T. This implies that $S, T \notin \mathbf{X}$, and moreover there is also an inducing path between S and T relative to $\mathbf{L}$ in $\mathcal{G}$ that is into both S and T. Hence there is an edge between S and T in $\mathcal{M}$, the MAG of $\mathcal{G}$. The edge in $\mathcal{M}$ is either $S \leftrightarrow T$ or, by Lemma 9, an invisible directed edge ($S \leftarrow T$ or $S \to T$).

Because $S, T \notin \mathbf{X}$, if $S \leftrightarrow T$ appears in $\mathcal{M}$, it also appears in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. If, on the other hand, the edge between S and T in $\mathcal{M}$ is directed, suppose without loss of generality that it is $S \to T$. Either $S \in \mathbf{Y}$, in which case we have $S \leftrightarrow T$ in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, because $S \to T$ is invisible in $\mathcal{M}$; or $S \notin \mathbf{Y}$, and $S \to T$ remains in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. In the latter case we need to show that $S \to T$ is still invisible in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. Suppose for the sake of contradiction that $S \to T$ is visible in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, that there is a vertex R not adjacent to T, such that either $R \ast\!\!\to S$ is in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ or there is a collider path c in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ between R and S that is into S on which every collider is a parent of T. We show that $S \to T$ is also visible in $\mathcal{M}$. Consider the two possible cases separately:

Case 1: $R \ast\!\!\to S$ is in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. If the edge is $R \to S$, it is also in $\mathcal{M}$, because manipulations of a MAG do not create new directed edges. We now show that R and T are not adjacent in $\mathcal{M}$. Suppose otherwise. The edge between R and T has to be $R \to T$ in $\mathcal{M}$. Note that $R \notin \mathbf{Y}$ for otherwise $R \to S$ would be deleted or changed into a bi-directed edge; and we have already shown that $T \notin \mathbf{X}$. It follows that $R \to T$ would be present in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ as well, a contradiction. Hence R and T are not adjacent in $\mathcal{M}$, and so the edge $S \to T$ is also visible in $\mathcal{M}$.

Suppose, on the other hand, the edge between R and S in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ is $R \leftrightarrow S$. In $\mathcal{M}$ the edge is either (i) $R \leftrightarrow S$, or (ii) $R \to S$. (It can't be $R \leftarrow S$ because then $S \in \mathbf{Y}$ and the edge $S \to T$ would not remain in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$.)

If (i) is the case, we argue that R and T are not adjacent in $\mathcal{M}$. Since $R \leftrightarrow S \to T$ is in $\mathcal{M}$, if R and T are adjacent, it has to be $R \leftrightarrow T$ or $R \to T$. In the former case, $R \leftrightarrow T$ would still be present in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ (because obviously $R, T \notin \mathbf{X}$), which is a contradiction. In the latter case, $R \to T$ is invisible in $\mathcal{M}$, for otherwise it is easy to see that $S \to T$ would also be visible. So either $R \to T$ remains in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ (if $R \notin \mathbf{Y}$), or it turns into $R \leftrightarrow T$ (if $R \in \mathbf{Y}$). In either case R and T would still be adjacent in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, a contradiction. Hence R and T are not adjacent in $\mathcal{M}$, and so the edge $S \to T$ is also visible in $\mathcal{M}$.

If (ii) is the case, then either R and T are not adjacent in $\mathcal{M}$, in which case $S \to T$ is also visible in $\mathcal{M}$; or R and T are adjacent in $\mathcal{M}$, in which case we now show that $S \to T$ is still visible. The edge between R and T in $\mathcal{M}$ has to be $R \to T$ (in view of $R \to S \to T$). Since R and T are not adjacent in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, and $R \to S$ is turned into $R \leftrightarrow S$ in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, by the definition of lower-manipulation (Definition 11), $R \to T$ is visible but $R \to S$ is invisible in $\mathcal{M}$. Because $R \to T$ is visible, by definition, there is a vertex Q not adjacent to T such that $Q \ast\!\!\to R$ is in $\mathcal{M}$ or there is a collider path in $\mathcal{M}$ between Q

and R that is into R on which every collider is a parent of T. But $R \to S$ is not visible, from which we can derive that $S \to T$ is visible in $\mathcal{M}$. Here is a sketch of the argument. If $Q \ast\!\!\to R$ is in $\mathcal{M}$, then Q and S must be adjacent (since otherwise $R \to S$ would be visible). It is then easy to derive that the edge between Q and S must be into S, which makes $S \to T$ visible. On the other hand, suppose there is a collider path c into R on which every collider is a parent of T. Then if there is a collider P on c such that $P \leftrightarrow S$ is in $\mathcal{M}$, we immediately get a collider path between Q and S that is into S on which every collider is a parent of T. This path makes $S \to T$ visible. Finally, if no collider on the path is a spouse of S, it is not hard to show that in order for $R \to S$ to be invisible, there has to be an edge between Q and S that is into S, which again makes $S \to T$ visible.

Case 2: There is a collider path c in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ between R and S that is into S on which every collider is a parent of T. We claim that every arrowhead on c, except possibly one at R, is also in $\mathcal{M}$. Because if an arrowhead is added at a vertex Q (which could be S) on c by the lower-manipulation, then $Q \in \mathbf{Y}$, but then the edge $Q \to T$ would not remain in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, a contradiction. So c is also a collider path in $\mathcal{M}$ that is into S. Furthermore, no new directed edges are introduced by lower-manipulation or upper-manipulation, so every collider on c is still a parent of T in $\mathcal{M}$.

It follows that if R and T are not adjacent in $\mathcal{M}$, then $S \to T$ is visible in $\mathcal{M}$. On the other hand, if R and T are adjacent in $\mathcal{M}$, it is either $R \leftrightarrow T$ or $R \to T$. Note that this edge is deleted in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. This implies that it is not $R \leftrightarrow T$ in $\mathcal{M}$: otherwise, the edge incident to R on c has to be bi-directed as well (since otherwise $\mathcal{M}$ is not ancestral), and hence if $R \leftrightarrow T$ is deleted, either the edge incident to R on c or the edge $S \to T$ should be deleted in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, which is a contradiction. So the edge is $R \to T$ in $\mathcal{M}$. Since $T \notin \mathbf{X}$ (for otherwise $S \to T$ would be deleted), $R \in \mathbf{Y}$, and $R \to T$ is visible in $\mathcal{M}$. But then it is easy to see that $S \to T$ is also visible in $\mathcal{M}$.

To summarize, we have shown that if $S \to T$ is visible in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, it is also visible in $\mathcal{M}$. Since it is not visible in $\mathcal{M}$, it is invisible in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ as well. Thus the edge between S and T is either a bi-directed edge or an invisible directed edge in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. Hence we have established (2).

The strategy to complete the proof is to show that $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ can be transformed into a supergraph of $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$ via a sequence of equivalence-preserving mark changes (Zhang and Spirtes, 2005; Tian, 2005). By (1) and (2), if $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ is not yet a supergraph of $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$, it is because some bi-directed edges in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$ correspond to directed edges in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. For any such directed edge $P \to Q$ in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ (with $P \leftrightarrow Q$ in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$), (2) implies that $P \to Q$ is invisible. It is then not hard to check that conditions in Lemma 1 of Zhang and Spirtes (2005)[22] hold for $P \to Q$ in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, and thus it can be changed into $P \leftrightarrow Q$ while preserving Markov equivalence. Furthermore, making this change will not make any other such directed edge in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ visible. It follows that $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ can be transformed into a Markov equivalent graph that is a supergraph of $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$. (We skip the details as they involve conditions for Markov equivalence we didn't have enough space to cover.)

Denote the supergraph by I. It follows that if there is an m-connecting path between A and B given $\mathbf{C}$ in $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$, the path is also m-connecting in I, the supergraph of $\mathcal{M}_{\mathcal{G}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}}$. Because $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ and I are Markov equivalent, there is also an m-connecting path between A and B given $\mathbf{C}$ in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. ■

22. Here is the Lemma: Let $\mathcal{M}$ be a MAG, and $A \to B$ a directed edge in $\mathcal{M}$. Let $\mathcal{M}'$ be the graph identical to $\mathcal{M}$ except that the edge between A and B is $A \leftrightarrow B$ in $\mathcal{M}'$. (In other words, $\mathcal{M}'$ is the result of simply changing $A \to B$ into $A \leftrightarrow B$ in $\mathcal{M}$.) $\mathcal{M}'$ is a MAG and Markov equivalent to $\mathcal{M}$ if and only if
(t1) there is no directed path from A to B other than $A \to B$ in $\mathcal{M}$;
(t2)] For every $C \to A$ in $\mathcal{M}$, $C \to B$ is also in $\mathcal{M}$; and for every $D \leftrightarrow A$ in $\mathcal{M}$, either $D \to B$ or $D \leftrightarrow B$ is in $\mathcal{M}$; and
(t3) there is no discriminating path for A on which B is the endpoint adjacent to A in $\mathcal{M}$.

Proof of Lemma 16

Proof It is not hard to check that for any two variables $P, Q \in \mathbf{O}$, if P and Q are adjacent in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, then they are adjacent in $\mathcal{P}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ (though the converse is not necessarily true, because an edge not definitely visible in $\mathcal{P}$ may still be visible in $\mathcal{M}$). Furthermore, when they are adjacent in both $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ and $\mathcal{P}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$, every non-circle mark on the edge in $\mathcal{P}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$ is "sound" in that the mark also appears in $\mathcal{M}_{\underline{\mathbf{Y}}\overline{\mathbf{X}}}$. The lemma obviously follows. ■

Proof of Lemma 21

Proof Spirtes and Richardson (1996), in proving their Lemma 18, gave a construction of an m-connecting path in $\mathcal{M}$ from a d-connecting path in $\mathcal{G}$. We describe the construction below.[23]

Let p be a minimal d-connecting path between A and B relative to $\mathbf{C}$ in $\mathcal{G}$ that is into A, minimal in the sense that no other d-connecting path between A and B relative to $\mathbf{C}$ that is into A is composed of fewer variables than p is.[24] Construct a sequence of variables in $\mathbf{O}$ in three steps.

Step 1: Form a sequence $\mathbf{T}$ of variables on p as follows. $\mathbf{T}[0] = A$, and $\mathbf{T}[n+1]$ is chosen to be the first vertex after $\mathbf{T}[n]$ on p that is either in $\mathbf{O}$ or a (latent) collider on p, until B is included in $\mathbf{T}$.

Step 2: Form a sequence $\mathbf{S}_0$ of variables in $\mathbf{O}$ of the same length as $\mathbf{T}$, which we assume contains m variables. For each $0 \leq n \leq m-1$, if $\mathbf{T}[n]$ is in $\mathbf{O}$, then $\mathbf{S}_0[n] = \mathbf{T}[n]$; otherwise $\mathbf{T}[n]$ is a (latent) collider on p, which, by the fact that p is d-connecting given $\mathbf{C}$, implies that there is a directed path from $\mathbf{T}[n]$ to a member of $\mathbf{C}$. So in this case, $\mathbf{S}_0[n]$ is chosen to be the first observed variable on a directed path from $\mathbf{T}[n]$ to a member of $\mathbf{C}$.

Step 3: Run the following iterative procedure:

k:=0

Repeat

If in $\mathbf{S}_k$ there is a triple of vertices $\langle \mathbf{S}_k[i-1], \mathbf{S}_k[i], \mathbf{S}_k[i+1] \rangle$ such that (1) there is an inducing path between $\mathbf{S}_k[i-1]$ and $\mathbf{S}_k[i]$ relative to $\mathbf{L}$ in $\mathcal{G}$ that is into $\mathbf{S}_k[i]$; (2) there is an inducing path between $\mathbf{S}_k[i]$ and $\mathbf{S}_k[i+1]$ relative to $\mathbf{L}$ in $\mathcal{G}$ that is into $\mathbf{S}_k[i]$; and (3) $\mathbf{S}_k[i]$ is in $\mathbf{C}$ and is an ancestor of either $\mathbf{S}_k[i-1]$ or $\mathbf{S}_k[i+1]$; then let sequence $\mathbf{S}_{k+1}$ be $\mathbf{S}_k$ with $\mathbf{S}_k[i]$ being removed;

k := k+1

Until there is no such triple of vertices in the sequence $\mathbf{S}_k$.

Let $\mathbf{S}_K$ denote the final outcome of the above three steps. Spirtes and Richardson (1996), in their Lemma 18, showed that $\mathbf{S}_K$ constitutes an m-connecting path between A and B relative to $\mathbf{C}$ in $\mathcal{M}$. We refer the reader to their paper for the detailed proof of this fact. What is left for us to show here is that the path constituted by $\mathbf{S}_K$ in $\mathcal{M}$ is either into A or out of A with an invisible edge.

In other words, we need to show that if the edge between $A = \mathbf{S}_K[0]$ and $\mathbf{S}_K[1]$ in $\mathcal{M}$ is $A \rightarrow \mathbf{S}_K[1]$, then this edge is invisible. Given Lemma 9, it suffices to show that there is an inducing path between

23. Their lemma addresses the more general case in which there may also be selection variables. The construction given here is an adaptation of theirs to fit our case.

24. In Spirtes and Richardson (1996), minimality means more than that the d-connecting path is a shortest one, but for this proof one only need to choose a shortest path.

A and $\mathbf{S}_K[1]$ relative to $\mathbf{L}$ in $\mathcal{G}$ that is into A. This is not hard to show. In fact, we can show by induction that for all $0 \leq k \leq K$, there is in $\mathcal{G}$ an inducing path between A and $\mathbf{S}_k[1]$ relative to $\mathbf{L}$ that is into A.

In the base case, notice that either (i) $\mathbf{S}_0[1]$ is an observed variable on p such that every variable between A and $\mathbf{S}_0[1]$ on p, if any, belongs to $\mathbf{L}$ and is a non-collider on p, or (ii) $\mathbf{S}_0[1]$ is the first observed variable on a directed path d starting from $\mathbf{T}[1]$ such that $\mathbf{T}[1]$ belongs to $\mathbf{L}$, lies on p and every variable between A and $\mathbf{T}[1]$ on p, if any, belongs to $\mathbf{L}$ and is a non-collider on p. In case (i), $p(A, \mathbf{S}_0[1])$ is an inducing path relative to $\mathbf{L}$, which is into A, because p is into A. In case (ii), consider $p(A, \mathbf{T}[1])$ and $d(\mathbf{T}[1], \mathbf{S}_0[1])$. Let W be the variable nearest to A on $p(A, \mathbf{T}[1])$ that is also on $d(\mathbf{T}[1], \mathbf{S}_0[1])$. ($W$ exists because $p(A, \mathbf{T}[1])$ and $d(\mathbf{T}[1], \mathbf{S}_0[1])$ at least intersect at $\mathbf{T}[1]$.) Then it is easy to see that a concatenation of $p(A, W)$ and $d(W, \mathbf{S}_0[1])$ forms an inducing path between A and $\mathbf{S}_0[1]$ relative to $\mathbf{L}$ in $\mathcal{G}$, which is into A because p is into A.

Now the inductive step. Suppose there is in $\mathcal{G}$ an inducing path between A and $\mathbf{S}_k[1]$ relative to $\mathbf{L}$ that is into A. Consider $\mathbf{S}_{k+1}[1]$. If $\mathbf{S}_{k+1}[1] = \mathbf{S}_k[1]$, it is trivial that there is an inducing path between A and $\mathbf{S}_{k+1}[1]$ that is into A. Otherwise, $\mathbf{S}_k[1]$ was removed in forming $\mathbf{S}_{k+1}$. But given the three conditions for removing $\mathbf{S}_k[1]$ in *Step 3* above, we can apply Lemma 32 (together with the inductive hypothesis) to conclude that there is an inducing path between A and $\mathbf{S}_{k+1}[1] = \mathbf{S}_k[2]$ relative to $\mathbf{L}$ in $\mathcal{G}$ that is into A. This concludes our argument. ■

Proof of Lemma 22

Proof This lemma is fairly obvious given Lemma 10. Let u be the path m-connecting A and B given $\mathbf{C}$ in $\mathcal{M}$. Let D (which could be B) be the vertex next to A on u. Construct a DAG $\mathcal{G}$ from $\mathcal{M}$ in the usual way: keep all the directed edges, replacing each bi-directed edge $X \leftrightarrow Y$ with $X \leftarrow L_{XY} \rightarrow Y$. Furthermore, if the edge between A and D is $A \rightarrow D$, it is invisible, so we can add $A \leftarrow L_{AD} \rightarrow D$ to the DAG. Then $\mathcal{G}$ is a DAG represented by $\mathcal{M}$. It is easy to check that there is a d-connecting path in $\mathcal{G}$ between A and B given $\mathbf{C}$ that is into A. ■

Proof of Lemma 23

Proof Note that because A is not an ancestor of any member of $\mathbf{C}$, if there is a path out of A d-connecting A and B given $\mathbf{C}$ in $\mathcal{G}$, the path must be a directed path from A to B. For otherwise there would be a collider on the path that is also a descendant of A, which implies that A is an ancestor of some member of $\mathbf{C}$. The sub-sequence of that path consisting of observed variables then constitutes a directed path from A to B in $\mathcal{M}$, which is of course out of A and also m-connecting given $\mathbf{C}$ in $\mathcal{M}$. The converse is as easy to show. ■

Proof of Lemma 27

Proof A path definitely m-connecting A and B given $\mathbf{C}$ in $\mathcal{P}$ is m-connecting in every MAG represented by $\mathcal{P}$, which is an immediate consequence of the definition of PAG. Let D be the vertex next to A on the definite m-connecting path in $\mathcal{P}$ between A and B given $\mathbf{C}$. All we need to show is that if the edge between A and D is not a definitely visible edge $A \rightarrow D$ in $\mathcal{P}$, then there exists a MAG represented by $\mathcal{P}$ in which the edge between A and D is not a visible edge out of A.

Obviously if the edge in $\mathcal{P}$ is not $A \rightarrow D$, there exists a MAG represented in $\mathcal{P}$ in which the edge is not $A \rightarrow D$, which follows from the fact that $\mathcal{P}$, by definition, displays all edge marks that are shared by all MAGs in the equivalence class.

So we only need to consider the case where the edge in $\mathcal{P}$ is $A \to D$, but it is not definitely visible. Now we need to use a fact proved in Lemma 3.3.4 of Zhang (2006, pp. 80): that we can turn $\mathcal{P}$ into a MAG by first changing every $\circ\!\!\to$ edge in $\mathcal{P}$ into a directed edge $\to$, and then orienting the circle component—the subgraph of $\mathcal{P}$ that consists of $\circ\!\!-\!\!\circ$ edges—into a DAG with no unshielded colliders.[25] Moreover, it is not hard to show, using the result in Meek (1995a), that we can orient the circle component—a chordal graph—into a DAG free of unshielded colliders in which every edge incident to A is oriented out of A.

Let the resulting MAG be $\mathcal{M}$. We show that $A \to D$ is invisible in $\mathcal{M}$. Suppose for the sake of contradiction that it is visible in $\mathcal{M}$. Then there exists in $\mathcal{M}$ a vertex E not adjacent to D such that either $E *\!\!\to A$ or there is a collider path between E and A that is into A and every collider on the path is a parent of D. In the former case, since $A \to D$ is not definitely visible in $\mathcal{P}$, the edge between E and A is not into A in $\mathcal{P}$, but then that edge will not be oriented as into A by our construction of $\mathcal{M}$. So the former case is impossible.

In the latter case, denote the collider path by $\langle E, E_1, ..., E_m, A\rangle$. Obviously every edge on $\langle E_1, ..., E_m, A\rangle$ is bi-directed, and so also occurs in $\mathcal{P}$ (because our construction of $\mathcal{M}$ does not introduce extra bi-directed edges). There are then two cases to consider:

Case 1: The edge between E and E_1 is also into E_1 in $\mathcal{P}$. Then the collider path appears in $\mathcal{P}$. We don't have space to go into the details here, but there is an orientation rule in constructing PAGs that makes use of a construct called "discriminating path" (e.g., Spirtes et al., 1999; Zhang, forthcoming), which would imply that if the collider path appears in $\mathcal{P}$, and every E_i ($1 \le i \le m$) is a parent of D in a representative MAG $\mathcal{M}$, then every E_i is also a parent of D in $\mathcal{P}$. It follows that $A \to D$ is definitely visible in $\mathcal{P}$, a contradiction.

Case 2: The edge between E and E_1 is not into E_1 in $\mathcal{P}$, but is oriented as into E_1 in $\mathcal{M}$. This is possible only if the edge is $E \circ\!\!-\!\!\circ E_1$ in $\mathcal{P}$. But we also have $E_1 \leftrightarrow E_2$ (E_2 could be A) in $\mathcal{P}$, which, by Lemma 3.3.1 in Zhang (2006, pp. 77), implies that $E \leftrightarrow E_2$ is in $\mathcal{P}$. Then $\langle E, E_2, \ldots, A\rangle$ makes $A \to D$ definitely visible in $\mathcal{P}$, which is a contradiction. ■

Proof of Lemma 28

Proof Note that since A does not have a descendant in $\mathbf{C}$, an m-connecting path out of A given $\mathbf{C}$ in $\mathcal{M}$ has to be a directed path from A to B such that every vertex on the path is not in $\mathbf{C}$. Then a shortest such path has to be uncovered,[26] and so will correspond to a definite m-connecting path between A and B given $\mathbf{C}$ in $\mathcal{P}$ (on which every vertex is a definite non-collider). This path is not into A in $\mathcal{P}$ because $\mathcal{P}$ is the PAG for $\mathcal{M}$ in which the path is out of A. ■

Proof of Lemma 29

Proof Let D be the vertex next to A on the definite m-connecting path in $\mathcal{P}$. Since the edge between A and D is not into A in $\mathcal{P}$, there exists a MAG represented by $\mathcal{P}$ in which the edge is out of A (which follows from the definition of PAG). Such a MAG obviously satisfies the lemma. ■

25. A triple of vertices $\langle X, Y, Z\rangle$ in a graph is called an *unshielded* triple if there is an edge between X and Y, an edge between Y and Z, but no edge between X and Z. It is an *unshielded collider* if both the edge between X and Y and the edge between Z and Y are into Y.
26. A path is called *uncovered* if every consecutive triple on the path is unshielded (cf. Footnote 25).

Abstract

The use of computational models is increasingly expected to play an important role in predicting the behaviour of biological systems. Models are being sought at different scales of biological organisation namely: sub-cellular, cellular, tissue, organ, organism and ecosystem; with a view of identifying how different components are connected together, how they are controlled and how they behave when functioning as a system. Except for very simple biological processes, system identification from first principles can be extremely difficult. This has brought into focus automated techniques for constructing models using data of system behaviour. Such techniques face three principal issues: (1) The model representation language must be rich enough to capture system behaviour; (2) The system identification technique must be powerful enough to identify substantially complex models; and (3) There may not be sufficient data to obtain both the model's structure and precise estimates of all of its parameters. In this paper, we address these issues in the following ways: (1) Models are represented in an expressive subset of first-order logic. Specifically, they are expressed as logic programs; (2) System identification is done using techniques developed in Inductive Logic Programming (ILP). This allows the identification of first-order logic models from data. Specifically, we employ an incremental approach in which increasingly complex models are constructed from simpler ones using snapshots of system behaviour; and (3) We restrict ourselves to "qualitative" models. These are non-parametric: thus, usually less data are required than for identifying parametric quantitative models. A further advantage is that the data need not be precise numerical observations (instead, they are abstractions like positive, negative, zero, increasing, decreasing and so on). We describe incremental construction of qualitative models using a simple physical system and demonstrate its application to identification of models at four scales of biological organisation, namely: (a) a predator-prey model at the ecosystem level; (b) a model for the human lung at the organ level; (c) a model for regulation of glucose by insulin in the human body at the extra-cellular level; and (d) a model for the glycolysis metabolic pathway at the cellular level.

Keywords: ILP, qualitative system identification, biology

1. Introduction

There is a general move in biology from seeking an understanding at the level of individual units (genes, proteins and so on) to an understanding at the system-level. Identifying single genes, proteins or metabolite levels cannot be expected to yield an answer to systemic behaviour any more than a list of radio parts could explain its behaviour (a point made in Lazebnik's humourous and perceptive article: Lazebnik, 2002). What is needed is an understanding of the function of each part and, crucially, how these components are connected, how they are controlled and the dynamic behaviour of the system as a whole. Biology, which for the last decade or so has been pre-occupied with establishing the "parts-list" is now moving to address these other issues. Besides the obvious scientific value of understanding whole systems, substantial benefits are expected to follow in clinical medicine. This is concerned with the application of computation and applied mathematics to improve existing pharmaceutical and medical practices. It is expected that results in systems-level biology will allow a better understanding of the nature of diseases, leading to a targeted design of new drugs and drug treatments. The importance of adopting a systemic approach to biology is not new: there are statements in Darwin's *Origin* that clearly anticipate this need. Its relevance in the modern biological context is summarised in a recent article in *Science* (W.Bialek and D.Botstein, 2004):

> The basic nature and goals of biological research is changing fundamentally. In the past, biological processes and the underlying genes, proteins, other molecules, and environmental factors were of necessity studied one by one in relative isolation. In contrast, today we are no longer satisfied with studies or answers that place each of these in a larger context. We now know that there are tens of thousands of genes encoded in the genome and that simple perturbations such as . . . heat shock, alter the expression of thousands of them . . . New goals are in sight, namely robust mathematical models and computer simulations that faithfully predict the behaviour of entire biological systems.

Some substantial research effort is being expended in trying to achieve these goals. The Physiome Project for example (see `http://www.physiome.org/`) lists its principal aim as being "to understand and describe the human organism, its physiology and pathophysiology quantitatively." This it hopes to achieve by using models at different levels (molecular to organ) that "include everything from diagrammatic schema suggesting relationships to fully quantitative computational models." Similarly, the United Kingdom's main research funding body in biology (the BBSRC) has invested over 15 million pounds in centres for integative systems biology: "the aim is to support research in such a way that all the components of the system under study can be researched at all relevant levels of biological organisation. It necessitates being able to to handle large experimental data sets and having the expertise and capacity to manipulate these and combine them with the theoretical base to develop new predictive and holistic models of how living systems function." (see *Bioscience for Society: A Ten Year Vision, January 2003* at `http://www.bbsrc.ac.uk/about/plans_reports/vision.html`).

In the physical sciences, the principal means of understanding complex systems has been through the use of mathematical models. This same approach is adopted in the field of mathematical biology. Following the pioneering work of Alan Turing (Turing, 1952) and Hodgkin and Huxley (1952) differential equations are now used to model a wide range of transport, reaction and conservation phenomena (Murray, 1993). However, while identification of models of physical systems can often

proceed from first principles (for example, balance equations, energy conservation and so on), the complexity of biological systems often force a much more experimental approach. The modeller selects those physical processes believed to be important, constructs a model and checks if solutions match the observed data. If not, the procedure is repeated until an adequate model is found. For example, a first attempt at modelling oxygen transport to red blood cells may consider a model that accounted for convection, diffusion and chemical reaction (these are the principal physical processes involved). In fact, convection makes a negligible contribution and reaction is only important for sick lungs. Once it is known that only the diffusion term is important, a parametric equation can be found relatively easily.

Broadly speaking, system identification can be viewed as "the field of modelling dynamic systems from experimental data" (Soderstrom and Stoica, 1989). We can distinguish here between: (a) classical system identification techniques, developed by control engineers and econometricians; and (b) machine learning techniques for system identification, developed by computer scientists. While the kinds of models identified by the two kinds of techniques are different, neither provides a foolproof method that can be employed without user interaction.

Classical system identification has concentrated on models largely constrained to be either ordinary differential equations (ODEs) or linear difference equations of some order. With this constraint on model structure, the input-output behaviour of the system is observed over a time interval and some statistical method is used to estimate parameters in the model. In its most general formulation, system identification proceeds by repeated estimation of both structure and parameters until an acceptable model is found. In practice, a small set of structures are given *a priori* and the procedure reduces to one of parameter estimation. Classical techniques have been used to identify linear time-invariant models for purposes of extracting control strategies (in engineering) or time-series predictions (in economics).

In this paper we are concerned instead with using machine learning techniques for system identification. Specifically, our interest is in methods that: (a) are not restricted to specific model structures; and (b) allow the incorporation of domain knowledge both to specify constraints on acceptable model structures and to direct the search through the space of acceptable structures. We believe both these features to be necessary in any empirical approach for identifying biological systems from data. Of the machine learning methods available that are capable of satisfying these requirements, those developed under the framework of Inductive Logic Programming (ILP) are amongst the most powerful. There are two reasons for this. First, the rich logic-based formalism used by ILP methods allows them to represent and identify a wide variety of relational descriptions. Second, ILP methods are unusual in that they make explicit provisions for the incorporation of domain knowledge to guide the model identification process. This includes mechanisms for the requirement in (b) above.

One question that is often raised in the context of ILP is that of efficiency. In the context here, this translates to asking if ILP methods are efficient enough to identify significantly complex biological models? As long as it is reasonable to identify such models in an incremental manner, we believe the answer to this question is "yes" and demonstrate this with the identification of four fairly complex systems at different scales of biological organisation (a predator-prey model at the ecosystem level; a model for the human lung at the organ level; a model for glucose regulation at the extra-cellular level; and the glycolysis metabolic pathway at the cellular level).

A second issue, unrelated to the use of ILP, but relevant to the empirical system identification task is the quantity and quality of data available. The identification of both the structure and parameter of quantitative models (like ODEs) requires a substantial amount of good quality numerical

data. While substantial amounts of quantitative data are being generated at some lower levels of biological organisation (a prominent example is provided by the use of DNA microarray data to estimate mRNA levels in a cell), quality is still variable: it is possible, for example to get very different expression profiles for the same tissue using different microarray technologies (Kuo et al., 2002). At higher levels (for example, at the organ or ecosystem level), data are sparse, although of perhaps better quality. In all cases, we believe it to be substantially easier and more reliable to obtain data that are of a qualitative nature. For example, it may be relatively easier to decide whether certain metabolites are present or absent in a cell, whether their levels have been increasing or decreasing and so on, rather than obtain precise measurements of the metabolites. In this paper, we will be concerned exclusively with system identification from such qualitative data. The resulting models are non-parametric: that is, parameter estimation is not required and data are only needed to identify the model structure. Clearly, these qualitative models cannot be treated as being equivalent to their quantitative counterparts. Nevertheless, they can be used to simulate possible system behaviours and may be much more understandable to a non-mathematical biologist than a quantitative model like a differential equation.

The rest of the paper is organised as follows. Section 2 describes an established approach to qualitative reasoning about dynamic systems. This involves the use of qualitative constraints which form the building blocks of qualitative models (these models include abstractions of ordinary differential equations). Section 3 describes informally the the basics of an ILP system used to identify qualitative models. This includes a variant that performs an incremental identification of increasingly complex models. Section 5.1 demonstrates this form of identification using a model physical system. The application to biological systems is in Section 6. Section 7 examines the automatic identification of stages for the incremental learner. Section 8 concludes the paper. Appendix A provides details of the ILP system used for incremental system identification. Appendix B provides details of the procedure for multi-stage decomposition.

2. Constraint-Based Qualitative Reasoning

Figure 1 (slightly modified from Bratko, 2001) shows four different qualitative abstractions of some numerical statements: (a) numbers are represented by intervals (marked by some distinguished values like *zero*,*end*, *inf* and so on); (b) derivatives are represented by directions of change (like *inc*); (c) functions are represented by monotonic relations (like `MPLUS` denoting "monotonically increasing"); and (d) entire sequences of behaviour are represented by qualitative statements that specify a qualitative values and directions of change.

Reasoning with qualitative abstractions requires a calculus: we propose to use the constraint-based formulation used in the qualitative simulation program QSIM (Kuipers, 1994) (here we provide an informal description along the lines described by Bratko 2001). In this, variables take qualitative values from *domains*. Domains are defined by a name and some ordered set of distinguished values called landmarks. For example, the variable *Amount* in Fig. 1 could be from the domain *level* with landmarks $minf, 0, inf$. A qualitative state of a variable is usually denoted by $Domain : QVal$ where $QVal$ is represented as a $\langle Qmag, Qdir \rangle$ pair, sometimes written $Qmag/Qdir$. $Qdir$ is the qualitative rate of change of the variable, which has a fixed, three-valued resolution (the three quantities being *inc*, for increasing; *dec*, for decreasing; and *std*, for steady). For example, the qualitative state of the variable *Amount* could be $level : 0...inf/inc$ (compare with (d) in Fig. 1).

	Quantitative Statement	Qualitative Statement
(a)	$Level(3.2\ s) = 2.6\ cm$	$Level(t1) = zero...inf$
(b)	$\frac{d}{dt}Level(3.2\ s) = 0.12\ m/s$	$\texttt{DERIV}(Level(t1)) = std$
(c)	$Amount = Level \times Level$	$\texttt{MPLUS}(Level, Amount)$
(d)	Time / Amount: 0.0 / 0.00; 0.1 / 0.02; ... / ...; ... / ...; 159.3 / 62.53	$Amount(zero...end) = zero...inf/inc$

Figure 1: Qualitative abstractions of numerical data (from Bratko, 2001).

The qualitative state of a system is simply a list of the qualitative states of the system's variables and a qualitative behaviour is a list of consecutive qualitative states.

Reasoning is accomplished using constraints. In this approach, pioneered by Kuipers (1994), there are four principal constraints: `ADD(A,B,C)`, for addition of qualitative variables `A` and `B` to give `C`;[1] `MULT(A,B,C)`, to denote $\texttt{A} \times \texttt{B} = \texttt{C}$; `MINUS(A,B)`, for sign inversion $\texttt{A} = -\texttt{B}$; and `DERIV(A,B)`, to denote that `B` is the a derivative of `A`. In this paper, we will also use `SUB(A,B,C)` to denote $\texttt{A} - \texttt{B} = \texttt{C}$. In addition to these, two functional constraints are also used: `MPLUS(A,B)`, to denote that when `A` increases then `B` increases as well; and `MMINUS(A,B)`, to denote that when `A` increases then `B` decreases. We will henceforth refer to these constraints as "the QSIM constraints".

Figure 2 shows a qualitative model for a simple physical system, expressed in terms of the QSIM constraints. A qualitative behaviour of this system—that is, a sequence of qualitative states of the system variables `La`, `Lb` and `Fab` that satisfy the model's constraints—is shown in Fig. 3

A number of advantages have been proposed for using qualitative models. First, in some cases they may be more appropriate than quantitative models. This is particularly so if quantitative measurements are either difficult to obtain or are noisy and what is of interest are the essential properties of the system. Second, the models are quite comprehensible. Both these features are particularly relevant to the modelling of biological systems. There is an additional advantage for automatic system identification of the kind we propose here. Since qualitative models are non-parametric all computational effort is focussed on identifying the model structure. This typically requires data of both less precision and quantity than that required for identification of quantitative models.

1. Constraints apply to the qualitative states of `A`, `B` and `C`. Recall that these are of the form $Domain : Qmag/Qdir$. Thus, the `ADD` constraint ensures that both magnitudes and directions of change are consistent. Thus $\texttt{ADD}(level : 0/inc, level : 0...inf/std, level : inf/inc)$ is true, but $\texttt{ADD}(level : 0...inf/inc, level : inf/std, level : 0...inf/inc)$ is not $(0...inf + inf \neq 0...inf)$. Similarly, $\texttt{ADD}(level : 0...inf/inc, level : 0...inf/std, level : 0...inf/inc)$ is true, but $\texttt{ADD}(level : 0...inf/inc, level : 0...inf/std, level : 0...inf/std)$ is not $(inc + std \neq std)$. It should also be apparent, that while quantitative addition is functional (the sum of a pair of numbers is a unique number) , qualitative addition ones is relational (that is, for a pair of qualitative states for `A` and `B`, `ADD` may be true for more than one qualitative state for `C`). Similar remarks apply to the other constraints.

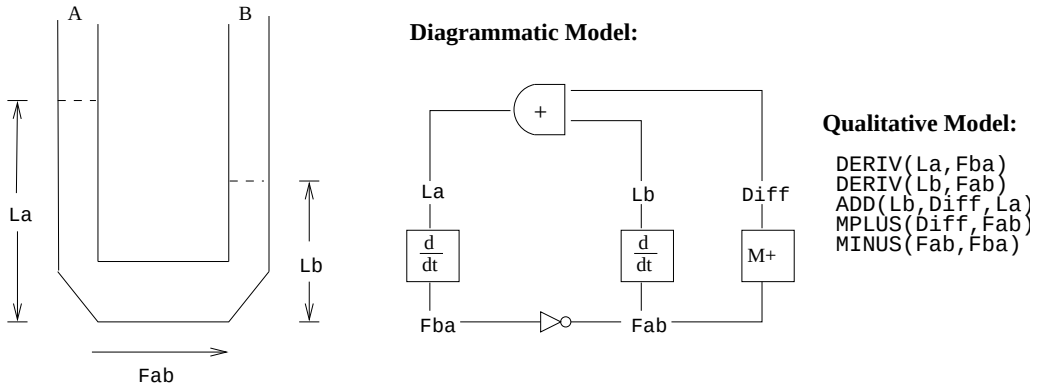

Figure 2: The U-tube and its qualitative model. There are three (measurable) system variables: the water-level in arm A (La); the water-level in arm B (Lb); and the flow of water from A to B (Fab). The diagrammatic model shows the system components involved (two differentiators, an adder, an inverter, and a monotonic function generator) and their interconnections. The qualitative model expresses the same information as a conjunction of constraints (here, we have used the QSIM constraints described in the paper).

La	Lb	Fab
$level : 0/std$	$level : 0/std$	$flow : 0/std$
$level : 0/inc$	$level : 0...inf/dec$	$flow : minf...0/inc$
$level : 0...inf/dec$	$level : 0/inc$	$flow : 0...inf/dec$
$level : 0...inf/dec$	$level : 0...inf/inc$	$flow : 0...inf/dec$
$level : 0...inf/std$	$level : 0...inf/std$	$flow : 0/std$
$level : 0...inf/inc$	$level : 0...inf/dec$	$flow : minf...0/inc$

Figure 3: A qualitative behaviour of the U-tube that is consistent with the qualitative model in Fig. 2. The rows are example states of the qualitative variables and have no implied ordering.

3. Model Identification using Inductive Logic Programming

Given correct definitions for the QSIM constraints, it is our aim in this paper to identify qualitative models such as that shown in Fig. 2, given qualitative states such as those shown in Fig. 3. Since the QSIM constraints are relational, automatic identification of such models clearly requires that the system identification method be able postulate and test relational models. Perhaps the most powerful framework for learning such models is that provided by Inductive Logic Programming (ILP, see Muggleton and Raedt, 1994). ILP is concerned with extracting models in an extremely expressive subset of first-order logic and reasonably efficient implementations have been developed.

To a good first approximation, the basic task addressed by an ILP system can be viewed as a discrete optimisation problem of finding the lowest cost elements amongst a finite set of alternatives. Many ILP systems solve this problem by employing a procedure that searches through a

directed acyclic graph representation of possible models. In this representation, a pair of models are connected in the graph if one can be transformed into another by an operation called "refinement". Figure 4 shows some parts of a graph for the U-tube in which a model is refined to another by the addition of a qualitative constraint. An optimal search procedure (branch-and-bound, for example) traverses this graph in some order, at all times keeping the cost of the best nodes so far. Whenever a node is reached where it is certain that it and all its descendents have a cost higher than that of the best nodes, then the node and its descendents are removed from the search. A portion of the search tree commencing at $\emptyset$ for one such search is shown in Fig. 5.

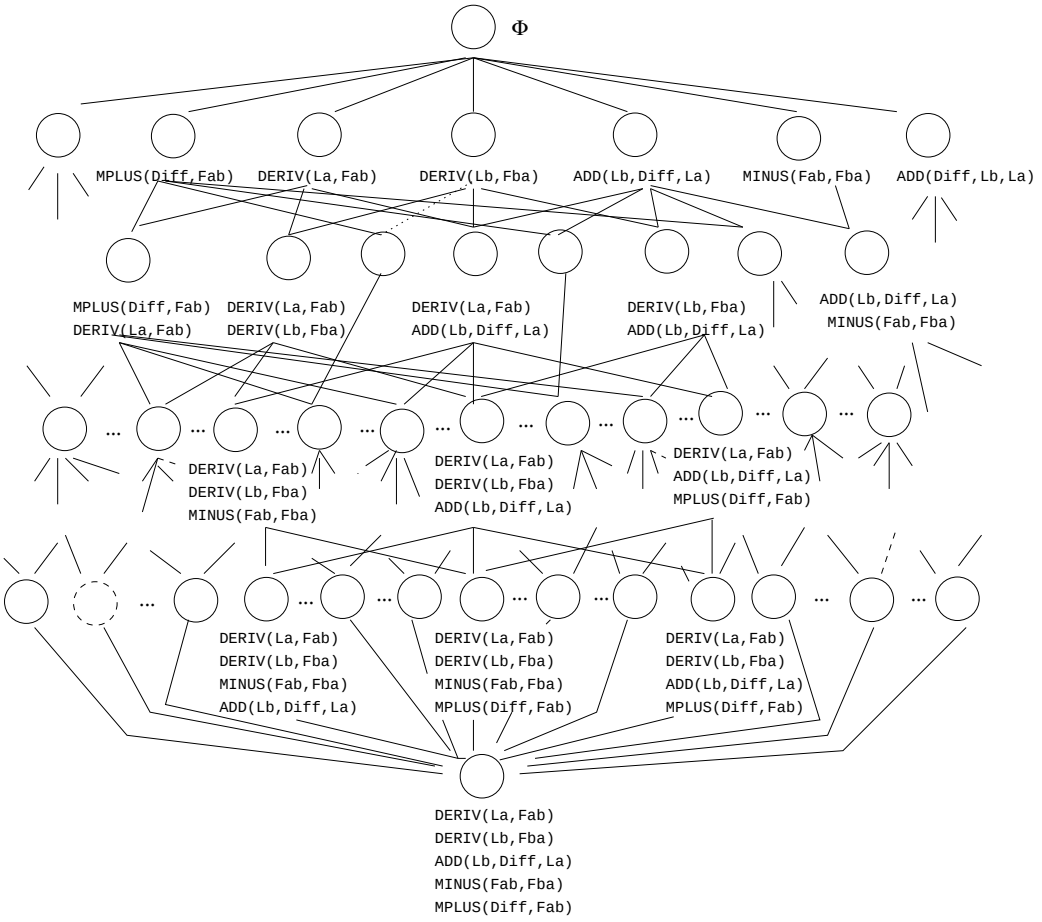

Figure 4: Portions of a refinement graph of models for the U-tube.

Enumerative procedures like branch-and-bound works best if the cost function is monotonic. That is, the score of each node in the search tree is at least as bad as all its descendents (this allows the nodes and its descendents to be removed from the search). The procedure is optimal in the sense that it is guaranteed to find the best solution(s). However in the worst case, it may require examining the entire search space.

Actually, there is more to an ILP system than search. The principal components of such systems are:

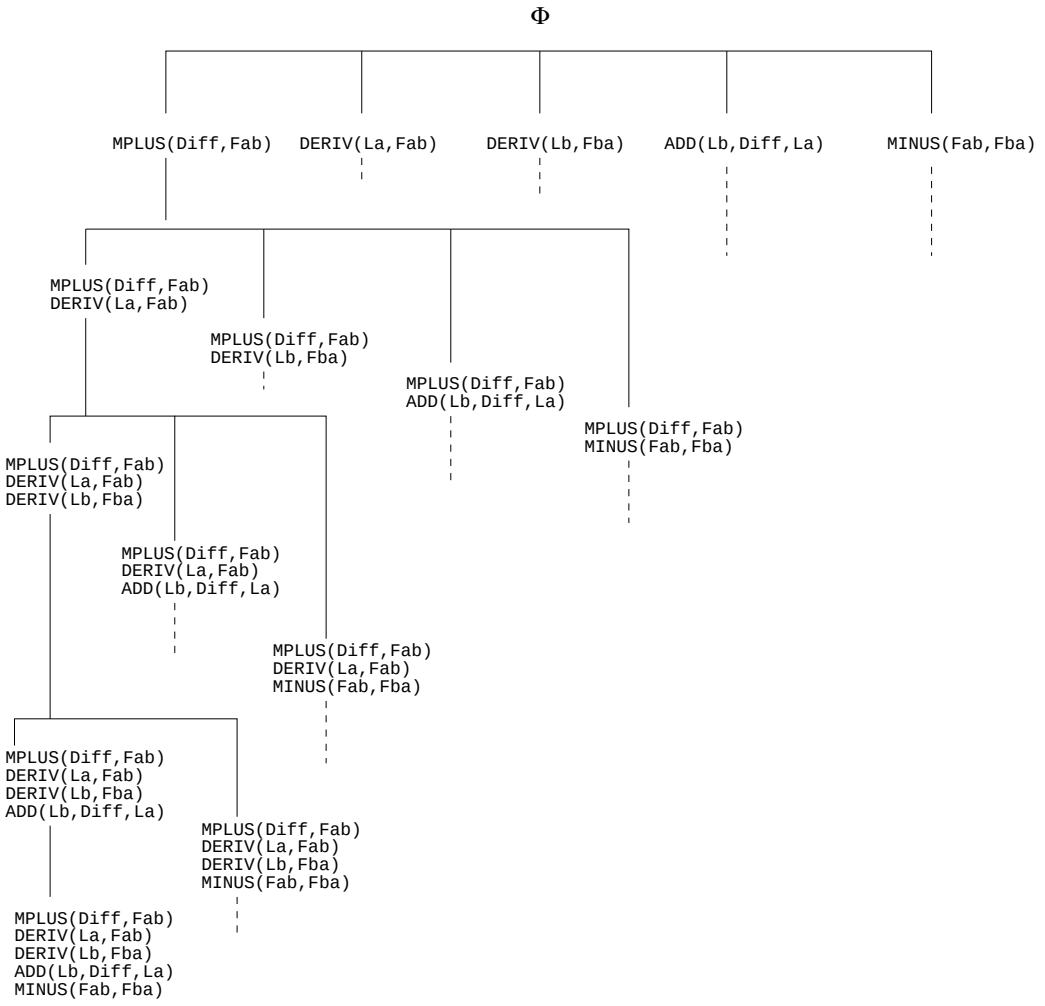

Figure 5: Portions of the search tree explored when searching for models for the U-tube. The search starts from $\emptyset$.

1. *Background knowledge B.* These are statements, usually written in some formal language that specify domain-specific information. We will include in this domain-specific constraints on the kinds of models that are acceptable (or unacceptable, if easier); and directions to the search procedure that allow the system to avoid useless search paths. Examples of these for qualitative model identification are:

   (a) Definitions for qualitative constraints like `DERIV`, `MPLUS`, `ADD` and so on, along with appropriate dimensionality checks *etc.* to ensure their correct usage.

   (b) A constraint specifying that models must not contain relations that are redundant. For example, the relation `ADD(Diff,Lb,La)` is redundant if the model already has `ADD(Lb,Diff,La)` (that is, `ADD` is commutative). The model must respect dimensional

constraints. This prevents relations like `ADD(Lb,Fab,La)` from appearing in the model (`Fab` being a flow has different units of measurement to the level `Lb`).

(c) A directive that the search need not examine models that explain below some proportion of the observed behaviours (more on "explain" in a moment).

2. *Examples E*. These are the observed data. For qualitative model identification, these would be qualitative observations of system behaviour of the form shown in Fig. 3. ILP systems also accept counter-examples of system behaviour. Since this is difficult to obtain for the problems we are concerned with, we do not pursue this further here. Given a set of examples, H is said to explain an observation e if H is consistent with B and e logically follows from B and H (see Appendix A for a precise mathematical formulation). For example, given correct definitions for the qualitative constraints `DERIV`, `MPLUS`, `ADD` and `MINUS` as background knowledge, the qualitative model described by the conjunction `DERIV(La,Fab)` $\wedge$ `DERIV(Lb,Fba)` $\wedge$ `ADD(Lb,Diff,La)` $\wedge$ `MPLUS(Diff,Fab)` $\wedge$ `MINUS(Fab,Fba)` is an explanation of the examples in Fig. 3.

3. *Refinement operator* ρ. This function defines the set of descendents for each node in the refinement graph. With most ILP systems, the set of descendents of a node are (minimal) generalisations or specialisations of the node. Roughly speaking, for qualitative models, generalisations correspond either: to removing one or more qualitative components from the diagrammatic model; or to "disconnecting" qualitative components from each other. Conversely, specialisations correspond to adding new components or connecting existing components.

4. *Cost function* f. This is a real-valued function for each node in the refinement graph. As mentioned earlier, monotonic cost functions are of some importance. A simple cost function satisfying this property in Fig. 4 is $f(H) = -P$, where P is the number of examples explained by model H. If every element H' of $\rho(H)$ contains at least one additional constraint, it can be shown that number of examples explained by H' (and recursively, all its descendents) would be at most P. It follows therefore that the cost of H is no worse than any of its descendents. In practice such a cost function is too simple to be of use (the search would trivially return the most general model), and modifications are made either to: (a) incorporate a trade-off between the explanatory power of the model and its complexity (Muggleton, 1996); or (b) include additional constraints in the background knowledge that prevent the selection of trivial models.

A description of an ILP implementation that uses these components can be found in Section A.2.

4. Identification of Qualitative Models

We refer the reader to Coghill et al. (2005) for an extended review of the literature on learning qualitative models. Briefly, Bratko and colleagues (Bratko et al., 1989; Mozetic, 1987) appear to have the been the first to use qualitative reasoning to build a static model for the electric activity of the heart. Coiera's GENMODEL (Coiera, 1989a,b) was the first machine learning system that constructed qualitative models for dynamic systems. A special-purpose ILP system, GENMODEL (and an updated version in Hau and Coiera, 1997) is restricted to finding qualitative relationships amongst the observed variables only (that is, no intermediate, or hidden, variables are hypothesised).

Model-identification systems that allowed intermediate variables were developed independently by Richards et al. (1992) and Bratko et al. (1992). Both use general-purpose ILP learners (although in different ways) and the principal advantages and shortcomings of these approaches and a later program called QSI (Say and Kuru, 1996) have been documented elsewhere (Coghill et al., 2005).

More recently, the QOPH system for identifying qualitative models exploited the possibility of providing the ILP system ALEPH with a special-purpose refinement operator (Coghill et al., 2002). This operator, with certain "built-in" constraints on acceptable qualitative models, is used by ALEPH to search the space of possible models. Extensive experiments are reported by Coghill et al. (2002) on the reconstruction of some model physical systems. While the results are promising, the scalability of the approach is unclear, since: (a) Model identification is assumed to be possible in a single step. Some simple complexity arguments (see Section A.2) suggest that the complexity of this task grows exponentially with the number of constraints in the model (this is the primary motivation for the incremental approach described in the next section); and (b) The special-purpose refinement operator is difficult to modify and its properties are difficult to analyse. Although not using a general-purpose ILP system, Suc and colleagues have proposed a hybrid approach of combining a logic-based qualitative learner followed by numeric modelling to construct quantitative models of systems (Suc et al., 2003). The approach, called Q^2-learning, first constructs "qualitative model trees". These are like decision trees, with monotonic QSIM constraints in the leaves. These constraints are then used to direct the construction of quantitative models (usually linear models). The success of this approach depends on the availability and quality of numeric data and the system being modelled by a composition of quantitative models (for example, like piecewise linear models).

The advantages of using of a purely qualitative representation for modelling metabolic pathways has been recently advocated (King et al., 2005). In that paper, a special-purpose system is used to generate possible models for the glycolysis pathway. The approach we propose here differs from that in two principal ways. First, it is a general approach as opposed to a specialised one for metabolic pathways. Second, the complexity of the implementation by King and his co-workers is of the same order as QOPH implementation. The incremental approach described in the next section will usually be significantly more efficient.

5. Incremental Model Identification with ILP

Modern ILP systems are largely "one-shot" model constructors. That is, given B, E, ρ and f, they attempt to identify models with the lowest cost in a single search. While this approach has been reasonably successful in the identification of small to medium-sized models (for example, qualitative models containing no more than 4 to 5 constraints), it is unclear whether the approach can scale up to the identification of substantially complex models. For example, the worst-case bound in Remark 2 in Section A.2 grows exponentially in the number of qualitative constraints in the model.

An obvious approach to control this increase in complexity is to decompose system identification into a series of stages, with the final model being some composition of models obtained at each stage. In this paper we use a simple incremental composition in which models identified at any stage are modified at the next stage. That is, one or more models are identified for the first stage (these are all the models consistent with the background knowledge and have the lowest cost). Each of these are then used to give models for the next stage and so on. This is easily achieved by starting the search at each stage at nodes in the refinement graph corresponding to the models found at the

previous stage. Formally the incremental learner is principally provided with: (a) an initial set of models H_0; (b) a sequence of pairs (B_i, E_i) corresponding to the background knowledge and examples for each stage i (the B_i and E_i do not all have to be different); (c) a general-purpose refinement operator ρ for all stages; and (d) a cost function f for all stages. The task of the incremental learner is to construct a set of models from this data (see Fig. 6 and Appendix A).

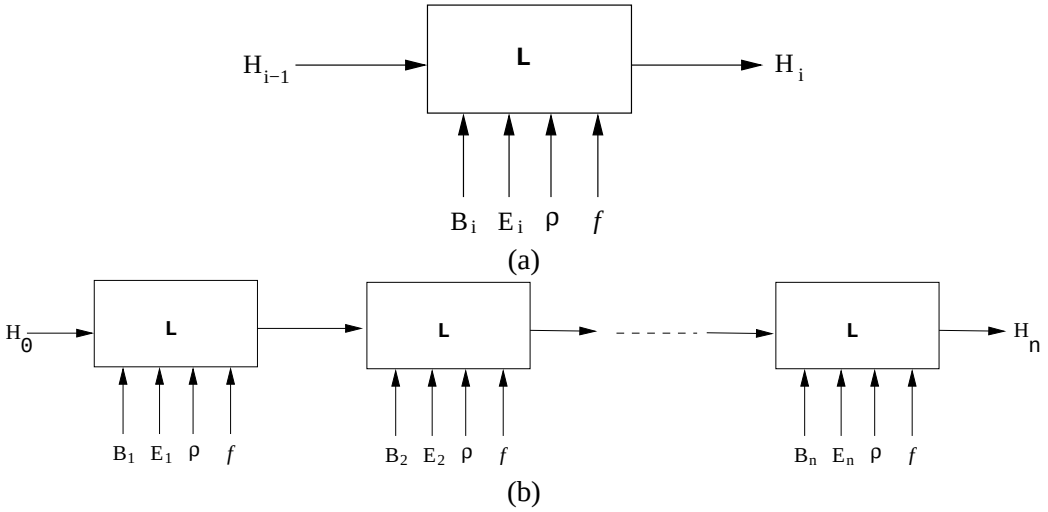

Figure 6: Incremental model identification with ILP. The basic element shown in (a) consists of an ILP learner L that takes as input a set of models, background knowledge, examples, a refinement operator ρ and a cost function f. In (b), this basic unit is repeatedly used to construct a model in n stages. "One-shot" model identification by normal ILP systems is a special case of this process, with $n = 1$ and $H_0 = \{\emptyset\}$ (here $\emptyset$ denotes the empty model).

The actual implementation in Section A.2 contains some additional aspects which are not shown in Fig. 6 (and similar figures in Section 6) for simplicity:

1. A refinement operator that performs both generalisations and specialisations can completely revise models found at a previous stage. However, this is computationally expensive. Instead, we use a refinement operator ρ_A that is restricted to performing specialisations only (for qualitative models, this amounts to adding qualitative constraints and connecting existing qualitative components). To correct partially for this shortcoming, models are subject to a limited generalisation before submission to any L. For qualitative models, this translates to retaining the qualitative components found at the previous stage but disconnecting some or all components, respecting any constraints provided on the usage of the components (in ILP terminology, this amounts to removing variable co-references, respecting any language constraints provided). This allows the incremental procedure to perform a particular kind of revision of models found at the previous stage;

2. Logically redundant models produced by any L are removed and a subset of the result is selected randomly;

3. A cost function f_{Bayes} described in Muggleton (1996) is used. For qualitative models, this performs a trade-off between the likelihood of a qualitative model and its complexity (a quantity related to the number of constraints in the model); and

4. An upper-bound is provided on the amount of search to be conducted by any L.

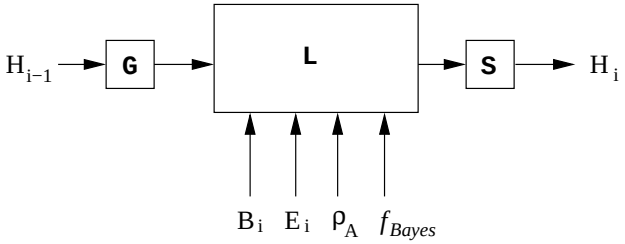

Figure 7: A more accurate representation of the implementation of the basic element used in this paper. Here G performs a limited generalisation of the input models, and can be eliminated for refinement operators that perform both generalisations and specialisations. S performs a random selection of the output models and can be eliminated if all models produced by L are sent to the next stage. ρ_A is a refinement operator that performs specialisations only; and f_{Bayes} is a Bayesian cost function. For simplicity, we will not show G and S in subsequent figures.

A more accurate representation of the basic element of the incremental learner, as implemented by the procedures in Section A.2, is shown in Fig. 7. With these implementation choices it can be shown that, for identification of qualitative models, the size of the search space of such an incremental procedure is dominated by maximum number of additional qualitative constraints that need to be identified at any one of the stages (see Section A.2 for the details). The savings over a non-incremental approach can be substantial, but two points are worthy of re-emphasis:

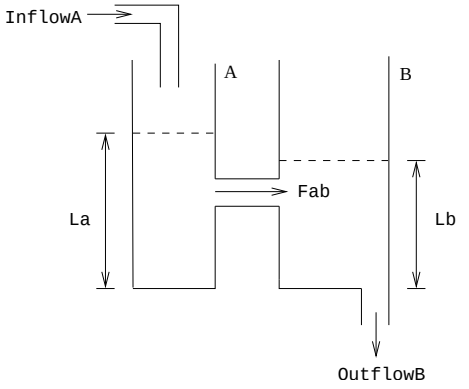
1. The incremental approach requires that a domain-specific decomposition into stages should be possible (by providing background knowledge and observational data for each stage); and

2. We can only guarantee correctness of the incremental approach to the extent that any model identified for a stage will logically entail the observations for that stage (given the background knowledge). The approach cannot, however, provably identify the lowest cost model in the search space. This follows naturally from the fact only lowest cost models are retained at the end of each stage: unless the cost function exhibits a form of monotonocity with stages (or we are simply constructing models in a single-stage), this is tantamount to using a greedy search, which is known to be sub-optimal.

These caveats aside, the incremental approach can be used either: (a) as a "single-shot" model constructor; or (b) to refine approximate models; or (c) to build increasingly larger models using sub-components of smaller ones. In the next section, we illustrate (c) using a model physical system.

5.1 Incremental Qualitative Model Identification: An Example

We consider identifying the qualitative model of the coupled-tanks system shown in Fig. 8. The measurable system variables are these: the input, `InflowA`, that pours into the top of tank A; the output, `OutflowB`, that pours out of the base of tank B; the flow of water from A to B, `Fab`; and the water-levels `La` and `Lb`.



Qualitative Model:

```
DERIV(La,NetflowA)
DERIV(Lb,NetflowB)
ADD(Lb,Diff,La)
MPLUS(Diff,Fab)
MPLUS(Lb,OutflowB)
ADD(NetflowB,OutflowB,Fab
ADD(Fab,NetflowA,InflowA)
```

Figure 8: A system comprised of two coupled tanks and its qualitative model.

The coupled tanks system consists of two tanks connected together. This allows us to decompose the identification of this model into two stages. In the first stage, we focus on identifying a model for tank B, using the single tank system in Fig. 10 (often called the "bathtub" system in qualitative modelling literature). Any consistent models identified for the single tank system are then extended to return final models for the coupled tanks system (see Fig. 9).

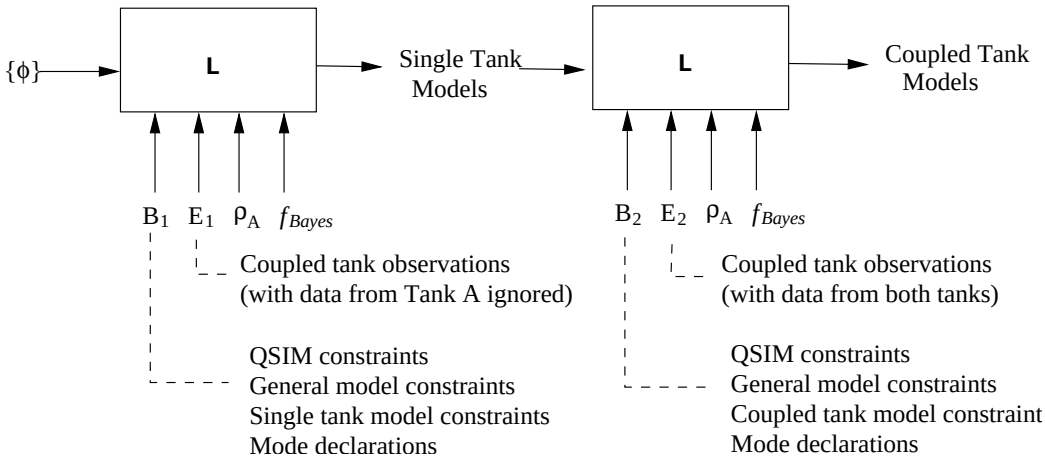


Figure 9: Incremental model identification for the coupled tanks system. Models are first identified by `L` for a single tank system. These are then refined by `L` to models for the coupled tank system. The term "mode declarations" is used in the sense described in Muggleton (1995) and refer to statements that provide domain and connectivity information for the qualitative variables.

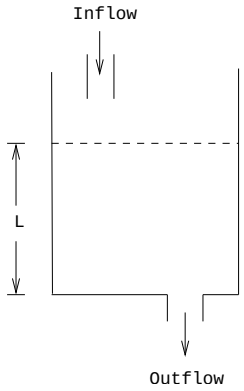
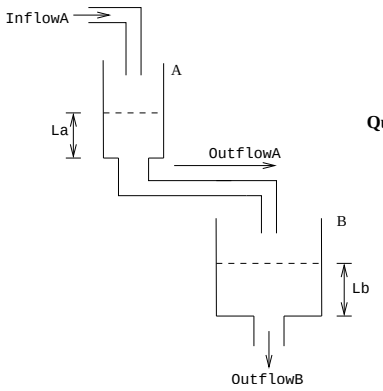
We note in passing that the final model for the coupled tanks is not simply a conjunction of two single tank models. This conjunction would not capture the fact that the flow from tank A to B is related to the difference in levels of fluid in A and B. The conjunction of the two models is, in fact, an appropriate model for the system of cascaded tanks shown in Fig. 11.



Qualitative Model:

```
DERIV(L,Netflow)
MPLUS(L,Outflow)
ADD(Outflow,Netflow,Inflo
```

Figure 10: A single tank system with an input and output. The system variables are `Inflow`, `Outlflow` and , `L`.



Qualitative Model:

```
DERIV(La,NetflowA)
MPLUS(La,Fab)
ADD(OutflowA,NetflowA,InflowA)
DERIV(Lb,NetflowB)
MPLUS(Lb,OutflowB)
ADD(NetflowB,OutflowB,OutflowA
```

Figure 11: A system comprised of two cascaded tanks. The qualitative model is simply a conjunction of two single tank models.

We elaborate further on the elements in Fig. 9:

1. *Background knowledge.* This is comprised of the following components:

   (a) Correct definitions of the QSIM constraints. Our definitions are based on those in Bratko (2001);

   (b) A set of general constraints on "well-posed" qualitative models. We describe these in more detail below;

(c) Stage-specific constraints on the models constructed. This consists of specifying the number of qualitative constraints in the final model for each stage. This is 3 for Stage 1 (the single tank model) and 7 for Stage 2 (the coupled tanks model); and

(d) Stage-specific "mode" declarations similar to the description in Muggleton (1995) that provide domain and connectivity information for the qualitative variables (see Fig. 12);

2. *Examples.* These are in the form of qualitative states for the system variables. Recall that for the coupled tanks system these are: `La`, `Lb`, `InflowA`, `Fab` and `OutflowB` (see Fig. 8). Clearly, flows and levels cannot be negative: we are further only interested in a system with a steady, non-negative input flow. That is, the only valid qualitative state for `InflowA` is $flow:0...inf/std$. `OutflowB`, on the other hand, can be any one of $flow:0/std$, $flow:0/inc$, $flow:0...inf/std$, $flow:0...inf/inc$, $flow:0...inf/dec$. The level of water `La` or `Lb` for the system can similarly assume any of the following qualitative states: $level:0/std$, $level:0/inc$, $level:0...inf/std$, $level:0...inf/inc$, $level:0...inf/dec$. Examples for Stage 1 ignore the values observed for levels and flows for Tank A (that is, `La` and `InflowA` are ignored: this can be easily specified using the mode declarations). Some observations for Stage 1 are shown in Fig. 13. Examples for Stage 2 contain the qualitative states of all the system variables.

3. *Refinement operator and cost function.* These are the operator ρ_A and f_{Bayes} described earlier.

5.2 General Constraints on "Well-posed" Models

In Coghill et al. (2005), the term "well-posed" qualitative models is used to denote those models that satisfy a number of domain-independent constraints. We use the the following constraints from that report:[2]

1. *Size.* A well-posed model must be of a particular size (measured by the number of qualitative constraints).

2. *Completeness.* The model must contain all the measured variables.

3. *Language.* The number of instances of any qualitative constraint in a well-posed model should be below some prescribed number.

4. *Sufficiency.* The model must adequately explain the observed data. By "adequate", we intend to acknowledge here that due to noise in the measurements, not all observations may be logical consequences of the model.[3] The percentage of observations that must be explainable in this sense is a user-defined value.

5. *Redundant.* The model must not contain relations that are redundant. For example, the relation `ADD(Inflow,Outflow,X)` is redundant if the model already has `ADD(Outflow,Inflow,X)`.

2. This list excludes two constraints from the report: the "Determinate" constraint can be effectively enforced by the "Size" constraint. The "Connected" constraint that requires all intermediate variables should appear in at least two qualitative constraints is enforced by the more general "Irrelevant variables" constraint here. All the constraints are assumed to be encoded in the background knowledge for any given stage.
3. Strictly speaking, the model in conjunction with the background knowledge.

Modes:

```
DERIV(+level,-flow)
ADD(+level,+level,-level)      ADD(+level,-level,+level)
ADD(+flow,+flow,-flow)         ADD(+flow,-flow,+flow)
MPLUS(+level,-level)           MPLUS(+level,-flow)
MPLUS(+flow,-flow)             MPLUS(+flow,-level)
MMINUS(+level,-level)          MMINUS(+level,-flow)
MMINUS(+flow,-flow)            MMINUS(+flow,-level)
MINUS(+level,+level)           MINUS(+flow,+flow)
```

A legal model:

```
MPLUS(L,Outflow)
DERIV(L,Netflow)
ADD(Outflow,Netflow,Inflow)
```

Two illegal models:

```
MPLUS(L,Outflow)
DERIV(L,Netflow)
ADD(Outflow,L,Inflow)
```

(ADD cannot add flows to levels)

```
MPLUS(L,Outflow)
ADD(Netflow,Outflow,Inflow)
DERIV(L,Netflow)
```

(ADD needs Netflow to be known)

Figure 12: Example "mode" declarations for the qualitative constraints. For example, the mode declaration `ADD(+level,+level,-level)` states that given values from domain "level" for the the first two arguments, `ADD` computes a value for the third argument (also from domain "level"). This is thus a simple form of dimensionality check. This prevents the ILP system from constructing model M2 (in which a variable from a "flow" domain is added to one from a "level" domain).

Fab	OutflowB	Lb
$flow : 0...inf/std$	$flow : 0/std$	$level : 0/inc$
$flow : 0...inf/std$	$flow : 0...inf/inc$	$level : 0...inf/inc$
$flow : 0...inf/std$	$flow : 0...inf/dec$	$level : 0...inf/dec$
$flow : 0...inf/std$	$flow : 0...inf/std$	$level : 0...inf/std$

Figure 13: Some example observations of the relevant system variables for identification of a single tank model. No ordering is implied amongst these observations.

6. *Contradictory.* The model must not contain relations that are contradictory given other relations present in the model.

7. *Dimensional.* The model must contain relations that respect the dimensionality of the variables involved (this prevents, for example, constraints like `ADD(Inflow,L,...)` from appearing in models for the single-tank system).

8. *Single.* Well-posed models should not contain two or more disjoint sub-models.

9. *Causal.* The model must be causally ordered (Iwasaki and Simon, 1986). In a simple sense, this requires a variable that appears on the right-hand side of a (qualitative) arithmetic constraint should have appeared on the left-hand side of a constraint earlier in the sequence.

The following constraints on the qualitative variables were also used. These are ad-hoc, but were nevertheless found to be extremely effective in constraining the space of possible models:

10. *New variables.* A well-posed model can contain no more than some prescribed number of new, or "hidden", variables. Increasing this number usually increases the value of b in Remark 3 (this is equal to 1 for the single tank model: the hidden variable is `Netflow`).

11. *Irrelevant variables.* Variables in one constraint that are never used by another constraint are taken to be irrelevant. A well-posed model can contain no more than some prescribed number of irrelevant variables (this is equal to 0 for the single tank model).

12. *Distinct variables.* All variables in any constraint are distinct.

13. *Dynamic variables.* Well-posed models must include `DERIV` constraints for any pre-specified "dynamic" variables (these are variables that are known to change with time).

With these inputs, we summarise the results of using incremental model construction to identify a model for the coupled tanks system. Model construction proceeds in two stages. In the first stage, we attempt to identify a single tank model, by ignoring observations for levels and flows in tank A. Figure 14 shows the well-posed models identified by the system. The model with the lowest cost is extended in an attempt to identify a model for the coupled tanks system. Recall that the models selected from Stage 1 are subject to a limited form of generalisation before attempting to identify a model in Stage 2. The result of this generalisation step is shown in Figure 15. Each of these models are extended in Stage 2 to construct final models for the coupled tanks system: the results are in Fig. 16 (the fourth one is the correct model for the system).

5	MPLUS(Lb,OutflowB) SUB(Fab,OutflowB,NetflowB) DERIV(Lb,NetflowB) SUB(InflowA,Fab,NetflowA) DERIV(La,NetflowA) MPLUS(NetflowB,Diff) ADD(Lb,Diff,La)	

Figure 16: Well-posed models identified for the coupled tank system. These were obtained by extending the lowest-cost model obtained for the single tank system in Fig. 14 (these are the first three constraints in all the models here). All models shown here have equal (lowest) cost. Model 4 is the target model

The coupled tank system identification task can clearly be decomposed into two stages: the identification of the single tank system consisting of 3 qualitative constraints, followed by its extension by 4 further constraints. It is instructive to illustrate the gain in efficiency from using the incremental procedure. Figure 17 shows the comparative effects of: (1) *No decomposition*. We

attempt to identify all seven constraints in a single stage (this is the "one-shot" approach); and (2) *Correct decomposition*. The single tank model is identified in Stage 1, and then extended to the coupled tank model in Stage 2. This resulted in the models in Figs. 14 and 16.

Figures 16 and 17 illustrate two points we wish to draw attention to about the procedure we have employed, namely:

1. The result may not be a unique model. For the identification of biological systems about which little is known, we do not see this as being a hindrance; and in many cases may even be preferable. New experiments could be proposed to discriminate between the models.

2. Decomposition can significantly increase the efficiency of system identification. No great significance should also be attached to the fact that the correct model is identified even with inappropriate decompositions—recall that the greedy search procedure employed is sub-optimal—although the robustness demonstrated is heartening, since in practice we may not be in a position to know the correct decomposition.

Decomposition	Correct Model Identified?	Time Taken
None	Yes	$>$ 5 days
Correct	Yes	2037 seconds

Figure 17: The effect of decomposition on system identification. The ILP system without decomposition was halted after 5 days of execution.

Finally, while most of the constraints 1–9 on well-posed models are motivated by some well-understood principles underlying qualitative reasoning, the constraints 10–13 on qualitative variables are not. Figure 18 provides some empirical justification for the use of these constraints, by illustrating the proportion of a (uniform) random sample of 10,000 models, all of which satisfy constraints 1–9, but fail these constraints. Based on this proportion constraint 13 has the single strongest effect, followed by 12, 11, and 10.

6. Applications to Biological Systems

In this section we demonstrate the application of the incremental technique described to biological system identification. The demonstrations here serve a dual purpose. First, they are intended to illustrate the ability of a general-purpose ILP system to identify qualitative models for biological systems at significantly different scales of organisation. For this, we have elected to examine modelling problems at the ecosystem, organ, extra-cellular and cellular levels. Second, we intend to demonstrate the ability of the incremental approach proposed to construct models in three different ways: in a single stage without providing any initial model (thus acting as a "one-shot" system identifier); in a single stage by refining an approximate model provided; and in multiple stages. In all cases, the ILP system will use the refinement operator and cost function described in Appendix A. The background knowledge will also largely be the same, consisting of definitions for qualitative constraints. All tasks are of a re-constructive nature and examples are observations generated using

Constraint	Description	Estimate of Proportion of Models Eliminated
10. New variables	New variables = 1	33.07%
	New variables = 2	8.84%
11. Irrelevant variables	Irrelevant variables = 0	73.81%
	Irrelevant variables = 1	33.15%
12. Distinct variables	Distinct variables = true	98.52%
	Distinct variables = false	0.00 %
13. Dynamic variables	Dynamic variables = true	100.00%
	Dynamic variables = false	0.00 %

Figure 18: Estimates of the reduction in the search space by the constraints introduced on qualitative variables. The last column represents the proportion of 10,000 models that satisfy the constraints 1–9 described in Coghill et al. (2005) but fail the corresponding constraint in the second column.

the target qualitative model. The goal in each case is to examine if this target model is amongst the models identified by the ILP system. More details can be found in Section A.3.

6.1 Ecosystem-Level System Identification

In this section we consider a problem in modelling the dynamics of populations. Specifically we are concerned with identification of a predator-prey model, following the description in Todorovski and Džeroski (2001), which in turn is based on mathematical models developed for the same problem in Murray (1993).

The ecosystem considered is a simple one consisting of populations of predator and prey species—foxes and rabbits, say—that interact in the following manner. Assume that foxes only eat rabbits and that rabbits only eat grass, of which there is an unlimited supply. If the rabbit population is large, the fox population grows. In turn, many rabbits are eaten, resulting in a fall in their numbers. A smaller number of rabbits causes more foxes to die of starvation. Fewer foxes then causes an increase in the rabbit population, which leads to the entire cycle being repeated. This kind of oscillatory behaviour of the two populations is shown in Fig. 19(a). The dynamics of the populations can be modelled using the Lotka-Volterra model, a variant of which is shown in Fig. 19(b). Under certain simplifying assumptions described, the qualitative model is in Fig. 19(c).

We examine reconstructing the model in Fig. 19(c) by using the incremental ILP system as a single-shot model constructor. For this, the ILP system is provided with: (a) the same background knowledge as in Section 5.1; (b) example observations of system behaviour generated using the target model in Fig. 19(c); and (c) the refinement operator and the Bayesian cost function described in Appendix A. The incremental search procedure commences with an empty model (by convention, denoted by $\emptyset$) as the initial hypothesis (see Fig. 20).

The results are shown in Fig.21. Model 1 is the target model. All models were constructed in a single-stage containing 6 qualitative constraints, in approximately 65 seconds of processor time.

```

(c)

Figure 19: Modelling predator-prey populations. The changes in populations are shown graphically in (a). There are two system variables: the predator population (P) and the prey population (N). At any given point in time, these variables satisfy the differential equation model in (b). This is a general form of the Lotka-Volterra model for population dynamics. The terms in the model are as follows: $g(N)$ represents the growth-rate of the of the prey in the absence of predators; $c(P)$ is the consumption rate of the predators; and $d(P)$ is the decay-rate of the predators. Under the simple assumptions of $g(N) \propto N$ and $d(P) \propto P$, the corresponding qualitative model is in (c).

6.2 Organ-Level System Identification

In this section we consider identification of a qualitative model for the human lung. The primary function of the lung is to act as a gas-exchanger. Exchange of gases across a barrier occurs simply because of a difference in pressures. The pulmonary artery carrying blood from the heart contains low concentrations of oxygen and high concentrations of carbon dioxide (at a constant temperature, the concentrations of the gases are proportional to their partial pressures). Oxygen diffuses across the barrier into the blood (and carbon dioxide diffuses into the lung), where is carried by haemoglobin molecules in the pulmonary vein to the heart. This oxygenated blood is then pumped by the heart to the rest of the body using the arterial network. A model of the lung acting in this man-

ner is shown in Fig. 22. The model is constructed using partial pressures of a measurable "marker" gas. A simplification of the model in Fig. 22(c) results from ignoring the blood vessels and treating the lung as a simple gas chamber as shown in Fig. 23(a). The resulting differential equation model is in Fig. 23(b) and the qualitative model is in Fig. 23(c).

We examine reconstructing a model for the lung by providing the ILP system with the approximate model Fig. 23(c): we are interested in investigating whether the ILP system can refine this to the model in Fig. 22(d). The ILP system is provided with: (a) the same background knowledge as in Section 5.1, with additional mode declarations needed for the `MULT` constraint; (b) example observations of system behaviour generated using the target model in Fig. 22(d); (c) the usual refinement operator and cost function. The incremental search is provided with an intial hypothesis consisting of an approximate model for the lung: `MULT(Va,Pa,F)`, `MULT(Vid,Pi,G)`, `DERIV(F,G)` (see Fig. 24).[4]

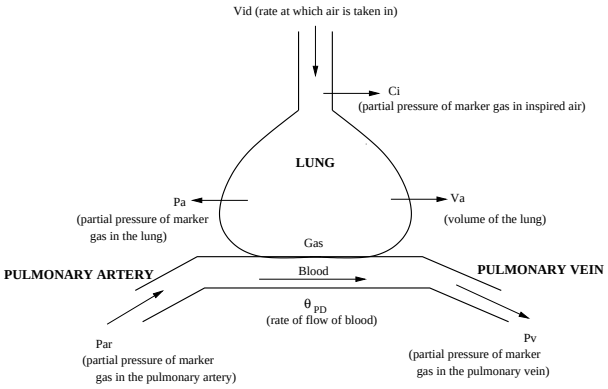
The results, shown in Fig.25, were obtained in 528 seconds of processor time. We note here that model identification required a generalisation of the approximate model provided (`DERIV(F,G)` is changed to `DERIV(F,H)`). Model 2 is the correct model.

6.3 Extra-Cellular System Identification

We use glucose-insulin balance in the human body as a third test case for incremental system identification by ILP. Hormones are chemical messengers, usually small proteins, that play a regulatory role in an organism. Of these, the best known is probably insulin, the first protein whose structure was determined (the amino acid sequence, or primary structure, was determined in 1953 by Sanger and Tuppy). The role of insulin is primarily in maintaining the balance of glucose in the blood. Glucose is used as a source of energy by the central nervous system and by the muscles, and as a source of fat by adipose tissue and the liver, that stores it in the form of a starch called glycogen (see Fig. 26a). If the concentration of glucose in the blood rises too high (usually after digestion of food in the small intestine) then specialised cells in the pancreas are stimulated to produce insulin, by a process involving glycolysis (which we consider in the next section). The presence of insulin signals muscles, fat tissue and the liver to consume glucose, thus lowering it content in the blood. This lower amount of glucose in turn inhibits the production of insulin, and sugar levels rise again until a balance is achieved. This feedback process is not dissimilar to the functioning of a thermostat to maintain a constant temperature in a house. A model of this regulatory mechanism is shown in Fig. 26(b). The model is from Clancy and Kuipers (1994), and is based on a compartmental differential equation model developed by Ironi and Stefanneli (Ironi and Stefanelli, 1994).

Our goal is to reconstruct the qualitative model in Fig. 26(b) using by starting from the empty model. We examine identification of the full model in two stages: the first stage being concerned with identifying the insulin component (the first three constraints in the qualitative model) and the second, the glucose component (the remaining six constraints in the model). As before, the ILP system is equipped with: (a) QSIM relations and their definitions along with additional model-specific constraints; (b) example observatons of system behaviour using the target model in Fig. 26(b); and

4. This is provided *a priori*. In this paper, we do not address how such an hypothesis could have been reached: one possible means could be using the kind of simplified reasoning shown in Fig. 23. There is, of course, nothing preventing the incremental learner described here to start from the empty model $\emptyset$ and construct increasingly better approximations. This would, however, require observational data: something we cannot obtain for the lung model in Fig. 23 (it is impossible to ignore the blood vessels in real-life).



(a)

$$\frac{d}{dt}(Va\ Pa) = (Vid\ Pi) - (\lambda\ \theta_{PD}\ (Par - Pv))$$

DERIV(X,Z3)
```

(d)

Figure 22: A model for the human lung. In this model, the marker gas is nitrous oxide. There are seven system variables: the rate of inspiration (*Vid*); the concentrations of the marker gas in the inspired air (*Ci*, which is taken to be proportional to the partial pressure *Pi*) and in the lung (*Ca*, proportional to the pressure *Pa*); the volume of the lung cavity (*Va*); the rate of flow of blood θ_{PD}; and the partial pressures in the artery *Par* and the vein *Pv*. On each inspiration, the variables satisfy the differential equation (b). The equation (c) represents the same quantitative model with the assumption that $Pa = Par$, which is reasonable when air is breathed in. The corresponding qualitative model is in (d).

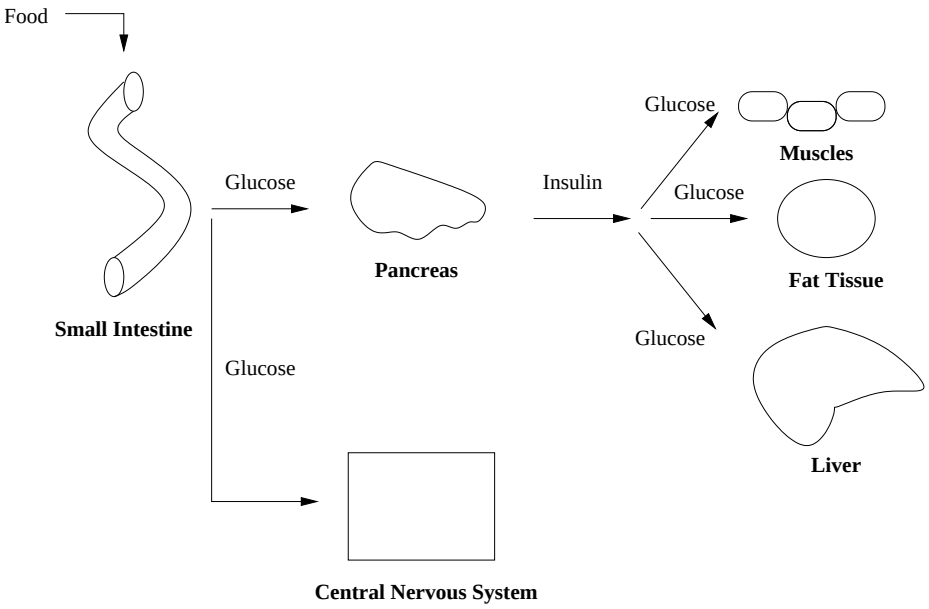
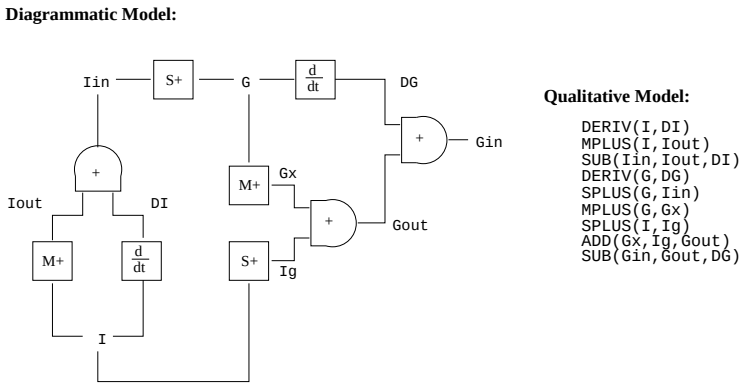
(c) the refinement operator ρ_A and cost function f_{Bayes}. The full system identification process is shown in Fig. 27.

Little difficulty was encountered in identifying the correct constraints for the insulin stage in no more than 1 second of processor time. However, we found it substantially harder to identify the correct constraints for the glucose stage. The principal problems were: (a) a large number of models—over 40, including the one sought—were consistent with the constraints provided; and (b) model evaluation in some cases was extremely slow. We have found two additional constraints to be very useful in reducing the number of models. First, we prevent additions of exogeneous and plasma levels of the same substances (for example, additions of `Iin` and `I`, or `Gin` and `G`). Some plausible justification of this is possible, on the grounds that the two levels are closely related to each other. Second, we prevent monotonic functions of exogeneous inputs `Gin` and `In`, requiring these to be approximated by functions of their counterparts in the blood (that is, `G` and `I`). In addition,



(a)



(b)

Figure 26: Glucose regulation in the blood, shown pictorially in (a), and modelled qualitatively in (b). In the model, `Gin` refers to the glucose intake (in the form of food) and `Iin`, the insulin produced by the pancreas. `G` and `I` are the glucose and insulin levels in the blood. `Gx` is the insulin-independent consumption of glucose by the central nervous system and `Ig` the insulin-dependent consumption of glucose by the muscles, fat tissue and the liver. The qualitative model in Clancy and Kuipers (1994) utilises a sigmoid function `SPLUS`. For the model here, we use the standard `MPLUS` function, which is consistent with the original formulation in Ironi and Stefanelli (1994)

.

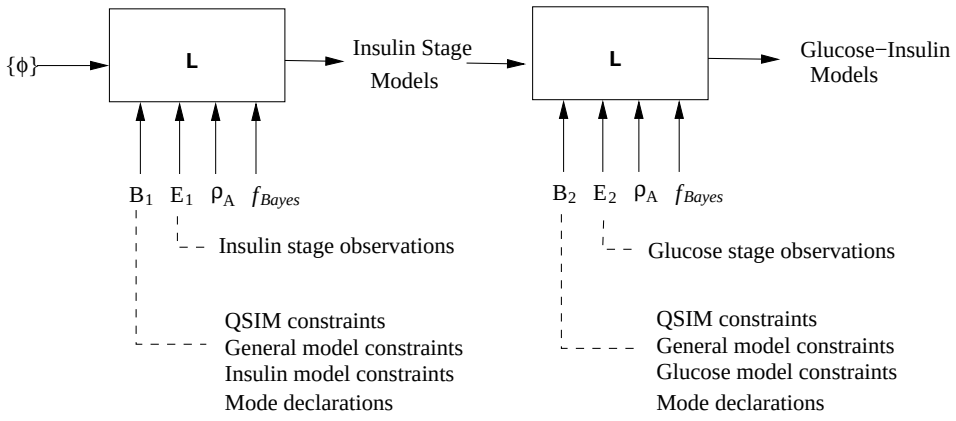


Figure 27: Incremental model identification of models for glucose regulation.

substantially more restrictive mode declarations than in other cases were needed to restrict the search space. Further, we restrict the search to occupy no more than 10,000 seconds of processor time. With these *ad hoc* constraints in place, we are able to repeat model identification using the two stages. The correct insulin model is obtained as before and the results after the glucose stage are shown in Fig.28. Model 3 is equivalent to the target model, given the equivalence of `SPLUS` and `MPLUS` in experiments here.

6.4 Cell-Level System Identification

We use the glycolysis pathway as the final test case for incremental system identification by ILP. Glycolysis is the archetypal pathway. It was historically one of the first to be unravelled, with Otto Meyerhof winning the Nobel prize for discovering key steps in it. Specifically, Meyerhof and colleagues "...were unusually accomplished in breaking down glycolysis into its many separate components, analysing each step separately, then reassembling the constituent parts within an overall system."[5] Glycolysis still presents a challenge to model accurately. The special interest here is that it is significantly different in nature to the models considered so far in the paper, which have all been abstractions of ordinary differential equations. We examine now how the qualitative representation language could be used to develop other kinds of models.

Our qualitative model for glycolysis uses 15 metabolites, namely: pyruvate (pv), glucose (glc), phosphoenolpyruvate (pep), fructose 6-phosphate (f6p), glucose 6-phosphate (g6p), dihydroxyacetone phosphate (dhap), 3-phosphoglycerate (3pg), 1,3-bisphos phoglycerate (1,3bpg), fructose 1,6-biphosphate (f16bp), 2-phosphoglycerate (2pg), glyceraldehyde 3-phosphate (g3p), ADP (adp), ATP (atp), NAD (nad), and NADH (nadh). We have not included H+, H_2O, or Orthophosphate as they are assumed to be ubiquitous. The set of reactions in the pathway are shown in Fig. 29.

We will use the following simple qualitative model for enzymes and metabolites. Metabolites are qualitative variables, whose domains are defined by the name of the metabolite and the landmarks 0 and inf. Qualitative states of the metabolites are restricted to $0/std, 0...inf/std, 0...inf/inc$, $0...inf/dec$. A "qualitative cell-state" is given by the qualitative states of the metabolites of interest in the cell. Enzymes are associated with "qualitative reactions", which result in a qualitative

Figure 28: Models for glucose-insulin regulation. The target model is Model 3.

decrease in the amounts of the reactants and a qualitative increase in the amounts of the products. Examples of each of these are in Fig. 30.

We are interested here in finding a sequence of qualitative reactions that are consistent with the qualitative cell-states before and after glycolysis. For this, we introduce a PATHWAY relation which, for a given sequence of qualitative reactions, holds for pairs of qualitative cell-states $\langle Before, After \rangle$ such that the qualitative state of each metabolite in *Before* can be transformed into its state in $After$ by the qualitative reactions. With this relation, the 3 stage glycolysis process can be modelled as shown in Fig. 31. The reader will note that in this model, reactions proceed sequentially. Of course, biologically speaking, this is not how things happen: reactions that can proceed, do so concurrently. While this can be modelled using a slightly different definition for the PATHWAY relation, the model used here is simpler. There are also good historical reasons to adopt this simpler approach. Glycolsis, as the quote above makes clear, and indeed most other pathways have been uncovered by first experimentally separating them into constituent parts (the qualitative modelling of pathways in (King et al., 2005) did not make this assumption, making the resulting models both difficult to identify—all reactions had to be identified in one-shot—and inefficient to execute).

We examine reconstructing a model for the glycolysis pathway in 3 stages (priming, splitting and phosphorylation). At each stage, the ILP system is provided with: (a) the same background knowledge as in Section 5.1, with additional definitions for the PATHWAY and associated relations. For efficiency, we include three restrictions in the definition of the PATHWAY relation, namely: no

1. (*Hexokinase*): glucose + ATP ⇔ glucose 6-phosphate + ADP.
2. (*Phosphoglucose isomerase*): glucose 6-phosphate ⇔ fructose 6-phosphate.
3. (*Phosphofructokinase*): fructose 6-phosphate + ATP ⇔ fructose 1,6-biphosphate + ADP.

4. (*Aldolase*): fructose 1,6-biphosphate ⇔ dihydroxyacetone phosphate + glyceraldehyde 3-phosphate.
5. (*Triose phosphate isomerase*): dihydroxyacetone phosphate ⇔ glyceraldehyde 3-phosphate.

6. (*Glyceraldehyde 3-phosphate dehydrogenase*): glyceraldehyde 3-phosphate + NAD ⇔ 1,3-bisphosphoglycerate + NADH.
7. (*Phosphoglycerate kinase*): 1,3-bisphosphoglycerate + ADP ⇔ 3-phosphoglycerate + ATP.
8. (*Phosphoglycerate mutase*): 3-phosphoglycerate ⇔ 2-phosglycerate.
9. (*Enolase*): 2-phosphoglycerate ⇔ phospoenolpyruvate.
10. (*Pyruvate kinase*): phospoenolpyruvate + ADP ⇔ pyruvate + ATP.

Figure 29: The reactions comprising the glycolysis pathway. The reactions that consume ATP and NADH are not explicitly included. Glycolysis proceeds in three stages: primary (reactions 1–3), splitting (reactions 4 and 5) and phosphorylation (reactions 6–10). The enzymes involved are in parentheses.

Qualitative states of some metabolites
$atp : 0...inf/std$, $dhap : 0/std$, $nad : 0...inf/dec$

A qualitative cell-state
$\{adp : 0/std, atp : 0...inf/std, f16bp : 0/std, f6p : 0/std, g6p : 0/std, glc : 0...inf/std\}$

A qualitative reaction
$glc + atp \rightsquigarrow g6p + adp$

Some cell-states consistent with $glc + atp \rightsquigarrow g6p + adp$
Before: $\{adp : 0/std, atp : 0...inf/std, f16bp : 0/std, f6p : 0/std, g6p : 0/std, glc : 0...inf/std\}$
After: $\{adp : 0...inf/inc, atp : 0...inf/dec, f16bp : 0/std, f6p : 0/std, g6p : 0...inf/inc, glc : 0...inf/dec\}$
After: $\{adp : 0...inf/inc, atp : 0/std, f16bp : 0/std, f6p : 0/std, g6p : 0...inf/inc, glc : 0...inf/dec\}$

Figure 30: Examples of the qualitative representation used for metabolites, cell-states and chemical reactions. In this, a qualitative reaction causes a qualitative decrease in the reactants and a qualitative increase in the products. The non-determinate nature of qualitative arithmetic means that a cell can be in one of several different states after a reaction.

more than 5 reactions are allowed in a pathway; reactions must use all the metabolites; and reactions have to satisfy some basic constraints of chemical feasibility.[6] In addition, the background knowledge contains an additional constraint that ensures that the model proposed is of the sequential form shown; (b) examples of system behaviour generated using the target model; and (c) the usual refinement operator and cost function. The incremental search procedure commences with the empty model $\emptyset$ as the initial hypothesis (see Fig. 32).

6. The obvious constraint is that products cannot contain elements not available in the reactants. A more sophisticated test estimates the number of chemical bonds broken, and restricts this to at most three: reactions that break more bonds are taken to require an infeasibly large amount of energy, and to be too complex even for an enzyme to manage.

GLYCOLYSIS($Before, After$) if
  PATHWAY($Before, S_1, \langle atp + glc \rightsquigarrow adp + g6p, g6p \rightsquigarrow f6p, atp + f6p \rightsquigarrow adp + f16bp \rangle$)
  PATHWAY($S_1, S_2, \langle f16bp \rightsquigarrow dhap + g3p, dhap \rightsquigarrow g3p \rangle$)
  PATHWAY($S_2, After, \langle g3p + nad \rightsquigarrow 1,3bpg + nadh, 1,3bpg + adp \rightsquigarrow 3pg + atp,$
    $3pg \rightsquigarrow 2pg, 2pg \rightsquigarrow pep, adp + pep \rightsquigarrow atp + pv \rangle$)

where:
PATHWAY($S, F, \langle R_1, R_2, \ldots R_n \rangle$)
  $i = 0$, $S_0 = S$
  for $i = 1 \ldots n$
    QREACTION(S_{i-1}, R_i, S_i)
  $F = S_n$

QREACTION($State, R, NewState$)
  QDECREASE($State, Reactants(R), S$)
  QINCREASE($S, Products(R), NewState$)

Figure 31: A qualitative model for glycolysis. Pathways consist of qualitative reactions, each of which result in a qualitative decrease in the reactants and a qualitative increase in the products. The non-determinacy of qualitative arithmetic means that a qualitative reaction acting on a cell-state could result in one of several new cell-states (since there would be several ways to decrease or increase the qualitative values of metabolites). The system identification task is to find the definition for GLYCOLYSIS given definitions for PATHWAY, QREACTION, QDECREASE and QINCREASE.

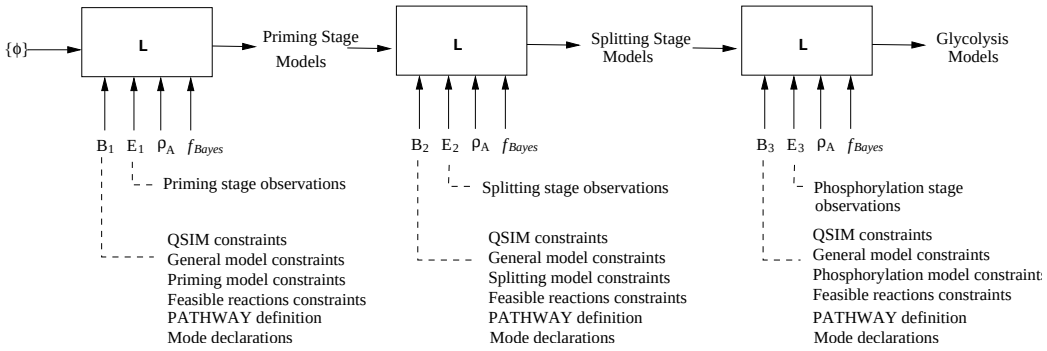

Figure 32: Incremental model identification of models for glycolysis.

The results are shown in Fig. 33. We note here that model identification at Stages 2 and 3 requires a generalisation of the model identified earlier (this removes the co-references to the $After$ variable). The different stages were obtained in 6 seconds (Stage1), 135 seconds (Stage 2) and 5296 seconds (Stage 3).

Stage	Model No.	Model
1	1	GLYCOLYSIS($Before, After$) if PATHWAY(($Before, After, \langle atp + glc \rightsquigarrow adp + g6p, g6p \rightsquigarrow f6p,$ $atp + f6p \rightsquigarrow adp + f16bp\rangle$)
2	1	GLYCOLYSIS($Before, After$) if PATHWAY(($Before, S_1, \langle atp + glc \rightsquigarrow adp + g6p, g6p \rightsquigarrow f6p,$ $atp + f6p \rightsquigarrow adp + f16bp\rangle$) PATHWAY($S_1, After, \langle f16bp \rightsquigarrow dhap + g3p, dhap \rightsquigarrow g3p\rangle$)
3	1	GLYCOLYSIS($Before, After$) if PATHWAY(($Before, S_1, \langle atp + glc \rightsquigarrow adp + g6p, g6p \rightsquigarrow f6p,$ $atp + f6p \rightsquigarrow adp + f16bp\rangle$) PATHWAY($S_1, S_2, \langle f16bp \rightsquigarrow dhap + g3p, dhap \rightsquigarrow g3p\rangle$) PATHWAY($S_2, After, \langle g3p + nad \rightsquigarrow 1, 3bpg + nadh, 1, 3bpg \rightsquigarrow 3pg,$ $3pg \rightsquigarrow 2pg, 2pg \rightsquigarrow pep, adp + pep \rightsquigarrow atp + pv\rangle$)
	2	GLYCOLYSIS($Before, After$) if PATHWAY(($Before, S_1, \langle atp + glc \rightsquigarrow adp + g6p, g6p \rightsquigarrow f6p,$ $atp + f6p \rightsquigarrow adp + f16bp\rangle$) PATHWAY($S_1, S_2, \langle f16bp \rightsquigarrow dhap + g3p, dhap \rightsquigarrow g3p\rangle$) PATHWAY($S_2, After, \langle g3p + nad \rightsquigarrow 1, 3bpg + nadh, 1, 3bpg + adp \rightsquigarrow 3pg + atp,$ $3pg \rightsquigarrow 2pg, 2pg \rightsquigarrow pep, adp + pep \rightsquigarrow atp + pv\rangle$)

Figure 33: Glycolysis models identified. The target model is Model 2 in Stage 3. The difference in the two models identified in Stage 3 arise in the seventh equation (the second in the last PATHWAY constraint). Model 1 proposes $1, 3bpg \rightsquigarrow 3pg$ and Model 2 proposes $1, 3bpg + adp \rightsquigarrow 3pg + atp$.

7. Decomposition as Search

So far, we have taken the position that the incremental learner will be provided with a decomposition of the system to be identified. While this may be entirely reasonable when we have access to appropriate expertise—a biologist specialising in the kind of systems we are modelling for example—it is of some interest to examine whether a suitable decomposition can be identified automatically. That is, given observations for some system variables, can we automatically decompose the learning task into one that uses a n-stage incremental learner of the form shown in Fig. 6.

Decomposition of complex systems has been studied extensively in econometrics, ever since the pioneering work of Simon and Ando (1961). In this, decomposability of a system is a property of the system by which some subsets of variables (usually non-intersecting) have a greater interaction with each other than other subsets. These subsets define sub-systems into which the larger system can be decomposed. Simon and Ando study the formal properties of linear dynamical systems of the form $x(t+1) = Ax(t)$, where A is some linear operator and the applicability of their results to evolutionary systems has been studied by Shpak et al. (2004a,b). Concerned as we are with a logical representation of a system, our problem is related more to the decomposition of Boolean functions. Most modern work on this stems from that of Ashenhurst (1957) and Curtis (1962). In this, a function f of n variables, denoted here by the set S, is decomposed into Boolean functions h and g, such that $f(X) = h(A, g(B))$, where $A, B \subset S$ and $A \cup B = S$. The techniques are devised for propositional logic, and it is not evident how they could be used to address the decomposition task here. Nevertheless, at least one important principle is directly applicable: both the Ashenhurst and Curtis formulations are essentially procedures that look for suitable decompositions by examining all possible partitions of S. In general though, finding the optimal decomposition of Boolean

functions is computationally hard (see, for example, Boros et al., 1994), and some form of heuristic search is inevitable. This is the basis of the work of Paulson and Wand (1992), who examine the decomposition of a system specified by state variables. Decomposition here means discovering both a partitioning into non-disjoint subsets of system variables, and an assignment of variables in each subset as being "input" or "output". Each subset constitutes a subsystem, and a pair of subsystems are related if an output variable of one is an input variable of another. The final decomposition is the result of a heuristic search process guided by: a set of constraints characterising "good decompositions", a set of rules for enumerating candidate decompositions, and a method of scoring each candidate based on the complexity of the resulting subsystems.

Unlike Paulson and Wand's procedure, we require that related subsystems share models (rather than system variables). Nevertheless, we are able to draw on their basic premise of decomposition being the result of a heuristic search process. Specifically, we use a randomised local search procedure that identifies each stage of the decomposition using a randomised local search procedure that executes the following steps: (a) A subset of system variables is selected randomly from candidate subsets for this decomposition; (b) A model is constructed using this set and its cost determined; (c) All possible "local moves" are constructed. These result in new subsets obtained by adding a system variable not in the original set and by removing a system variable included in the original set; (d) The best local move (the new subset having a model with least cost) is selected and Steps (c)–(d) repeated (the number of repetitions denoted by M). The procedure halts after some fixed number of such iterations, and the best scoring subset is returned. Actually, Steps (a)–(d) are repeated several times (denoted by R) with each repetition starting with a different random subset in Step (a). The best scoring subset across all repetitions is returned and the the entire procedure repeated for the next stage. The reader will recognise the procedure as the GSAT algorithm (Selman et al., 1992) adapted to the problem of automatic decomposition. As with all such procedures, the goal is to obtain an efficient (but sub-optimal) solution to an inherently intractable problem (see Appendix B for details). Needless to say that with this, as with the Paulson and Wand work, automatic decomposition is only worthwhile provided the additional computational burden imposed by searching for the decomposition is less than that of attempting to find the complete model using a one-shot (single-stage) learner.

We apply the procedure to the task of decomposing the coupled tanks system. The reader will recall that this system (shown in Fig 8) is specified by 5 system variables: `InflowA`, `OutflowB`, `Fab`, `La` and `Lb`. The automatic decomposition task is as follows: given values for the 5 system variables, identify the single tank "subsystem" specified by `OutflowB`, `Fab` and `Lb` and then identify the the final model using the single tank submodel and the remaining system variables. Figure 34 summarises the result of employing the randomised local search procedure just described to identify the correct decomposition.

It is evident that for such a small problem, we will quickly explore all of the search space as R and M are increased. Nevertheless, the tabulation shows that very small values of R and M yield variable results. The extent to which the success with moderate values of R and M can be replicated on larger, real systems remains a topic for future research. In Appendix B, we are able to offer some insight by considering artificial problems created by random decompositions of larger sets of variables. These experiments suggest that a 2-stage decomposition of a system like the coupled tanks would require R and M values of approximately 5.

We turn now to the automatic decomposition of the first multi-stage biological system considered in this paper. The glucose-insulin system is comprised of 4 independent system variables

R	M		
	1	2	3
1	0.27	0.70	0.40
2	0.50	0.60	0.90
3	0.40	0.90	1.00

Figure 34: Probability estimates of identifying the correct decomposition of the coupled tanks system, using the randomised local search procedure described in Appendix B. Here R denotes the number of restarts of the randomised procedure and M the number of iterations of local moves. Each entry is is the probability of identifying correctly the single-tank model, followed by the correct coupled tanks model, with the corresponding values of R, M. Probability estimates required for each stage are obtained from 10 repeats of the randomised procedure.

(`Gin`, `G`, `Iin`, `I`), and requires a 2-stage decomposition. Once again, using the experiments on synthetic problems as a guide, we are able to obtain a correct decomposition for this system using low values of R and M (5 in this case). Unfortunately, the decomposition procedure we have just described cannot be used to obtain a decomposition for the glycolysis problem. Here, system variables (metabolites) are re-used across the different stages, which violates a key assumption of the approach (simply speaking, variables used in a stage cannot be re-used at a later stage). This violation makes the search vastly harder, putting in perspective the achievement of Meyerhof and his colleagues.

8. Concluding Remarks

The focus in biology has, until recently, been mainly on individual units. Molecular biology, for example, has mainly focussed on individual molecules and on their properties as isolated entities or as complexes in very simple model systems. However, biological molecules in living systems participate in very complex networks, including regulatory networks for gene expression, intracellular metabolic networks and both intra- and inter-cellular communication networks. Such networks are involved in the maintenance (homeostasis) as well as the differentiation of cellular systems of which we have a very incomplete understanding. Nevertheless, the progress of molecular biology has made possible the detailed description of the components that constitute living systems, notably genes and proteins. Large scale genome sequencing means that we can (at least in principle) delimneate all macromolecular components of a given cellular system. Microarray experiments as well as large scale proteomics will soon give us large amounts of experimental data on gene regulation, molecular interactions and cellular networks. The challenge now becomes to understand how these individual components integrate to complex systems and the function and evolution of these systems, thus scaling up from molecular biology to "systems" biology that provides an understanding at different levels of biological organisation.

Our experience in the physical sciences suggests that the only tractable way of understanding complex systems is through the use of mathematical models. However, biological systems are usually far more complex than physical or human-engineered ones and progress in determining functionality will be crucially dependent on the development of mathematical, and computational tech-

niques specially devised for biological data analysis, modelling and simulation. In this paper, we argue that a qualitative representation of values, along with a powerful machine-learning approach like ILP, provides a useful tool for system-identification at different levels of biological organisation. We have sought to back this claim by demonstrating the use of a general-purpose ILP system to identify models for systems at three disparate levels of biological organisation, namely, ecosystem, organ and cellular. The results are promising, with the target model being amongst a small set of answers returned in each case. While the applications presented have been re-construction of known models, this is clearly not the use we envisage for the approach. Specifically, we expect its principal utility will be in situations where there is some quantitative data of variable quality and quantity, and not much is known about a suitable mathematical model. In these circumstances, the data can be converted to a qualitative representation (in the manner described by Hau and Coiera, 1997) and one or more qualitative models identified. These can then form the basis of understanding the system better and could even be used to direct the construction of quantitative model. For example, they could form the basis of the grammars required for an automated technique such as the one described in Todorovski et al. (2000) (in some sense, this is like extending the Q^2-learning framework in Suc et al. (2003) to the discovery of mathematical models). An additional feature of our work here is that the approach is an incremental one, that seeks to construct the final model in stages. The value of decomposition as an aid to understanding complex systems has long been recognised: Courtois (1985) describes some general principles that motivate the need for such an approach. We believe that when attempting to construct large models with ILP, some form of structured induction (in the sense intended in Shapiro, 1987) would be required. The decomposition into a sequence of stages is an example of such a structuring.

The work presented here has a number of limitations. There are limitations to the power of the qualitative representation used: (1) they can only provide clues to the precise mathematical structure. This may be sufficient for common-sense reasoning about a system, but is clearly insufficient for a complete understanding; (2) simulations with qualitative models can contain spurious behavious; and (3) abstractions appear to be largely restricted to ODE models. It has been suggested that the use of "multivariate constraints" (Wellman, 1991) may allow abstractions of PDE models, but little has been done on that front.

An important limitation of the incremental approach is that the user needs to provide an adequate decomposition of the system-identification task into stages along with the number of constraints in the model for each stage. The latter restriction can be relaxed by providing an upper-bound on the number of constraints. We have described a randomised procedure that attempts to construct a suitable decomposition automatically. The results are encouraging, but the procedure still involves constructing many models and its performance on real problems requires further investigation. The randomised procedure itself is an adaptation of the GSAT algorithm of Selman and colleagues. Minor modifications of this yield procedures akin to WalkSat (Selman et al., 1994) and simulated annealing. Both may yield better algorithms for automatic decomposition than the one here; as would modifications that would allow estimation of model performance without actually requiring their explicit construction.

In the implementation of the incremental learner, the primary limitation of the greedy strategy adopted means that we cannot prove that the models returned are the best possible. A further limitation is the use of a refinement operator that can only perform a restricted kind of refinement of models found at a previous stage: this was done solely to keep the space of possible models within manageable limits (in effect, a limited form of theory-revision is performed). A refinement

operator that performs both generalisations and specialisations could be used, but the computational cost would be substantial.

Finally, applications of the approach have been restricted to re-construction of known target models using simulated data. Clearly, it remains to be shown that similar success can be achieved with real experimental data.

These limitations notwithstanding, we believe the combination of a qualitative representation and an incremental ILP approach to be particularly well-suited to the identifying systems at different levels of biological organisation, for the following reasons: (1) The qualitative representation overcomes some inherent limitations in the data—specifically, noise and sparsity—which make quantitative modelling difficult; (2) Qualitative models provide the correct level of comprehensibility for the non mathematically-minded biologist; and (3) Models of interest usually involve the relationship between a number of different components. Currently, ILP provides the most powerful—and in many cases, the only—framework for identifying such relations, but its use is often hampered by concerns of efficiency. The incremental approach we have described provides one way of overcoming these concerns.

Acknowledgments

The authors would like to thank George Coghill for helping us understand the constraints defining well-posed qualitative models and pointing out an important practical flaw in an early attempt at constructing the lung model. David Gavaghan, of the Computing Laboratory, Oxford helped us with quantitative models for the human lung. Binesh Mangar attempted to construct some of the qualitative models for the coupled tanks and the lung during the course of his M.Sc. at Oxford. Simon Garrett performed extensive experiments with a one-shot ILP model constructor for model physical systems and with a different representation for glycolysis. The results from those experiments were very helpful in motivating the approach described here. Thanks are also due to Ravi Kothari, of the IRL, who drew our attention to the work of Ashenhurst on the decomposition of switching functions. The authors would like to dedicate this paper to the memory of Donald Michie, who died as this paper was being written. He taught us much of what we know in science and machine learning and his guiding hand is greatly missed.

Appendix A. ILP Details

We now describe the specification and implementation details relevant to the ILP system used in the paper.

A.1 Specification

In this paper, we closely follow the specification provided by Muggleton (1994) for an ILP system designed to construct models (usually called hypotheses in the ILP literature) given background knowledge B and observations (usually called examples in the ILP literature) E In this specification an ILP algorithm is one that satisfies the following requirements (reproduced with minor changes from Srinivasan and Kothari, 2005):

Given:

R1. $B \in \mathcal{B}$: background knowledge encoded as statements in logic. This includes I: a set of constraints that should not be violated by an acceptable hypothesis.

R2. $E \in \mathcal{E}$: a finite set of examples $= E^+ \cup E^-$ where:

$E^+ = \{e_1, e_2, \ldots\}$ is a set of definite clauses (these are the positive examples);
$E^- = \{\overline{f_1}, \overline{f_2} \ldots\}$ is an optional set of Horn clauses (these are the negative examples); and
$B \not\models E^+$

Find:

R3. $H \in \mathcal{H}$: a hypothesis such that the following conditions are met:

Sufficiency. This consists of:

$S1$. $B \cup H \models E^+$

Consistency. This consists of:

$C1$. $B \cup H \not\models \square$; and

$C2$. $B \cup H \cup E^- \not\models \square$

The requirement $C1$ ensures that H does not violate any of the constraints I in B. The requirement $C2$ is intended to ensure that H does not contain any over-general clauses. Often, implementations do not require clauses to meet this requirement, as some members of E^- are taken to be noisy. This specification is then refined to allow theories to be inconsistent with some negative examples. We will use the phrase "H explains E, given B" to denote that at least $S1$ and $C1$ are met. An "acceptable H" is any H that explains E, given B.

The specification does not state how acceptable H's are to be constructed, or, if several H's explain the E, then which of them are to be selected. For this, we introduce the following functions:

- A "downward" refinement operator $\rho : \mathcal{H} \rightarrow 2^{\mathcal{H}}$ s.t. $\rho(h) \subseteq \{h' | h \models h'\}$. Given a $h \in \mathcal{H}$, this function returns a subset of the elements of $\mathcal{H}$ that are implied by h.
- A cost function $f : \mathcal{H} \times \mathcal{B} \times \mathcal{E} \rightarrow \Re$. Given a $h \in \mathcal{H}$, $B \in \mathcal{B}$ and $E \in \mathcal{E}$, this function returns an evaluation of h;

Let $\rho^1(h) = \rho(h)$; $\rho^n(h) = \{h'' | \exists h' \in \rho^{n-1}(h)$ s.t. $h'' \in \rho^1_A(h')\}, (n \geq 2)$; and $\rho^*(h) = \rho^1(h) \cup \rho^2(h) \cup \ldots$. With some abuse of notation, let $\rho^1(\{h_1, h_2, \ldots\}) = \rho^1(h_1) \cup \rho^1(h_2) \cup \ldots$; $\rho^n(\{h_1, h_2, \ldots\}) = \rho^n(h_1) \cup \rho^n(h_2) \cup \ldots$; and $\rho^*(\{h_1, h_2, \ldots\}) = \rho^1(\{h_1, h_2, \ldots\}) \cup \rho^2(\{h_1, h_2, \ldots\}) \cup \ldots$

Then, given an initial set of hypotheses $H_0 \subseteq \mathcal{H}$ we specify a particular kind of ILP algorithm $\mathtt{L}(B, E, H_0, \rho, f)$ by modifying the requirement R3 above to:

R3′. $H = \mathtt{L}(B, E, H_0, \rho, f) \subseteq \rho^*(H_0)$: a set of hypotheses such that for each $h \in H$ the following are met:

Sufficiency. This consists of:

$S1$. $B \cup h \models E^+$

Consistency. This consists of:

$C1$. $B \cup h \not\models \square$; and

$C2$. $B \cup h \cup E^- \not\models \square$

Minimal Cost. This consists of:

$F1$. For all $h' \in \rho^*(H_0)$ $f(h', B, E) \geq f(h, B, E)$

We are now in a position to specify an incremental ILP system that uses the algorithm L. Given a finite sequence $\langle S_1, S_2, \ldots, S_k \rangle$ ($k \geq 1$), where each S_i consists of the tuple (B_i, E_i), ($B_i \in \mathcal{B}$ and $E_i \in \mathcal{E}$); $H_0 \subseteq \mathcal{H}$; a downward refinement operator ρ; and a cost function f, find H_k, where $H_i = \mathtt{L}(B_i, E_i, H_{i-1}, \rho, f)$ ($1 \leq i \leq k$).

A.2 Implementation

The basic task of addressed by L described in the previous section can be viewed as a discrete optimisation problem. In general terms, this is posed as follows: given a finite discrete set S and a cost-function $f : S \rightarrow \Re$, find a subset $H \subseteq S$ such that $H = \{s | s \in S \text{ and } f(s) = \min_{s_i \in S} f(s_i)\}$. An optimal algorithm for solving such problems is the "branch-and-bound" algorithm, shown in Fig. 35 (the correctness, complexity and optimality properties of this algorithm can be found in Papadimitriou and Steiglitz, 1982). A specific variant of this algorithm is available within the software environment comprising ALEPH (Srinivasan, 1999). The modified procedure is in Fig. 36. The principal differences from Fig. 35 are:

1. The procedure is given a set of starting points H_0, instead of a single one (i in Fig. 35);
2. A limitation on the number of nodes explored (n in Fig. 36);
3. The use of a boolean function $acceptable : \mathcal{H} \times \mathcal{B} \times \mathcal{E} \rightarrow \{FALSE, TRUE\}$. $acceptable(k, B, E)$ is $TRUE$ if and only if k satisfies requirements $S1$ and $C1$ in Section A.1 (given B and E);
4. Inclusion of background knowledge and examples (B and E in Fig. 36). These are arguments to both the refinement operator ρ (the reason for this will become apparent shortly) and the cost function f.

We now describe an implementation for an incremental procedure for model identification that assumes that the task has been decomposed into a finite sequence of stages $\langle S_1, S_2, \ldots, S_k \rangle$ ($k \geq 1$). Each S_i consists of the tuple (B_i, E_i), where B_i and E_i refer to the background knowledge and examples relevant to stage i. With this decomposition in place, Fig. 37 shows a simple greedy implementation used to identify the final models.
Finally, we turn to some points concerning the implementation used in this paper:

- Qualitative models are represented as definite clauses. Given a definite clause C, the qualitative constraints in the model (the size of the model) are obtained by counting the number of qualitative constraints in C. This will also be called the "size of C".
- Constraints, such as the restrictions to well-posed models, are assumed to be encoded in the background knowledge;
- $acceptable(C, B, E)$ is $TRUE$ for any qualitative model C that is consistent with the constraints in B, given E.

$bb(i, \rho, f)$: Given an initial element i from a discrete set S; a successor function $\rho : S \rightarrow 2^S$; and a cost function $f : S \rightarrow \Re$, return $H \subseteq S$ such that H contains the set of cost-minimal models. That is for all $h_{i,j} \in H$, $f(h_i) = f(h_j) = f_{min}$ and for all $s' \in S \backslash H$ $f(s') > f_{min}$.

1. *Active* := $\langle (i, -\infty) \rangle$.
2. *worst* := ∞
3. *selected* := $\emptyset$
4. while *Active* $\neq \langle\rangle$
5. begin
   (a) remove element $(k, cost_k)$ from *Active*
   (b) if $cost_k < worst$
   (c) begin
      i. $worst := cost_k$
      ii. $selected := \{k\}$
      iii. let $Prune_1 \subseteq Active$ s.t. for each $j \in Prune_1$, $\underline{f}(j) > worst$ where $\underline{f}(j)$ is the lowest cost possible from j or its successors
      iv. remove elements of $Prune_1$ from *Active*
   (d) end
   (e) elseif $cost_k = worst$
      i. $selected := selected \cup \{k\}$
   (f) $Branch := \rho(k)$
   (g) let $Prune_2 \subseteq Branch$ s.t. for each $j \in Prune_2$, $f_{min}(j) > best$ where $f_{min}(j)$ is the lowest cost possible from j or its successors
   (h) $Bound := Branch \backslash Prune_2$
   (i) for $x \in Bound$
      i. add $(x, f(x))$ to *Active*
6. end
7. return *selected*

Figure 35: A basic branch-and-bound algorithm. The type of *Active* determines specialised variants: if *Active* is a stack (elements are added and removed from the front) then depth-first branch-and-bound results; if *Active* is a queue (elements added to the end and removed from the front) then breadth-first branch-and-bound results; if *Active* is a prioritised queue then best-first branch-and-bound results.

- *Active* is a prioritised queue sorted by f;
- The successor function used is ρ_A. This is defined as follows. Let S be the size of an acceptable model and C be a qualitative model of size S' with $n = S - S'$. We assume B constains a set of mode declarations in the form described in Muggleton (1995). Then, given a definite clause C, obtain a definite $C' \in \rho_A(C, B, E)$ where $\rho_A = \rho_A^n = \langle D' | \exists D \in \rho_A^{n-1}(C, B, E)$ s.t. $D' \in \rho_A^1(D, B, E) \rangle, (n \geq 2)$. $C' \in \rho_A^1(C, B, E)$ is obtained by adding a literal L to C, such that:
  - Each argument with mode $+t$ in L is substituted with any input variable of type t that appears in the positive literal in C or with any variable of type t that occurs in a negative literal in C;
  - Each argument with mode $-t$ in L is substituted with of any variable of C of type t that appears before that argument or by a new variable of type t;

$bb_A(B,E,H_0,\rho,f,n)$: Given background knowledge $B \in \mathcal{B}$; examples $E \in \mathcal{E}$; a set of initial elements H_0 from a discrete set of possible hypotheses $\mathcal{H}$; a successor function $\rho : \mathcal{H} \times \mathcal{B} \times \mathcal{E} \rightarrow 2^{\mathcal{H}}$; a cost function $f : \mathcal{H} \times \mathcal{B} \times \mathcal{E} \rightarrow \Re$; and a maximum number of nodes $n \in \mathcal{N}$ ($n \geq 0$) to be explored, return $H \subseteq \mathcal{H}$ such that H contains the set of cost-minimal models of the models explored.

1. $Active = \langle\rangle$
2. for $i \in H_0$
   (a) add $(i, -\infty)$ to $Active$
3. $worst := \infty$
4. $selected := \emptyset$
5. $explored := 0$
6. while ($explored < n$ and $Active \neq \langle\rangle$)
7. begin
   (a) remove element $(k, cost_k)$ from $Active$
   (b) increment $explored$
   (c) if $acceptable(k,B,E)$
   (d) begin
      i. if $cost_k < worst$
      ii. begin
         A. $worst := cost$
         B. $selected := \{k\}$
         C. let $Prune_1 \subseteq Active$ s.t. for each $j \in Prune_1$, $\underline{f}(j,B,E) > worst$ where $\underline{f}(j,B,E)$ is the lowest cost possible from j or its successors
         D. remove elements of $Prune_1$ from $Active$
      iii. end
      iv. elseif $cost_k = worst$
         A. $selected := selected \cup \{k\}$
   (e) end
   (f) $Branch := \rho(k,B,E)$
   (g) let $Prune_2 \subseteq Branch$ s.t. for each $j \in Prune_2$, $\underline{f}(j,B,E) > worst$ where $\underline{f}(j,B,E)$ is the lowest cost possible from j or its successors
   (h) $Bound := Branch \backslash Prune_2$
   (i) for $x \in Bound$
      i. add $(x, f(x,B,E))$ to $Active$
8. end
9. return $selected$

Figure 36: A variant of the basic branch-and-bound algorithm, implemented within the ALEPH system. Here $\mathcal{B}$ and $\mathcal{E}$ are sets of logic programs; and $\mathcal{N}$ the set of natural numbers.

– Each argument with mode $\#t$ in L is substituted with a ground term of type t. This assumes the availability of a generator of elements of the Herbrand universe of terms; and
– $acceptable(C',B,E)$ is $TRUE$.

The following properties of ρ_A^1 (and, in turn to ρ_A) can be shown to hold (Riguzzi, 2005):

– It is locally finite. That is, $\rho_A^1(C,B,E)$ is finite and computable (assuming the constraints in B are computable);

incsearch(S, H_I, ρ, f, n, m) : Given a sequence of stages $S = \langle (B_1, E_1), (B_2, E_2), \ldots, (B_k, E_k) \rangle$, $(1 \leq k < \infty)$ where $B_i \in \mathcal{B}$; $E_i \in \mathcal{E}$; a set of initial elements H_I from a discrete set of possible hypotheses $\mathcal{H}$; a successor function $\rho : \mathcal{H} \times \mathcal{B} \times \mathcal{E} \rightarrow 2^{\mathcal{H}}$; and a cost function $f : \mathcal{H} \times \mathcal{B} \times \mathcal{E} \rightarrow \Re$; a maximum number of nodes $n \in \mathcal{N}$ $(n \geq 0)$ to be explored at each stage; and a maximum number of models $m \in \mathcal{N}$ $(m \geq 0)$ to be returned at each stage; and return $H \subseteq \mathcal{H}$

1. $H_0 := randomselect(m, I)$
2. $i := 1$
3. while $(i \leq k)$
4. begin
   (a) $H'_{i-1} := \{h' | h \in H_{i-1}$ and $h' = generalise(h)\}$
   (b) $H'_i := \{h' | h' = bb_A(B_i, E_i, H'_{i-1}, \rho, f, n)\}$
   (c) $H''_i := nonredundant(B_i, H'_i)$
   (d) $H_i := randomselect(m, H''_i)$
   (e) increment i
5. end
6. return H_k

Figure 37: A simple incremental procedure for system identification. Given a decomposition into k stages, the best models found at each stage are refined further.

- It is weakly complete. That is, any clause containing n literals can be obtained in n refinement steps from the empty clause;
- It is not proper. That is, C' can be equivalent to C;
- It is not optimal. That is, C' can be obtained multiply by refining different clauses.

In addition, it is clear by definition that given a qualitative model C, $accep\ table(C', B, E)$ is $TRUE$ for any model $C' \in \rho^1_A(C, B, E)$. In turn, it follows that $acceptable(C', B, E)$ is $TRUE$ for any $C' \in \rho_A(C, B, E)$.

- The cost function used is $f_{Bayes}(C, B, E) = -\mathrm{P}(C|B, E)$ where $\mathrm{P}(C|B, E)$ is the Bayesian posterior probability estimate of clause C, given background knowledge B and positive examples E. Finding the model with the maximal posterior probability (that is, lowest cost) involves maximising the function (McCreath, 1999):

$$Q(C) = \log D_{\mathcal{H}}(C) + p \log \frac{1}{g(C)}$$

where $D_{\mathcal{H}}$ is a prior probability measure over the space of possible models; $p = |E|$, the number of positive examples; and g is the generality of a model. We use the approach used in the the ILP system C-Progol to obtain values for these two functions. That is, the prior probability is related to the complexity of models (more complex models are taken to be less probable, *a priori*); and the generality of a model is estimated using the number of random examples entailed by the model (the details of this are in Muggleton, 1996);

- The function $randomselect(m, H)$ in Fig. 37 randomly selects (without replacement) m elements of the set H (or all the elements of H if its cardinality is less than m);

- For all stages i in Fig. 37, the bb_A constructs no more than n models for each stage. Here we restrict n to 1000;

- For all stages i in Fig. 37, no more than m of the lowest-cost models are returned; Here we restrict m to 1000;

- The function *generalise* in Fig. 37 is restricted to "splitting" variable co-references apart (see Definition 27 and Lemma 31 in Muggleton (1995) and Remark 4 below for more on this); and

- The function *nonredundant* in Fig. 37 returns a set of non-redundant models. Given background knowledge B and a set of models S encoded as definite clauses, a model $C_1 \in S$ is redundant, iff for $S_1 = S - \{C_1\}$, $B \cup S \equiv B \cup S_1$. It can be shown that this entails checking that $B \cup S_1 \models C_1$. $nonredundant(B,H)$ returns all elements $C \in H$ which do not satisfy this redundancy check.

We now report on some properties of the various procedures described. It is evident that *incsearch* in Fig. 37 performs the same function as a non-incremental (single-shot) ILP system if $k = 1$, $H_I = \{\emptyset\}$ (that is, H_I consists of the empty model) and $m \geq n$.

Remark 1 Termination, correctness and sub-optimality *Termination of bb_A follows trivially if the number of nodes searched (n) is finite; and calls to acceptable and f terminate. It is also easy to see that the conditional statement on Step 7c ensures that, for all models $k \in selected$, $acceptable(k,B,E)$ is TRUE. All models returned by bb_A are correct in this sense. Since models returned by incsearch on any iteration i are a subset of the models returned by bb_A, it follows that all models returned by incsearch are also correct. The branch-and-bound procedure is known to be optimal, in that can identify the lowest cost models in the search space $\mathcal{H}$. However, bb_A with $\rho = \rho_A$ is optimal if and only if $n \geq |\mathcal{H}|$ and $H_I = \{\emptyset\}$. It follows that incsearch with $\rho = \rho_A$ is only optimal if and only if $k = 1$, $H_I = \{\emptyset\}$, $n \geq |\mathcal{H}|$, and $m \geq n$.*

Although a general statements about search complexity can be made, the following remarks refer specifically to the search for qualitative models.

Remark 2 Search space for qualitative models. *Let the number of qualitative constraints in acceptable models be restricted to some size d. Given element a single starting element i size d_i, the task of bb_A (we will assume n to be large) is to return all models of size d. This is done by examining all models returned by ρ_A that adds $d - d_i$ constraints to i. In the worst case, each $i = \emptyset$ and ρ_A has to return all models of size d. If the maximum recall number of any mode declaration be bound by some constant b, then there are at most b extensions of size 1, b^2 extensions of size 2 and so on, up to b^d models of size d. That is, given a model i, the number of acceptable models of size d constructed by ρ_A is at most b^d.*

We now consider an incremental procedure that simply selects some of the best qualitative models found at a stage for refinement at the next stage. It follows that the size of the search space depends principally on the maximum number of qualitative constraints added at any stage.

Remark 3 Incremental search space for qualitative models. (simple case). *Assume as before that the target model is restricted to d constraints and the maximum recall of any mode declaration is b. Assume further that model identification can be decomposed into $k \geq 1$ stages, with each stage resulting in models with $d_1, d_2, \ldots, d_k$ constraints (we will assume that all models in the initial set H_I have $d_0 \geq 0$ constraints and that $d_{i+1} \geq d_i$). At each stage i, a model is constructed by addition of $d_i^+ = d_i - d_{i-1}$ constraints to a model selected at stage $i-1$. For each model selected at stage $i-1$, we know from Remark 2 that bb_A constructs at most $b^{d_{i-1}^+}$ acceptable models. Since no more than m are selected at stage $i-1$, the total number of models constructed at stage i is $mb^{d_{i-1}^+}$. The total number of models constructed by the entire procedure is no more than $\sum_{i=1}^{k} mb^{d_i^+}$. That is, the total number of models constructed is $O(b^{d_{max}^+})$ where $d_{max}^+ = \max(d_1^+, d_2^+, \ldots, d_k^+)$.*

Models at a stage may not consist of a simple addition of constraints to those found earlier and we consider generalising models by splitting variables, before adding constraints (as shown in Fig. 37). For qualitative models, this translates to retaining the qualitative components found at the previous stage but disconnecting connections between some or all pairs whose outputs are connected together. While a general analysis will require a detailed description of the variable splitting procedure, a less detailed calculation is possible for the kinds of qualitative models sought here. The simplification results primarily from the "Distinct variables" restriction on well-posed models.

Remark 4 Incremental search space for qualitative models (limited generalisation). *Assume as before that the target model is restricted to d constraints and the maximum recall of any mode declaration is b. Assume further that model identification can be decomposed into $k \geq 1$ stages, with each stage resulting in models with $d_1, d_2, \ldots, d_k = d$ constraints (we will assume that all models in the initial set H_I have $d_0 \geq 0$ constraints and that $d_{i+1} \geq d_i$). We will now examine the effect of allowing generalisation by variable splitting only. For a model M selected at stage i, it is evident that if all variables in a constraint are distinct, then there can be at most $n_i = \max(d_i - 1, 0)$ co-references to any one variable v in M. Let the set of positions with co-references to a variable v be E_v. Variable splitting essentially renames variables at some or all of these positions into new ones. This is tantamount to partitioning the set E_v into equivalence classes, with positions in each equivalence class having the same variable; and each such partitioning giving rise to a model M' that is more general than m (in the sense that M' θ-subsumes Plotkin, 1970). The* nth *Bell number $B(n)$ gives the number of ways in which a set of size n can be partitioned into equivalence classes.*[7] *Thus, the number of models resulting from splitting variable co-references to a variable v in a model M from stage i is at most $B(n_i)$. If the maximum number of variables in any qualitative constraint is bounded by A, then there can be at most $s_i = Ad_i$ splittable variables in any model M from stage i. Therefore the number of models after generalisation of any M from stage i is at most $G(i) = B^{s_i}(n_i)$ Since there are no more than m models at any stage i, the total number of models after generalisation is no more than $mG(i)$. Recall each of these is then specialised by bb_A to construct a model for stage $i+1$. The total number of models constructed by the entire procedure is thus no more than $\sum_{i=1}^{k} mG(i-1)\, b^{d_i^+}$.*

7. The *n*th Bell number is equal to $\sum_{k=0}^{n} S_n^{(k)}$. $S_n^{(k)}$, or Stirling numbers of the second kind, describe the way a set of *n* elements can be partitioned into *k* disjoint, non-empty subsets. These can be computed using the formula $S_n^{(k)} = S_{n-1}^{(k-1)} + kS_{n-1}^{(k)}$ (with $S_n^{(1)} = 1$).

In general, it is evident that variable splitting is not the only form of generalisation that may be needed: components found at a previous stage may have to be discarded entirely before constructing a model for the current stage. It is evident that allowing this form of generalisation will significantly increase the worst-case search complexity.

Remark 5 Incremental search space for qualitative models (general case). *Assume as before that the target model is restricted to d constraints and the maximum recall of any mode declaration is b. Assume further that model identification can be decomposed into $k \geq 1$ stages, with each stage resulting in models with $d_1, d_2, \ldots, d_k$ constraints (we will assume that all models in the initial set H_I have $d_0 \geq 0$ constraints and that $d_{i+1} \geq d_i$). From Remark 4 above, we know that the number of models after generalisation by splitting variables at stage i is $mG(i)$, each with d_i constraints. Each of these models can be generalised further by dropping one or more constraints. This results in a total of $mG(i)2^{d_i}$ models, each of which is then specialised by bb_A to construct a model for stage $i+1$. In the worst case, all the constraints found in each of the models at stage i are removed by the generalisation step and the specialisation step at stage $i+1$ has to construct models with $i+1$ constraints in each case. The total number of models constructed by the entire procedure is thus no more than $\sum_{i=1}^{k} mG(i-1)2^{d_{i-1}}\, b^{d_i}$.*

A.3 Application

In all cases, the application tasks are of a re-constructive nature. That is, a known target model for each stage of the incremental process is used to generate examples for that stage. These, along with the background knowledge and a set of random examples for the stage are given to the learner. (the random examples are needed for the Bayesian calculation described in the previous section) We then check to see if the target model is amongst the results returned by the learner. All experiments were conducted on a laptop equipped with a 1.5 GHz Intel Pentium M Processor and 768 MB of main memory. Examples are restricted to a random sample of no more than 500 observations of system behaviour and no more than 500 random observations (these are needed for the Bayesian cost calculations). Incremental construction of models was accomplished using ALEPH version 5, with the YAP compiler (version 5.0.1).

We describe here the background knowledge and examples relevant to each of the application tasks presented in the paper. Common to all tasks are definitions of the QSIM constraints. The definitions we use are based on those in Bratko (2001) and are available on request from the first author. In the following sections we describe the encoding of the examples, the mode declarations and the values of the main parameters used for each application task. The principal parameters for system identification are these: (1) The number of constraints in the model (the "size" constraint described in Section 5.1 on well-posed models); (2) Upper bound on the number of occurrences of any kind of constraint (the "language" constraint described in Section 5.1); (3) Upper bound on the the number of nodes to be seached (*n* in the *incsearch* procedure); (4) Upper bound on the the number of models to be selected from a stage (*m* in the *incsearch* procedure); (5) Upper bound on the number of new variables in any model (constraint 10 described in Section 5.1); (6) Upper bound on the number of irrelevant variables in any model (constraint 11 in Section 5.1).

A.3.1 THE TANK MODELS

System variables for the coupled tanks system are `La`, `Lb`, `InflowA`, `Fab` and `OutflowB`. Examples for both the coupled tanks and single tank system are encoded using a $state/5$ predicate (the argu-

```
state(l:0/inc,l:0/std,f:0...inf/std,f:0/inc,f:0/std).

ments refer to the system variables `La`–`OutflowB`, in the order just listed). Some of the observations are shown in Fig. 38 (the syntax used is in the Prolog language):
22 observations are generated in all using the correct model for the coupled tank system. For the first stage of learning—the single tank system—observations made for Tank A (that is, `La` and `InflowA`) are ignored. This is achieved using the following mode declaration for $state/5$ (here, the "_" denotes that the corresponding argument is to be ignored):

```
STATE(_,+level,_,+flow,+flow)
```

In contrast, the mode declaration for $state/5$ for the coupled tank system is as follows:

```
STATE(+level,+level,+flow,+flow,+flow)
```

Mode declarations for the QSIM constraints for both single and coupled tanks are shown in Fig. 39.

The values of the principal parameters for the two stages are shown in the tabulation below.

A.3.2 THE PREDATOR-PREY MODELS

System variables for the predator-prey system are the predator population `P` and the prey population `N`. Examples for the system are encoded using a *state*/2 predicate (the arguments of which are `P` and `N`). Some of the observations are shown in Fig. 40.
5 observations of system behaviour are obtained using the target model. The mode declaration for the *state*/2 predicate is

```
STATE(+predator,+prey)
```

Mode declarations for the QSIM constraints are shown in Fig. 41.

The values of principal parameters are shown in the tabulation below.

Parameter	Value
Size	6
Language	2
n	1000
m	1000
Newvars	5
Irrelev	0

A.3.3 THE LUNG MODELS

System variables for identifying the human lung model are `Pa`, `Va`, `Pi`, `Vid` and `Pv`. Examples for the system are encoded using a *state*/5 predicate (the arguments of which are `Pa`–`Pv` in the order just listed). Some of the observations are shown in Fig. 42.
500 observations of system behaviour are obtained using the target model. The mode declaration for the *state*/5 predicate is:

```
state(p:0/std,v:0/inc,p:0...inf/inc,f:0/inc,p:0/inc).
state(p:0/std,v:0...inf/dec,p:0/std,f:0...inf/dec,p:0/std).
state(p:0/std,v:0...inf/dec,p:0/inc,f:0/inc,p:0/inc).
state(p:0/std,v:0...inf/dec,p:0/inc,f:0...inf/std,p:0/inc).
state(p:0/std,v:0...inf/dec,p:0/inc,f:0...inf/inc,p:0/std).
```

Figure 45: Mode declarations used for identifying the glucose-insulin models.

A.3.4 THE GLUCOSE-INSULIN MODELS

System variables for the glucose-insulin models are `Gin`, `G`, `DG`, `Iin`, `I`, and `DI`. Of these `DG` and `DI` are dependent on the glucose and insulin variables and could have been inferred from them. Examples for both the insulin and glucose stages are encoded using a *state*/6 predicate (the arguments refer to the system variables `Gin`–`DI`, in the order just listed). Some of the observations are shown in Fig. 44 (the syntax used is in the Prolog language):
24 observations are generated in all using the correct model for glucose-insulin regulation. For the first stage of learning—the insulin stage—observations relevant to glucose (that is, `Gin`, `G` and `DG`) are ignored. This is achieved using the following mode declaration for *state*/6 (here, the "_" denotes that the corresponding argument is to be ignored):

```
STATE(_,_,_,+ilevel,+ilevel,+iflow)
```

In contrast, the mode declaration for *state*/6 for the glucose stage is as follows:

```
STATE(+glevel,+glevel,+gflow,+ilevel,+ilevel,+iflow)
```

Mode declarations for the QSIM constraints for both insulin and glucose stages are shown in Fig. 45. The values of the principal parameters for the two stages are shown in the tabulation below.

A.3.5 THE GLYCOLYSIS MODELS

System variables for identifying models at any stage of glycolysis are cell-states before and after the stage. Examples for a stage are encoded using a *glycolysis*/2 predicate (the arguments of which are the cell-state before and after the reactions involved in that stage). Some of the observations for the first stage (priming) are shown in Fig. 46.
500 observations of system behaviour are obtained using the target models for each stage. The mode declaration for the *glycolysis*/2 predicate is:

```
GLYCOLYSIS(+cellstate,-cellstate)
```

Although QSIM constraints form the basis of qualitative reactions, the models constructed use a *pathway*/3 predicate. The mode declaration for this predicate is simply:

```
PATHWAY(+cellstate,#qreactions,-cellstate)
```

(Here the "#" indicates that a corresponding argument is a ground term: in this case a sequence of qualitative reactions).

The values of principal parameters for the three stages are shown in the tabulation below.

Figure 47: Number of partition-sequences to be searched for a given number of system variables.

Appendix B. Automatic Decomposition

We present here a specification for the problem of automatic decomposition addressed in the latter half of the paper, along with implementation details of a search procedure that identifies an acceptable decomposition.

B.1 Specification

We will assume that we are looking to decompose a system specified by a set of qualitative system variables. The problem can be specified as follows. Given a non-empty set S of system variables, consider first the notion of a "partition-sequence" $(S_1, S_2, \ldots, S_n)$, in which $S_i \subset S$, and $S_1, S_2 \ldots S_n$ form a partition of S. Given a set E of observed values for the system variables S, background knowledge B, a refinement operator ρ, a cost function f, and a partition-sequence $P = (S_1, S_2, \ldots, S_n)$, we are able to construct a n-stage incremental learner of the form shown in Fig. 6(b) that returns a set of models $H_n = \mathsf{L}(B, E_n, \rho, f, H_{n-1})$ with minimal cost, where $H_0 = \{\emptyset\}$ and at each stage i, E_i are the values observed for variables $S_1 \cup S_2 \cdots S_i$. Let us assume that we are also able to obtain the cost of H_n, which, for reasons that will become obvious immediately, we call C_P. With automatic system decomposition, we are concerned with a procedure that returns an optimal partition-sequence P^* such that, of all possible partition sequences P, $C_{P^*} \leq C_P$ (that is, P^* yields models with the least cost).

Remark 6 Search space for decompositions. *We are able to provide some details on the combinatorics of the search for decompositions. Recall that the number of partitions of a set of n elements into exactly k non-empty blocks is given by $S_n^{(k)}$ (Stirling's number of the second kind). For each such partition, a valid answer is given by an ordering of the blocks into some sequence. The number of k-length partition-sequences is thus $D_n^{(k)} = k!S_n^{(k)}$. We have an additional constraint that requires the first block in any partition-sequence to contain at least 2 elements. This means that we are only interested in partition-sequences of length $1, 2, \ldots, n-2$. The total number of partition-sequences to be considered is therefore $D_n^{(1)} + D_n^{(2)} + \cdots + D_n^{(n-2)}$. This is at most $(n-2)D_n^{(n-2)}$. Of course, models have be constructed with each element of any partition-sequence. The complexity of this has be estimated in the previous section.*

Fig. 47 tabulates the size of the search space for some values of n (the number of system variables), showing how an addition of a system variable increases the size of the search space by an order of magnitude (the number appears always to be greater than 10^{n-3}).

B.2 Implementation

Figure 48 shows a GSAT-like randomised local search procedure that identifies a partition-sequence based on a greedy selection of elements. In experiments for the paper we have made one modification to this procedure, which we have not shown in the figure for simplicity. In Fig. 48 variable subsets are compared simply on costs. If a pair of variable subsets V_1 and V_2 have the same cost, we further examine the following. For each of $V_{1,2}$ we obtain a best-case estimate of the length of the final partition-sequence. The subset with the shorter length is preferred. If these lengths are also the same, then the subset with fewer variables is preferred (on the assumption that the resulting ILP model would be simpler). In addition, of course, we will use $\rho = \rho_A$ and $f = f_{Bayes}$.

Remark 7 Space searched by *rls***.** *Let $|S| = n$. The procedure contains 3 loops in Steps 4, 4f, and 4(f)viii The loop in Step 4(f)viii iterates at most M times. On each iteration, there are at most n local moves from any subset. Therefore, at most Mn subsets are examined by the loop in Step 4(f)viii. This is called no more than R times by the loop in Step 4f, resulting in at most MRn subsets. The outermost loop in Step 4 can iterate no more than n times, which means the number of subsets examined are at most MRn^2.*

B.3 Application

We consider first 3 artificial problems obtained by a random decomposition of a set of 10 variables into 2, 3 and 4 stages. For each problem and stage, the "correct" variable subset is assigned the least cost possible. All other subsets are assigned costs randomly. The task is to find the correct variable subset at each stage for each of the 3 problems.[8] The search space has approximately 10^8 elements (in contrast to the coupled tanks problem, which has about 10^2). Figures 49 summarises the results of attempting to identify the correct decompositions for each of the 3 problems.

More generally, we examine the values of R and M needed for identifying the correct decomposition.[9] The values required using artificial problem sets of the kind just described, with $n = 4, 5, 6, 8,$ and 10 variables with $k = 2, 3,$ and 4 stages are shown in Fig. 50. The probability of obtaining the correct decomposition are shown in Fig. 51.

From these results, it is evident that both an increase in the number of variables or the number of stages usually requires an increase in the values of R and M (Fig. 50a), and that as the values of R and M are increased, the probability of obtaining the correct decomposition increases (Fig. 50b). Both these observations may be evident to the reader since an increase in either the number of variables or stages makes the search space larger. Increasing R and M then allows a more extensive search. A further characteristic of the automatic decomposition problem that may not be as obvious is this: since the number of variables left at each stage less than at the previous stage, we should, in principle, be able to achieve the same performance by starting with high values of R and M and progressively reducing their values after each stage. We do not explore this further, as such a progressive reduction is not a feature of the procedure here.

8. The procedure in the previous section has to be modified slightly, since there is no need to construct models using an ILP learner for these problems.
9. We note that the experiments are concerned with exact identification of the correct decomposition. Approximate identification, not addressed here, would yield higher probabilities.

$rls(S, B, E, \rho, f, R, M)$: Given a non-empty set of system variables S; background knowledge B; a set of values for the system variables E; a refinement operator ρ; a cost function f; an upper bound on the number of restarts R; and an upper bound on the depth of local moves M, returns a partition-sequence $(S_1, S_2, \ldots, S_k)$, in which each S_i results in the lowest cost model at stage i, given models constructed for S_{i-1}.

1. $i = 0$

Abstract

The computational complexities arising in motor control can be ameliorated through the use of a library of motor synergies. We present a new model, referred to as the Greedy Additive Regression (GAR) model, for learning a library of torque sequences, and for learning the coefficients of a linear combination of sequences minimizing a cost function. From the perspective of numerical optimization, the GAR model is interesting because it creates a library of "local features"—each sequence in the library is a solution to a single training task—and learns to combine these sequences using a local optimization procedure, namely, additive regression. We speculate that learners with local representational primitives and local optimization procedures will show good performance on nonlinear tasks. The GAR model is also interesting from the perspective of motor control because it outperforms several competing models. Results using a simulated two-joint arm suggest that the GAR model consistently shows excellent performance in the sense that it rapidly learns to perform novel, complex motor tasks. Moreover, its library is overcomplete and sparse, meaning that only a small fraction of the stored torque sequences are used when learning a new movement. The library is also robust in the sense that, after an initial training period, nearly all novel movements can be learned as additive combinations of sequences in the library, and in the sense that it shows good generalization when an arm's dynamics are altered between training and test conditions, such as when a payload is added to the arm. Lastly, the GAR model works well regardless of whether motor tasks are specified in joint space or Cartesian space. We conclude that learning techniques using local primitives and optimization procedures are viable and potentially important methods for motor control and possibly other domains, and that these techniques deserve further examination by the artificial intelligence and cognitive science communities.

Keywords: additive regression, motor primitives, sparse representations

1. Introduction

To appreciate why motor control is difficult, it is useful to quantify its computational complexity. Consider, for example, an agent whose goal is to apply torques to each joint of a two-joint arm so that the endpoint of the arm moves from an initial location to a target location in 100 time steps. Also suppose that torques are discretized to one of ten possible values. In this case, the agent needs

to choose one sequence of torques from a set of 10^{200} possible sequences. Searching this set of possible sequences is clearly a computationally intractable problem.

To ameliorate the computational challenges arising in motor control, it has been hypothesized that biological organisms use "motor synergies" (Bernstein, 1967). A motor synergy is a dependency among the dimensions or parameters of a motor system. For example, a coupling of the torques applied at the shoulder and elbow joints would be a motor synergy. Motor synergies are useful because they reduce the number of parameters that must be independently controlled, thereby making motor control significantly easier (Bernstein, 1967). Moreover, synergies are often regarded as "motor primitives". For our current purposes, we focus here on frameworks in which an agent with a library of motor synergies quickly learns to perform complex motor tasks by linearly combining its synergies. This idea has motivated a great deal of neuroscientific research. For example, Mussa-Ivaldi, Giszter, and Bizzi (1994) identified frogs' motor synergies by stimulating sites in the frogs' spinal cords. Importantly, these authors verified that stimulation of two sites leads to the vector summation of the forces generated by stimulating each site separately.

The idea of characterizing complex movements as linear combinations of motor synergies has also been influential in the fields of artificial intelligence and cognitive science. In these fields, an important research question is how to build an agent with a useful set of synergies or, alternatively, how an agent can learn a useful set of synergies. Approaches to these issues are typically based on techniques from the machine learning literature. Some researchers have developed theories motivated by kernel-based techniques. For example, Thoroughman and Shadmehr (2000) studied the errors in people's reaching movements and concluded that humans learn the dynamics of reaching movements by combining primitives that have Gaussian-like tuning functions. Other researchers have speculated that motor primitives can be learned using dimensionality-reduction techniques. For example, Sanger (1995) analyzed people's cursive handwriting using principal component analysis (PCA) to discover their motor synergies. He showed that linear combinations of these synergies closely reconstructed human handwriting. Other examples using dimensionality-reduction to learn motor primitives include Chhabra and Jacobs (2006), d'Avella, Saltiel, and Bizzi (2003), Fod, Matarić, and Jenkins (2002), Jenkins and Matarić (2004), Safanova, Hodgins, and Pollard (2004), Sanger (1994), and Todorov and Ghahramani (2003, 2004).[1]

The fact that novel motor tasks can often be performed by linearly combining motor synergies is a surprising result. To see why this result is unexpected, consider the case in which an agent needs to control a two-joint arm to perform a motor task. Suppose that a task is defined as a sequence of desired joint angles (i.e., desired angles for the shoulder and elbow joints at each time step of a movement), that a cost function is defined as the sum of squared error between the desired and actual joint angles, and that the agent has a library of motor synergies where a synergy is a sequence of torques (i.e., torques for the shoulder and elbow joints at each time step of a movement). The agent attempts to perform the motor task by finding a set of coefficients for a linear combination of synergies minimizing the cost function. (This optimization might be performed, for example, using a gradient descent procedure, known as policy gradient, in which an agent uses the gradient of the cost function with respect to the coefficients, Sutton, McAllester, Singh, and Mansour, 1999;

1. Our review focuses on frameworks in which complex movements are expressed as linear combinations of motor primitives. There are, of course, frameworks that use motor primitives in other ways. A reader interested in this topic may want to see Bentivegna (2004), Ijspeert, Nakanishi, and Schaal (2003), Lau and Kuffner (2005), Lee, Chai, Reitsma, Hodgins, and Pollard (2002), Peters and Schaal (2006), and Stolle and Atkeson (2006), among other articles.

Williams, 1992.) Should we expect that a good set of linear coefficients—a set that leads to a near-zero value of the cost function—will exist and, if so, be easy to find? We believe that the answer is no. Recall that synergies are defined in terms of torques, the agent **linearly** combines synergies, the cost function is defined in terms of joint angles, and there is a **nonlinear** relationship between torques and joint angles. Finding a good set of linear coefficients should be a difficult optimization problem because the nonlinear function relating coefficient values to values of the cost function will contain many local minima. As a matter of terminology, we refer to this as the "Motor Basis Optimization Problem".

The Motor Basis Optimization Problem motivates the need to think about good ways of constructing a library of synergies, and good ways of learning to linearly combine the synergies to perform novel motor tasks. In this paper, we propose a new learning model that learns a sparse and overcomplete representation of the space of potentially useful motor commands, and learns to linearly combine elements of this representation using a "greedy additive regression" procedure. At a high level of abstraction, our procedure closely resembles the use of greedy additive schemes for feature selection in recent machine learning systems (e.g., Perkins, Lacker, and Theiler, 2003; Viola and Jones, 2004). For example, Viola and Jones (2004) used AdaBoost (Freund and Schapire, 1997; Schapire, 1990) to create a fast and robust classifier for detecting faces in visual images. They started by creating a large library of image feature detectors. They then constructed a classifier in an additive manner. At each iteration, a new classifier was created by adding a feature detector to the old classifier. The feature detector that was added was the one whose use reduced the error of the old classifier by the largest amount. The end result after several iterations was a successful classifier with a sparse representation in the sense that it used relatively few feature detectors from the library.

This paper introduces a new learning model for motor control referred to as the Greedy Additive Regression (GAR) model. The GAR model maintains a library of torque sequences (i.e., motor synergies). If possible, the GAR model learns new movements by additively combining sequences in this library. If not possible, new movements are learned by other means (e.g., via feedback error learning). The torque sequences for these new movements are then added to the library. (Unlike Viola and Jones, we do not construct a library of primitives by hand. Instead, we learn the primitives in this library using the set of training tasks.)

We present results comparing the performances of the GAR model with those of another model, referred to as the PCA model, that can be regarded as a generic example from a large class of approaches commonly used in the artificial intelligence and cognitive science literatures. The PCA model learns a library of motor primitives using PCA, and finds coefficients for linearly combining the primitives using gradient descent. Whereas the PCA model often yields poor results, the GAR model consistently shows excellent performance. We find that the acquisition of new movements by the GAR model is rapid when the library is used. Moreover, the library is overcomplete and also sparse, meaning that only a small fraction of the stored torque sequences are used when learning a novel movement. The library is also robust in at least two different ways. First, after an initial training period, nearly all novel movements can be learned as additive combinations of sequences in the library. Consequently, learning from scratch via, for example, feedback error learning becomes rarer over time. Second, the library is also robust in the sense that it shows good generalization when an arm's dynamics are altered between training and testing conditions. If, for example, an arm is suddenly required to carry a payload during testing, torque sequences in the library can still be additively combined to rapidly learn new movements with this altered arm. We also demonstrate that the model works well regardless of whether motor tasks are specified in joint space or Cartesian

space. Based on these results, we believe that the GAR model contains several desirable properties, including a library which maintains a sparse and overcomplete representation of the space of potentially useful motor commands, and an additive regression optimization procedure which is fast and robust.

This article is organized as follows. Section 2 describes the two-joint arm that we simulated, and Section 3 describes the motor tasks that we used. Section 4 describes the Greedy Additive Regression model. Section 5 reports the simulation results comparing the performances of the GAR and PCA models under a variety of conditions. In Section 6, we briefly consider the performances of these models when the system to be controlled is a linear system with redundancy. Section 7 states our conclusions and directions for future research.

2. Simulated Two-Joint Arm

We simulated a two-joint arm that coarsely resembles a human arm (Li and Todorov, 2004). The arm can be written as a second-order nonlinear dynamical system (Hollerbach and Flash, 1982):

$$\mathcal{M}(\theta)\ddot{\theta} + \mathcal{C}(\theta,\dot{\theta}) + \mathcal{B}\dot{\theta} = \tau$$

where τ is a vector of torques, $\theta, \dot{\theta}$, and $\ddot{\theta}$ are vectors of joint angle positions, velocities, and accelerations, respectively, $\mathcal{M}(\theta)$ is an inertial matrix, $\mathcal{C}(\theta,\dot{\theta})$ is a vector of Coriolis forces, and $\mathcal{B}$ is a joint friction matrix. The mathematical forms of these variables are as follows:

$$\begin{aligned}
\mathcal{M}(\theta) &= \begin{pmatrix} a_1 + 2a_2\cos\theta_2 & a_3 + a_2\cos\theta_2, \\ a_3 + a_2\cos\theta_2 & a_3 \end{pmatrix}, \\
\mathcal{C}(\theta,\dot{\theta}) &= \begin{pmatrix} -\dot{\theta_2}(2\dot{\theta_1} + \dot{\theta_2}), \\ \dot{\theta_1}^2 \end{pmatrix} a_2\sin\theta_2, \\
\mathcal{B}(\theta) &= \begin{pmatrix} b_{11} & b_{12}, \\ b_{21} & b_{22} \end{pmatrix}, \\
a_1 &= I_1 + I_2 + m_2 l_1^2, \\
a_2 &= m_2 l_1 s_2, \\
a_3 &= I_2
\end{aligned}$$

where I_1 and I_2 are the moments of inertia of the two links, m_1 and m_2 are the masses of the two links, and s_1 and s_2 are the distances from the joints to the links' center of masses. We used the same parameter values for the arm as Li and Todorov (2004). These values are given in Table 1.

3. Motor Tasks

A motor task is to apply torques to the arm so that it follows a desired trajectory defined in joint space. A desired trajectory is specified by a sequence of joint angles written as a 2×50 matrix of 2 joint angles over 50 time steps, where each time step corresponds to 7 ms of simulation. This trajectory is created in several stages (see Figure 1). First, we generate a trajectory in Cartesian space. To generate this trajectory, an initial position for the end-effector of the arm is chosen by randomly sampling each joint angle from a uniform distribution between 0 and $\pi/2$. Then a final position for the end-effector is chosen as the end point of a vector v of length d at an angle ψ starting

Constant	Value	Constant	Value
b_{11}	0.05 kgm^2s^{-1}	b_{22}	0.05 kgm^2s^{-1}
b_{21}	0.025 kgm^2s^{-1}	b_{12}	0.025 kgm^2s^{-1}
m_1	1.4 kg	m_2	1.0 kg
l_1	0.30 m	l_2	0.33 m
s_1	0.11 m	s_2	0.16 m
I_1	0.025 kgm^2	I_2	0.045 kgm^2

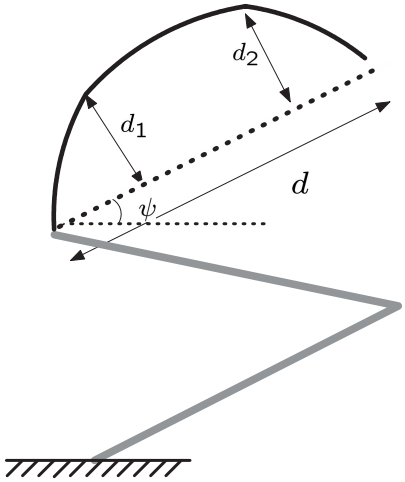

Figure 1: Schematic drawing depicting how a motor task is generated.

at the end-effector's initial position, where d and ψ are chosen uniformly at random between 10 cm and 30 cm, and between 0 and 2π, respectively. Next, two via points are chosen at distances d_1 and d_2 perpendicularly away from the vector v at locations $d/3$ and $2d/3$. Both d_1 and d_2 are drawn uniformly at random between -10 cm and 10 cm. Finally, a trajectory is generated by fitting a smooth cubic spline between the initial position, the two via points, and the final position. The Cartesian-space trajectory is converted to a joint-space trajectory by solving the robot arm's inverse-kinematics using the MATLAB robotics toolbox (Corke, 1996). The duration of movement is set to 350 ms, and the resulting joint-space trajectory is sampled at 7 ms intervals to get the 2×50 matrix defining a desired trajectory.

Given a desired joint-space trajectory, a motor task is to apply a time-varying torque to the arm so that the arm follows the desired trajectory. Torques are sampled every 7 ms, meaning that torques can be written as a 2×50 matrix. The cost function corresponding to the motor task is the sum of

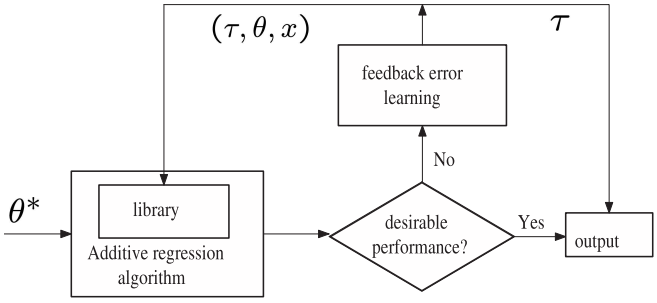

Figure 2: A schematic description of the Greedy Additive Regression(GAR) model. A desired trajectory θ^* is given as an input to the model. An additive regression algorithm is then used to construct a torque sequence by linearly combining sequences from the library. If this algorithm fails to find a linear combination yielding good performance, the model acquires a new torque sequence by other means (e.g., via feedback error learning), and then adds this new sequence to the library.

squared error between the desired and actual joint positions:

$$J = \sum_{t=1}^{50} \sum_{i=1}^{2} (\theta_i^*(t) - \theta_i(t))^2 \tag{1}$$

where $\theta_i^*(t)$ and $\theta_i(t)$ are the desired and actual angles of joint i at time t, respectively.

The motor tasks defined here are more complex than tasks often used in the literature in at least two respects. First, the desired Cartesian-space trajectories used here are typically highly curved, as opposed to straight-line reaching movements which are commonly used in experimental and computational studies of motor control. Second, our tasks specify desired joint angles at every time step. These tasks are more constrained than tasks that specify initial and final desired joint angles but allow an arm to have any joint angles at intermediate time steps.

4. The Greedy Additive Regression Model

We propose a model of motor learning called the Greedy Additive Regression (GAR) model. This model rapidly learns new motor tasks using a library of torque sequences. A schematic description of the model is given in Figure 2.

When a new motor task arrives, the model first checks whether a linear combination of sequences from the library achieves good performance on this task. Good performance is defined as a cost J less than ε (we set $\varepsilon = 0.05$ in our simulations). A potentially good linear combination is found via the additive regression algorithm which is described below. If a linear combination with good performance can be found, then this linear combination is used and nothing else needs to be done. If, however, such a linear combination is not found, then the model needs to learn a new torque sequence by other means. In the simulations reported in Section 5, we used feedback error learning to learn this new torque sequence (Kawato, Furukawa and Suzuki, 1987; see also Atkeson

and Reinkensmeyer, 1990, and Miller, Glanz, and Kraft, 1987).[2] The new torque sequence is then added to the library. Because a library has a fixed size of K, the addition of a new sequence may require the removal of an old sequence. Intuitively, the model removes the torque sequence that has been least used during the motor tasks that it has performed. Let n be an index over motor tasks, k be an index over sequences in the library, and $|\rho^k(n)|$ be the absolute value of the linear coefficient $\rho^k(n)$ assigned to sequence k on task n by the additive regression algorithm. The percent of the model's "total activation" that sequence j accounts for, denoted a^j, is defined as:

$$a^j = \frac{\sum_n |\rho^j(n)|}{\sum_n \sum_k |\rho^k(n)|} \times 100.$$

A sequence with large coefficients (based on magnitude, not sign) on many tasks would account for a large percent of the model's total activation, whereas a sequence with near-zero coefficients would account for a small percent. The model removes the torque sequence that accounts for the smallest percent of its total activation.

To complete the description of the GAR model, we need to describe the additive regression algorithm for finding potentially good linear combinations of torque sequences from the library for a motor task. As mentioned above, this algorithm is motivated by recent machine learning systems that have used greedy additive procedures for feature selection (Perkins, Lacker, and Theiler, 2003; Viola and Jones, 2004).

The additive regression algorithm is an iterative procedure. At iteration t, the algorithm maintains an aggregate torque sequence $F^{(t)}$ to perform a motor task such that:

$$F^{(t)} = \sum_{j=1}^{t} \rho_j f_j \tag{2}$$

where f_j is a sequence in the library and ρ_j is its corresponding coefficient. Note that the aggregate sequence $F^{(t)}$ is a weighted sum of t sequences from the library, but these sequences are not necessarily distinct. It is possible that the same sequence appears more than once in the summation in Equation 2. At each iteration of the algorithm, a sequence from the library is selected (with replacement), and a weighted version of this sequence is added to $F^{(t)}$ in order to create $F^{(t+1)}$. That is,

$$F^{(t+1)} = F^{(t)} + \rho_{t+1} f_{t+1} \tag{3}$$

where f_{t+1} is the library sequence selected to be added and ρ_{t+1} is its corresponding coefficient.

How does the algorithm choose f_{t+1} and ρ_{t+1}? Each torque sequence in the library is associated with a trajectory of joint angles. For computational convenience, the algorithm sets this trajectory to

2. In brief, feedback error learning proceeds as follows. An adaptive feedforward controller is used in conjunction with a fixed feedback controller. At each moment in time, the feedforward controller receives the desired joint positions, velocities, and accelerations, and produces a feedforward torque vector. The feedback controller receives the current and desired joint positions and velocities and produces a feedback torque vector. The sum of the feedforward and feedback torque vectors is applied to the arm, and the resulting joint accelerations are observed. During the learning portion of the time step, the inputs to the feedforward controller are set to the current joint positions, velocities, and accelerations, and the target output is set to the torque vector that was applied to the arm. This controller's parameters are then adapted so that it better approximates the mapping from the inputs to the target output in the future. Early in training, the outputs of the feedforward controller are near zero and most of the torques are supplied by the feedback controller. As training progresses, the feedforward controller better approximates the arm's inverse dynamics, and it supplies most of the torques. Feedback error learning is an attractive learning procedure because it is unsupervised; it does not require an external teacher but only a simple feedback controller.

a "prototypical" trajectory in the following sense. The position of the arm is initialized so that each joint angle is at its average initial value (i.e., each joint angle is initialized to $\pi/4$). The joint-angle trajectory associated with a torque sequence is then found by applying the sequence to the arm. A sequence is evaluated by correlating its joint-angle trajectory with $\partial J/\partial F^{(t)}$, the gradient of the cost function J with respect to the current aggregate torque sequence. This gradient indicates how the aggregate sequence should be modified so as to reduce the cost. In our simulations, it was obtained by numerically computing the partial derivative of the cost function with respect to each element of the aggregate sequence $F^{(t)}$.[3] The torque sequence whose trajectory is maximally correlated with this gradient, denoted f_{t+1}, is selected. To find the best coefficient ρ_{t+1} corresponding to this sequence, the algorithm performs a line search, meaning that the algorithm searches for the value of ρ_{t+1} that minimizes the cost $J(F^{(t)} + \rho_{t+1} f_{t+1})$ (we implemented a golden section line search; see Press, Teukolsky, Vetterling, and Flannery, 1992, for details). $F^{(t+1)}$ is then generated according to Equation 3, and the optimization proceeds to the next iteration. This process is continued until the value of the cost function converges (see Algorithm 1).

There are several possible perspectives on the additive regression algorithm. The idea of greedily selecting the next primitive from a library has also been explored in the feature selection literature. For example, Perkins, Lacker, and Theiler (2003) used a gradient-based heuristic at each iteration of their learning procedure to select the best feature from a set of features to add to a classifier. Our work differs from their work in many details because the domain of motor control forces us to confront the complexities inherent in learning to control a dynamical system (see also Tassa, Erez, and Smart, 2008). In addition, an appealing aspect of our work is that we use the solutions from prior tasks to create a library of primitives. We find that this practice leads to an overcomplete representation of the control space. Overcomplete representations have been shown to be useful in a wide range of applications (e.g., Lewicki and Sejnowski, 2000; Smith and Lewicki, 2006). In addition, the additive regression algorithm can be seen as performing gradient descent where the direction of the gradient at each iteration is projected onto the library sequence whose trajectory is maximally correlated with this gradient. The algorithm then minimizes the cost function by optimizing the coefficient corresponding to this sequence. The algorithm can also be seen as performing a type of "functional gradient descent" via boosting (readers interested in this perspective should see Bühlmann, 2003, or Friedman, 2001). Lastly, the algorithm can be seen as using "matching pursuit" to identify the next library sequence to add to the aggregate sequence at each iteration (see Mallat and Zhang, 1993, for details).

5. Simulation Results

This section reports a number of results using the GAR model. We compare the performances of the GAR model with those of another model, referred to as the PCA model, that can be regarded as a generic example from a large class of approaches commonly used in the artificial intelligence and cognitive science literatures. The PCA model performs dimensionality-reduction via PCA to learn a library of motor primitives. When given a novel motor task, the PCA model learns to perform the

3. $F^{(t)}$ is a 2×50 matrix. The partial derivative of the cost function with respect to element (j,k) of $F^{(t)}$ was computed by evaluating the cost of $F_+^{(t)}$ and $F_-^{(t)}$, where $F_+^{(t)}$ is the same as $F^{(t)}$ except that its $(j,k)^{\text{th}}$ element is set to $F^{(t)}(j,k) + \delta$ (similarly, $F_-^{(t)}$ is set to $F^{(t)}(j,k) - \delta$; we set $\delta = 0.01$.) The partial derivative was then approximated by $\frac{J(F_+^{(t)}) - J(F_-^{(t)})}{2\delta}$.

task using a policy gradient optimization procedure (Sutton, McAllester, Singh, and Mansour, 1999; Williams 1992) to learn a set of coefficients for linearly combining the motor primitives. (We regard the PCA model as generic because we regard PCA and gradient descent as generic dimensionality-reduction and optimization procedures, respectively.)

5.1 GAR versus PCA

In the PCA model, the library of motor synergies was created as follows. We first generated 3000 motor tasks as described in Section 3, and then used feedback error learning to learn a torque sequence for each task. This gave us 3000 sequences, each defined by a matrix of size 2×50. We re-stacked the rows of each matrix to form a vector of size 1×100. This gave us 3000 vectors (or data points) lying in a 100-dimensional space. We then performed dimensionality reduction via PCA. The 100 principal components accounted for all the variance in the data and, thus, these components were used as the library for the PCA model. We refer to these components as PCA sequences.

To learn to perform a novel motor task from a test set, the PCA model searched for good linear combinations of the PCA sequences. This search was conducted using a policy gradient procedure (Sutton, McAllester, Singh, and Mansour, 1999; Williams 1992). The linear coefficients were initialized to random values. At each iteration of the procedure, the gradient of the cost function with respect to the coefficients was numerically computed, and a line search in the direction of the gradient was performed (a golden section search method was implemented; see Press, Teukolsky, Vetterling, and Flannery, 1992, for details). This process was repeated until the cost function converged.

The GAR model was implemented as follows. Its library of torque sequences was created by running the model on 3000 motor tasks. The model's library size was set to 100. The sequences in this library at the end of training are referred to as GAR sequences. To learn to perform a novel motor task from a test set, the GAR model learned to linearly combine the GAR sequences using the additive regression algorithm described above.

The PCA and GAR models are two possible combinations of ways of creating libraries—one can create libraries of either PCA or GAR sequences—and ways of linearly combining sequences from

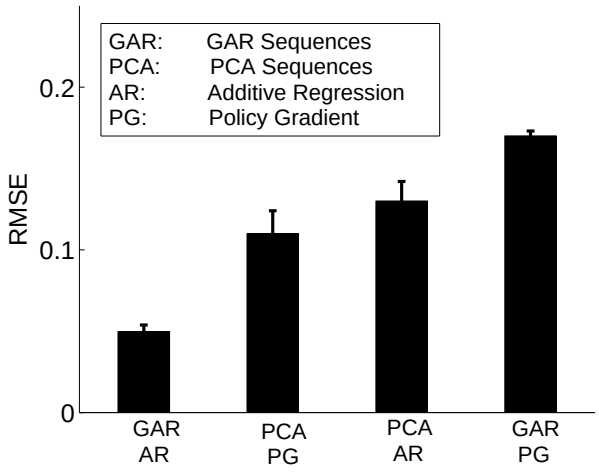

Figure 3: Average root mean squared errors of four systems on a test set of 100 novel motor tasks (the error bars show the standard errors of the means). The four systems use: (i) GAR sequences with additive regression (GAR model); (ii) PCA sequences with policy gradient (PCA model); (iii) PCA sequences with additive regression; and (iv) GAR sequences with policy gradient.

a library—one can learn linear coefficients through policy gradient or additive regression. The PCA model combines PCA sequences with policy gradient, whereas the GAR model combines GAR sequences with additive regression. For the sake of completeness, we also studied the remaining two combinations, namely, the combination of PCA sequences with additive regression and the combination of GAR sequences with policy gradient.

The results are shown in Figure 3. The horizontal axis gives a system's combination of library sequences and optimization technique. The vertical axis gives a system's average root mean squared error (RMSE where the error is between the desired and actual joint angles) on a test set of 100 novel motor tasks. Clearly, the GAR model (leftmost bar in figure) performed better than the PCA model (second bar from left). To further illustrate this point, the solid line in Figure 4 shows the Cartesian-space desired trajectory for a sample test task. The dashed line shows the trajectory achieved by the GAR model, and the dotted line shows the trajectory achieved by the PCA model. Whereas the GAR model found a curved trajectory that closely approximated the desired trajectory, the PCA model converged to a relatively straight-line movement which coarsely approximated the desired trajectory. Our simulation results suggest that this is a common outcome for the PCA model. It appears that the PCA model (and perhaps any system that uses policy gradient; see Figure 3) is prone to finding poor local minima of the error surface.

In addition to showing that the GAR model outperformed the PCA model, Figure 3 also shows that the GAR model outperformed the other systems considered here. Overall, the results are interesting because they suggest that it is not enough to choose a good library—consider that the system using GAR sequences with policy gradient performed poorly—and that it is also not enough to use a good optimization procedure—the system using PCA sequences with additive regression

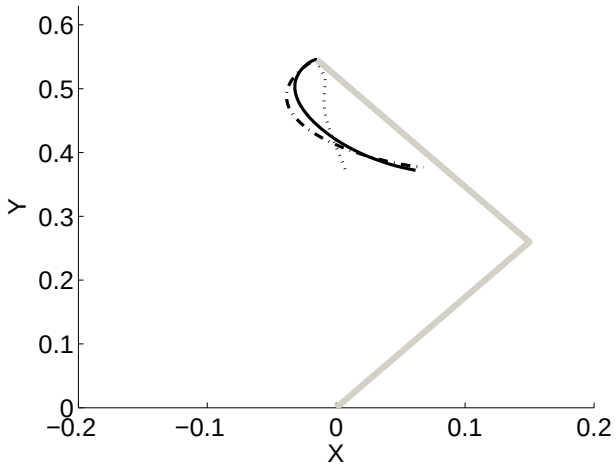

Figure 4: The solid line shows the Cartesian-space desired trajectory for a sample test task. The dashed line shows the trajectory achieved by the GAR model, and the dotted line shows the trajectory achieved by the PCA model.

performed poorly too. Instead, to achieve good performance it is necessary to consider the representational primitives and the optimization procedure as a pair. Representational primitives and optimization procedures are effective if a given procedure is able to find good solutions when the search space is based on these primitives.

Why does the GAR model work so well? Our results suggest that its due to its combination of "local" representational primitives (the GAR sequences) and a "local" optimization procedure (additive regression). To appreciate the coupling between representational primitives and optimization procedures, its important to keep in mind the differences between GAR and PCA sequences, and the differences between additive regression and gradient descent optimization procedures. Each individual GAR sequence is a solution to some task in the training set, whereas an individual PCA sequence is not necessarily a solution to a task but, rather, reflects properties of many tasks. In this sense, a GAR sequence can be regarded as a "local feature," and a PCA sequence can be regarded as a "global feature." Similarly, additive regression can be considered as a local optimization procedure because it adds at most one new feature to its linear combination at each iteration and because, at convergence, its linear combination tends to contain relatively few features. In contrast, gradient descent is a global optimization procedure because it finds linear combinations of all possible features. Because some features can have opposite effects, global optimization procedures lead to interference. Interference can be avoided by using a local optimization method. Local optimization methods have been shown to be effective in motor control in previous research. For example, Atkeson, Moore, and Schaal (1997) stored all previous experiences on control tasks in memory, and used a relatively local regression scheme (where locality was specified in terms of both space and time) to compute control signals for new tasks. They showed that their local learning method performed well, and also ameliorated the problem of global interference from features with opposing effects.

For linear systems and quadratic cost functions, we predict that the use of GAR versus PCA sequences, or additive regression versus gradient descent optimization procedures, should not matter much. Indeed, simulations on a linear system in Section 6 show that all four library/algorithm combinations work equally well. This is because a linear combination of either GAR or PCA sequences is, by linearity, a solution to some task. When searching for a good linear combination, a learner is searching among a set of task solutions for the particular solution which yields good performance on the current target task. This remains true regardless of whether a learner uses GAR or PCA sequences, or additive regression or gradient descent optimization procedures.

For nonlinear systems, however, this is not necessarily the case. With nonlinear systems, our results show that a learner using local primitives (which are task solutions) and local optimization procedures is preferable. This is because, when searching for a good linear combination, the local optimization procedure searches a set of combinations which are relatively close to solutions for some task. In the context of the GAR model, for example, we conjecture that each iteration of the additive regression procedure finds a linear combination of GAR sequences (again, each sequence is a solution to a task in the training set) which is itself close to a solution for some task due to the local nature of its search. In contrast, a global optimization procedure, such as gradient descent, would search among linear combinations which are far from any task solution. Finally, our results are consistent with empirical findings in the machine learning literature showing that additive schemes outperform gradient descent when searching for good linear combinations of features for novel classification tasks (Friedman, 2001; Perkins, Lacker, and Theiler, 2003; Viola and Jones, 2004).[4]

5.2 Visualizing Torque Sequences

The library of a GAR model is created on the basis of a wide variety of motor tasks. The torque sequences in the library should, therefore, be "representative" of the tasks they encode. Our goal here is to examine these sequences.

We trained a GAR model with 3000 training tasks using a library of size 100. We then ordered the sequences in the library by the percent of the model's total activation that a sequence accounted for. Figure 5 shows the Cartesian-space trajectories generated by the top three sequences. To generate these trajectories, the shoulder and elbow joint angles of the arm were initialized to $\pi/4$ and $\pi/2$ respectively. Each torque sequence was then applied to the arm, first with a coefficient of 1 and then with a coefficient of -1. Note that the trajectories span a wide range of directions. Several of the trajectories are highly curved, whereas others are closer to straight lines. This range is a result of the diverse set of tasks used to create the sequences. This graph illustrates that, even though the sequences are added to the library in an arbitrary order, the important sequences that remain in the library are representative of the motor tasks.

5.3 The GAR Model with Libraries of Different Sizes

Above we set the size of the library used by the GAR model to 100. Here we compare the model's performances with libraries of different sizes. If the size, denoted K, is too small, then torque sequences that are often useful for learning novel motor tasks might be removed. In contrast, if K is too big, then the library will contain many sequences which are nearly never used. Consequently, there ought to be an optimal value for K. We implemented the GAR model as described above

4. We thank an anonymous reviewer whose suggestions inspired these comments.

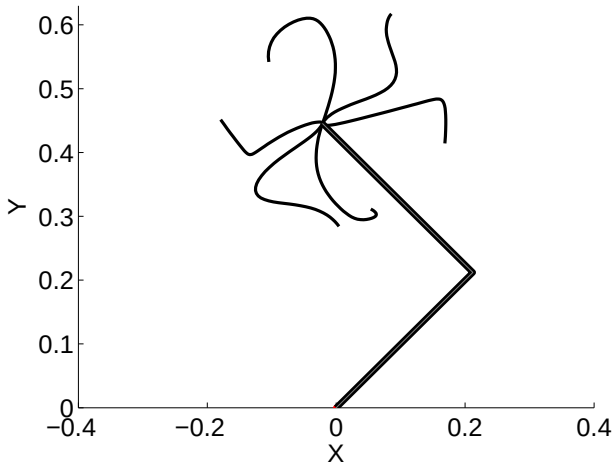

Figure 5: Cartesian-space trajectories generated by the three torque sequences that accounted for the largest percent of a GAR model's total activation. These trajectories were generated by initializing the shoulder and elbow joint angles of the arm to $\pi/4$ and $\pi/2$ respectively, and then applying the sequences to the arm with coefficients of 1 and -1.

using 3000 motor tasks. Three versions of the GAR model were used where the versions differed in the sizes of their libraries.

The results are shown in Figures 6 and 7. In Figure 6, the horizontal axis shows the number of motor tasks, and the vertical axis shows the percent of tasks in which a version of the GAR model needed to learn a torque sequence via feedback error learning. The latter value was obtained as follows. The motor tasks were divided into 60 blocks of 50 trials each. The percents for the blocks were then smoothed using a moving window of width 5. Results are reported for versions of the GAR model with library sizes of 50, 100, and 200. Early in training, a library has relatively few sequences, and feedback error learning must often be used. As training progresses, the library has many more useful sequences, and most novel motor tasks can be performed by linearly combining sequences from the library. In this case, feedback error learning is infrequently used. A comparison of the versions with different library sizes shows that the version with a library size of 50 used feedback error learning more often than versions with library sizes of 100 or 200. This suggests that a library size of 50 is too small.

From top to bottom, the three graphs in Figure 7 correspond to versions of the GAR model with library sizes of 50, 100, and 200. The sequences in a library are ordered according to the percent of a model's total activation that a sequence accounted for. The horizontal axis of each graph in Figure 7 plots the sequence number, and the vertical axis plots the percent of total activation that a sequence accounted for. The versions with libraries of size 100 and 200 show similar patterns of activation. In both cases, approximately the top 50 sequences accounted for nearly all the activation. The remaining sequences were rarely used. In contrast, the version with a library of size 50 had a different pattern of activation. Roughly all of the sequences in this library contributed to the model's total activation. We measured the average task error for each model (based on Equation 1) using

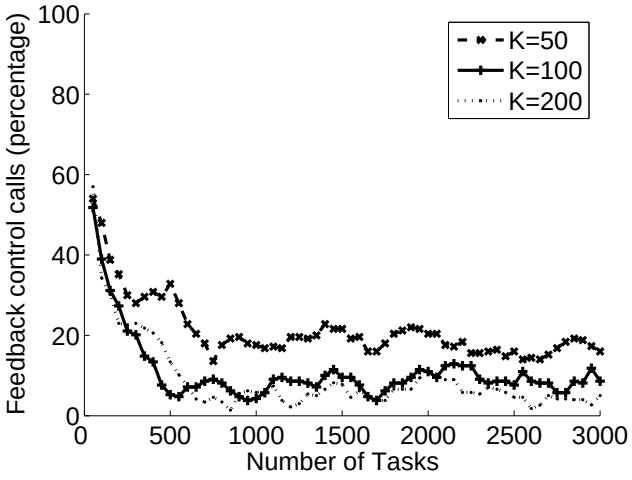

Figure 6: The horizontal axis shows the number of motor tasks, and the vertical axis shows the percent of tasks in which a version of the GAR model needed to learn a torque sequence via feedback error learning. The three curves in the figure correspond to versions of the GAR model with library sizes of 50, 100, and 200.

the last 1000 motor tasks. When $K = 50$, the average task error was 0.0925; when $K = 100$, the error was 0.0723; and when $K = 200$, the error was 0.0744. The corresponding standard error of the means were 0.010, 0.012, and 0.009. It seems that $K = 100$ is most efficient in the sense that it yielded good performance with a memory of moderate size. Furthermore, the version with $K = 100$ has the property that its use of sequences was relatively sparse. The top 10, 20, and 30 sequences accounted for 60, 78, and 88 percent of the version's total activation, respectively. Clearly, only a small fraction of the stored sequences tended to be used when learning a novel task.

5.4 GAR versus PCA in the Presence of Altered Dynamics

People are robust to changes in their arms' dynamics. For example, people can make accurate and smooth arm movements regardless of whether they carry no payload, a light payload, or a heavy payload. In this subsection, we compare the performances of the GAR and PCA models when they were trained without a payload, but a payload was added to the simulated arm during test trials.

The libraries for the GAR model (with a library of size 100) and the PCA model were created as described above with an arm that did not carry a payload. These models were then tested when the arm did carry a payload. Test trials were conducted as described above; that is, for each test task, a linear combination of torque sequences in a library was found via the additive regression algorithm for the GAR model, and via policy gradient for the PCA model. A set of 100 novel test tasks was generated. Models were evaluated on this set four times, once for each possible payload (payloads of 0, 1, 3, and 5 kg were used). Payloads were added to an arm by increasing the mass of the arm's elbow-wrist link (m_2 in Table 1). For the sake of completeness, we also tried the other two

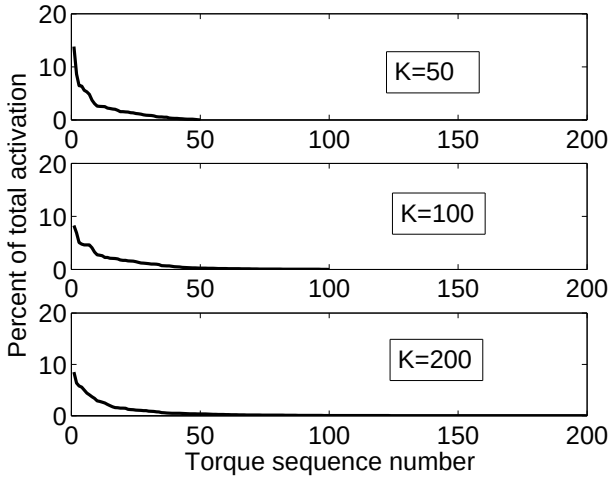

Figure 7: From top to bottom, the three graphs correspond to versions of the GAR model with library sizes of 50, 100, and 200. The sequences in a library are ordered according to the percent of a model's total activation that a sequence accounted for. The horizontal axis of each graph plots the sequence number, and the vertical axis plots the percent of total activation.

combinations of libraries with optimization algorithms, namely, the GAR sequences with policy gradient, and the PCA sequences with additive regression.

The results are shown in Figure 8. The vertical axis plots the average RMSE for each model for each payload. (The results for a payload of 0 are identical to those in Figure 3). For each payload, there are four bars corresponding to the four library/algorithm combinations. The performances of the PCA model degraded rapidly as the payload increased (2^{nd} bar in each set of bars). In contrast, the performances of the GAR model were robust (1^{st} bar in each set). We regard this successful generalization as a highly surprising result. It clearly demonstrates that the GAR model develops a useful library of torque sequences, and that the additive regression algorithm is a powerful optimization procedure for finding good linear combinations, even under test conditions that are very different from training conditions.

Why did the GAR model generalize so successfully? To address this question, we performed an additional analysis. The idea behind this analysis is to evaluate whether the GAR model generates similar libraries for different payloads. If this is the case, then additive regression should work well for tasks with novel payloads, even when using a library of GAR sequences constructed from zero-payload trials. We first generated a library of 100 GAR sequences using a training set of 3000 tasks where the simulated arm did not contain a payload. We then generated libraries for each non-zero payload using the same set of tasks. We compared each non-zero payload library to the zero-payload library. For each GAR sequence in a non-zero payload library, we found the sequence in the zero-payload library that was maximally correlated with this GAR sequence. For each non-zero payload, the average value of this maximum correlation is reported in Table 2. The GAR model successfully generalized from zero payloads to non-zero payloads because these correlations are large. The

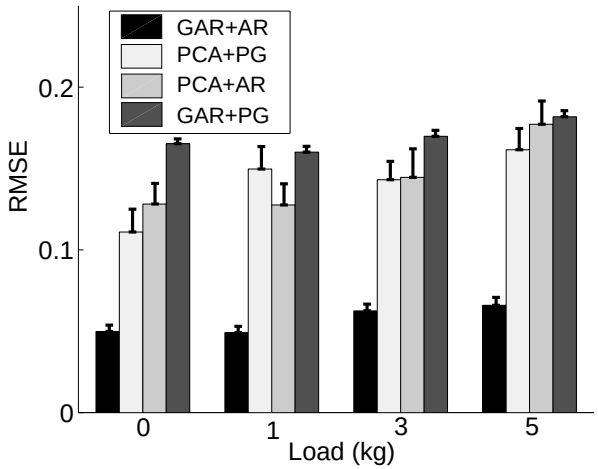

Figure 8: Average RMSEs of the GAR and PCA models on the test tasks when the arm carried different payloads.

Payload (kg)	Average maximum correlation	Standard error
1	0.84	0.08
3	0.81	0.04
5	0.73	0.06

other systems we evaluated were not able to take advantage of the similarities between solutions for zero-payload and non-zero payload tasks.

5.5 Motor Tasks Specified in Cartesian Space

In this subsection, we consider learning sequences for motor tasks when the desired trajectories are specified in Cartesian space instead of joint space. Using Cartesian trajectories adds an additional level of complexity. In addition to modeling the arm's inverse dynamics (a mapping from desired joint coordinates to torques), a system also needs to model the arm's inverse kinematics (a mapping from desired Cartesian coordinates to joint coordinates). An appealing feature of Cartesian trajectories is that they can be easily planned based on visuospatial information.

The cost function for this simulation is the sum of squared error between desired and actual positions of the arm's end-effector in Cartesian space:

$$J = \sum_{t=1}^{50} (r_x^*(t) - r_x(t))^2 + (r_y^*(t) - r_y(t))^2$$

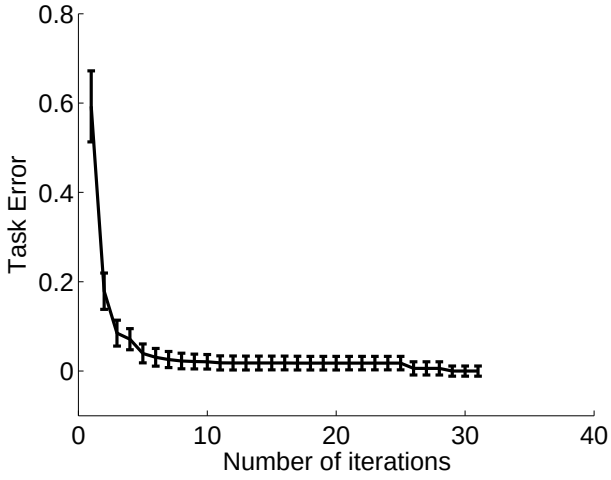

Figure 9: Results when motor tasks were specified in Cartesian space. The horizontal axis plots the number of iterations used by the GAR model, and the vertical axis show the average task error at each iteration.

where $(r_x^*(t), r_y^*(t))$ is the desired (x,y)-coordinates of the arm's end-effector in Cartesian space at time t, and $(r_x(t), r_y(t))$ is the actual coordinates. The GAR model was trained using 3000 motor tasks with a library of size 100. The library was constructed in the same way as before. An error threshold of $\varepsilon = 0.02$ was used to determine if a linear combination of torque sequences from the library provided a "good" aggregate sequence for a task (note that this is different from a threshold of $\varepsilon = 0.05$ used in previous simulations because the cost function is in different units now). We then created a test set of 100 tasks, and used the additive regression algorithm to learn a set of linear coefficients for each test task.

The results are shown in Figure 9. The horizontal axis plots the number of iterations used by the additive regression algorithm, and the vertical axis shows the average task error (Equation 8) at each iteration. Note that this error declined rapidly to a near-zero value. This outcome indicates that the GAR model has wide applicability in the sense that it is effective regardless of whether motor tasks are specified in joint space or Cartesian space.

6. GAR Model Applied to a Redundant and Unstable System

Until now, our simulations used a robotic arm. This section reports simulation results with a spring-mass system. In contrast to the robotic arm, this system allows us to evaluate different learners when the system to be controlled has linear dynamics, redundancy (three control signals move the system in a two-dimensional space), and is inherently unstable (zero or random control signals lead to divergent behavior). The system is schematically illustrated in Figure 10.

The spring-mass system has three elastic spring-like sticks that produce an opposing force when stretched or compressed. Stick 1 has resting length of l and connects the ground to point mass m_1. Stick 2 also has a resting length of l and connects m_1 to point mass m_2. Stick 3 has a resting length

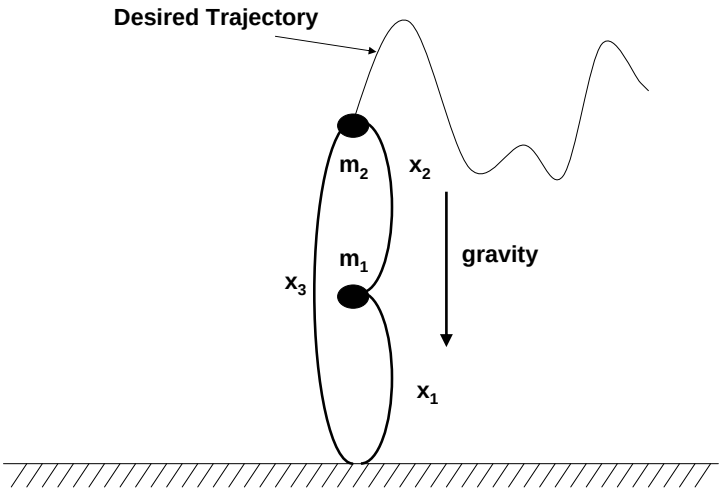

Figure 10: Schematic description of the spring-mass system used for the simulations.

of $2l$ and connects the ground to point mass m_2. All sticks have second-order linear dynamics. The dynamics of this system are governed by the following set of equations:

$$\begin{aligned} f_1 &= (l-x_1)k_1 + b_1\dot{x_1} + h_1u_1, \\ f_2 &= (l-x_2)k_2 + b_2\dot{x_2} + h_2u_2, \\ f_3 &= (2l-x_1)k_3 + b_3\dot{x_3} + h_3u_3, \\ x_3 &= x_1 + x_2, \\ \ddot{x_1} &= (f_1 - f_2 - mg)/m, \\ \ddot{x_2} &= (2f_2 + f_3 - f_1)/m \end{aligned}$$

where x_1, x_2, and x_3 are the current lengths of the sticks, f_1, f_2, and f_3 are the forces applied by the sticks due to elasticity, and the point masses m_1 and m_2 have the same weight m. Because the damping coefficients b_1, b_2, and b_3 were set to zero, the system exhibits a positive feedback effect which causes its behavior to diverge (this can be seen by setting the control signals u_1, u_2, and u_3 to zero). The constraint $x_3 = x_1 + x_2$ makes the system redundant as there are three inputs, u_1, u_2 and u_3, and only two free variables, x_1 and x_2. The parameter values are given in Table 3.

For this system, a task was defined by the desired trajectory for mass m_2 over a course of $T = 2.5$ seconds. A desired trajectory was generated as follows. First, four sine waves were generated with random frequencies ω_1, ω_2, ω_3, and ω_4, where ω_i was picked uniformly at random from the interval $[0.03, 0.3]$. The desired trajectory x_t^* was generated by $x_t^* = sin(\omega_1 t)sin(\omega_2 t) + sin(\omega_3 t)sin(\omega_4 t)$.

Constant	Value	Constant	Value	Constant	Value
k_1	20 kgm^2s^{-1}	k_2	20 kgm^2s^{-1}	k_3	40 kgm^2s^{-1}
b_1	0.0 kgm^2s^{-1}	b_2	0.0 kgm^2s^{-1}	b_3	0.0 kgm^2s^{-1}
h_1	10 $kgms^{-2}$	h_2	10 $kgms^{-2}$	h_3	20 $kgms^{-2}$
l	0.50 m	m	0.5 kg	g	10 ms^{-2}

Table 3: Values of constants used in the simulations of the spring-mass system.

Performance errors were quantified using a quadratic cost function:

$$c(x_3;x^*) = \int_0^T (x_t^* - x_{3,t})^2 dt$$

where $x_{3,t}$ is the position of mass m_2 at time t. Because this is a linear system with a quadratic cost function, the sequence of optimal (feedforward) control signals for a task can be computed using standard optimal control techniques. In our simulations, we discretized the system in time steps of size 0.025 seconds and integrated the system using a first-order Runge-Kutta method.

We created libraries of sequences as follows. We first generated a training set of 1000 tasks. For each task, we also computed the optimal sequence of control signals. Using these optimal sequences as data items, we created a library of PCA sequences by extracting the top thirty principal components based on these data items. We created a library of thirty GAR sequences using the additive regression procedure described above, with the exception that an optimal sequence (as opposed to a sequence found via feedback error learning) was added to the library when a good linear combination of library sequences could not be found.

As above, we compare the performances of four learning systems comprising all four combinations of representational primitives (PCA and GAR sequences) and optimization procedures (policy gradient and additive regression). The results on 100 test tasks are shown in Figure 11 (the leftmost bar in this figure gives the average RMSE using optimal control sequences). Note that all four learners performed nearly optimally. This is unsurprising as the quadratic error surface contains a single (global) minimum, and any reasonable optimization procedure will find this minimum. Also note that all four learners showed similar levels of performance (the differences in their performances are not statistically significant). This result is consistent with our predictions for linear systems with quadratic cost functions (see Section 5.1).

Although the learners showed similar levels of performance, a main point of this section is that they are not equivalent in terms of processing time. To quantify processing time, we examined the number of calls each learner made to the simulator of the spring-mass system. This simulator must be called each time a gradient is computed. On average, the learner using GAR sequences and additive regression made 49 calls, the learner using PCA sequences and policy gradient made 3879 calls, the learner using PCA sequences and additive regression made 62 calls, and the learner using GAR sequences and policy gradient made 3422 calls. Clearly, the additive regression algorithm is efficient in the sense that it made significantly fewer calls to the spring-mass simulator, irrespective of the library used.

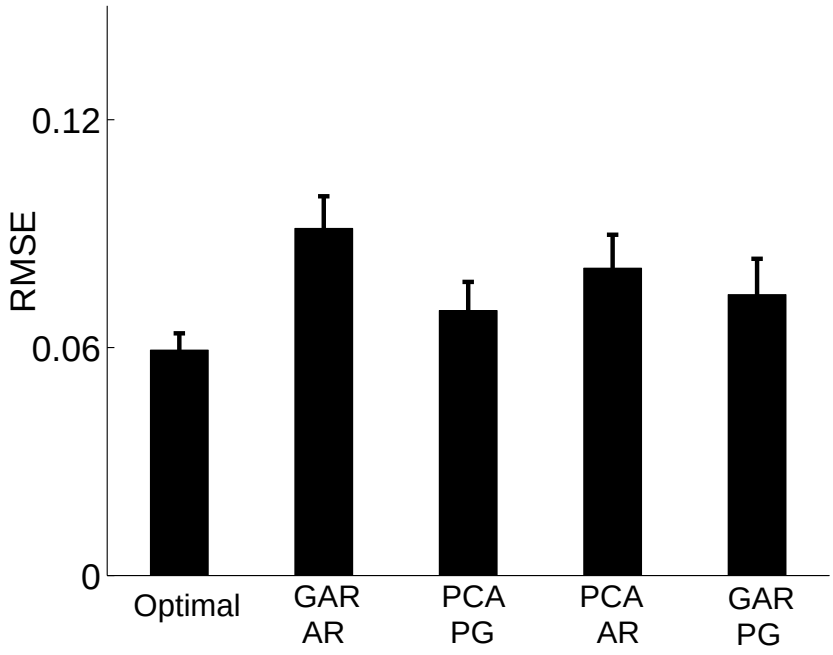

Figure 11: Results with the spring-mass system. The vertical axis shows the average RMSE on a test set with 100 tasks. The horizontal axis shows the learning system: (i) Optimal: optimal control signals; (ii) GAR+AR: GAR sequences with additive regression; (iii) PCA+PG: PCA sequences with policy gradient; (iv) PCA+AR: PCA sequences with additive regression; and (v) GAR+PG: GAR sequences with policy gradient.

7. Conclusions

In summary, the computational complexities arising in motor control can be ameliorated through the use of a library of motor synergies. We presented a new model, referred to as the Greedy Additive Regression (GAR) model, for learning a library of torque sequences, and for learning the coefficients of a linear combination of library sequences minimizing a cost function. Results using a simulated two-joint arm suggest that the GAR model consistently shows excellent performance in the sense that it rapidly learns to perform novel, complex motor tasks. Moreover, its library is overcomplete and sparse, meaning that only a small fraction of the stored torque sequences are used when learning a new movement. The library is also robust in the sense that, after an initial training period, nearly all novel movements can be learned as additive combinations of sequences in the library, and in the sense that it shows good generalization when an arm's dynamics are altered between training and test conditions, such as when a payload is added to the arm. Additionally, we showed that the GAR model works well regardless of whether motor tasks are specified in joint space or Cartesian space.

The GAR model appears to consistently outperform the PCA model, as described above. A comparison of these two models suggests why this is the case. The GAR model uses a library of local features—each sequence in its library is a solution to a single task from the training set—and a local optimization procedure, namely, additive regression. In contrast, the PCA model uses a library of global features—each item in its library reflects properties of all tasks in the training set—and policy gradient which is a global optimization procedure because it seeks good combinations of all items in its library. We conjecture that the local versus global nature of the GAR versus PCA models accounts for the performance advantages of the GAR model on nonlinear tasks. This account is consistent with other empirical findings in the machine learning literature (Friedman, 2001; Perkins, Lacker, and Theiler, 2003; Viola and Jones, 2004). Future work will need to provide a theoretical underpinning for this intuitive conjecture. The GAR and PCA models represent two ends of a local/global continuum. Future work should also study models that lie at intermediate points along this continuum, such as models that form linear combinations by adding a small number of features at each iteration, instead of the addition of a single feature as in the GAR model.

We have focused here on defining and evaluating the GAR model from a machine learning perspective. Future research will need to focus on the implications of the model for our understanding of motor control in biological organisms, the theoretical foundations of the model, and further empirical evaluations. In regard to our understanding of biological motor control, it would be interesting to know whether sets of motor synergies used by biological organisms are sparse and overcomplete as suggested by the GAR model, or are full-distributed and non-redundant as suggested by the PCA model. If they are sparse and overcomplete, then the computational advantages of the GAR model may help us understand why organisms have evolved or developed to use this type of representation. In regard to theoretical foundations, the engineering community is often reluctant to adopt new adaptive procedures for control unless these procedures have proven stability and performance guarantees. At the moment, no such guarantees exist for the GAR model. Future work will need to address these issues. In regard to empirical evaluations, future research will need to evaluate the GAR model with larger and more complex motor systems and motor tasks.

Abstract

This paper investigates statistical performances of Support Vector Machines (SVM) and considers the problem of adaptation to the margin parameter and to complexity. In particular we provide a classifier with no tuning parameter. It is a combination of SVM classifiers.

Our contribution is two-fold: (1) we propose learning rates for SVM using Sobolev spaces and build a numerically realizable aggregate that converges with same rate; (2) we present practical experiments of this method of aggregation for SVM using both Sobolev spaces and Gaussian kernels.

Keywords: classification, support vector machines, learning rates, approximation, aggregation of classifiers

1. Introduction

We consider the binary classification setting. Let $\mathcal{X} \times \{-1,1\}$ be a measurable space endowed with P an unknown probability distribution on $\mathcal{X} \times \{-1,1\}$. Let $D_n = \{(X_i,Y_i), i = 1,\dots n\}$ be n realizations of a random variable (X,Y) with law P (in the sequel we also write P_X for the marginal distribution of X). Given this training set D_n, the goal of Learning is to predict class Y of new observation X. In other words, a classification algorithm builds a decision rule from $\mathcal{X}$ to $\{-1,1\}$ or more generally a function f from $\mathcal{X}$ to $\mathbb{R}$ where the sign of $f(x)$ determines the class of an input x.

The efficiency of a classifier is measured by the *generalization error*

$$R(f) := \mathbb{P}(\text{sign}(f(X)) \neq Y),$$

where $\text{sign}(y)$ denotes the sign of $y \in \mathbb{R}$ with the convention $\text{sign}(0) = 1$. A well-known minimizer over all measurable functions of the generalization error is called the *Bayes rule*, defined by

$$f^*(x) := \text{sign}(2\eta(x) - 1)$$

where $\eta(x) := \mathbb{P}(Y = 1|X = x)$ for all $x \in \mathcal{X}$. Unfortunately, the dependence of f^* on the unknown conditional probability function η makes it uncomputable in practice.

A natural way to overcome this difficulty is to provide an empirical decision rule or classifier based on the data D_n. It has to mimic the Bayes. The way one measures the efficiency of a classifier $\hat{f}_n := \hat{f}_n(D_n)$ is via its *excess risk*:

$$R(\hat{f}_n, f^*) := R(\hat{f}_n) - R(f^*), \tag{1}$$

where here $R(\hat{f}_n) := \mathbb{P}(\text{sign}(\hat{f}_n(X)) \neq Y | D_n)$. Given P, we hence say that a classifier $\hat{f}_n$ is consistent if the expectation of (1) with respect to $P^{\otimes n}$ (the distribution of the training set) goes to zero as n goes to infinity. Finally, we can look for a way of quantifying this convergence. A classifier $\hat{f}_n$ learns with rate $(\psi_n)_{n\in\mathbb{N}}$ if there exists an absolute constant $C > 0$ such that for all integer n,

$$\mathbb{E}R(\hat{f}_n, f^*) \leq C\psi_n, \tag{2}$$

where in the sequel $\mathbb{E}$ is the expectation with respect to $P^{\otimes n}$. Of course (2) ensures consistency of $\hat{f}_n$ whenever (ψ_n) goes to zero with n.

It has been shown in Devroye (1982) that no classifier can learn with a given rate for all distributions P. However several authors propose different rates reached by restricting the class of joint distributions. Pionneering works of Vapnik (Vapnik and Chervonenkis, 1971, 1974) investigate the statistical procedure called Empirical Risk Minimization (ERM). The ERM estimator consists in searching for a classifier that minimizes the empirical risk

$$R_n(f) = \frac{1}{n}\sum_{i=1}^{n} \mathbb{1}_{\{\text{sign}(f(X_i))\neq Y_i\}}, \tag{3}$$

over a class of prediction rules $\mathcal{F}$, where $\mathbb{1}_A$ denotes the indicator function of the set A. If we suppose that the class of decision rules $\mathcal{F}$ has finite VC dimension, ERM reaches the parametric rate $n^{-\frac{1}{2}}$ in (2) when f^* belongs to the class $\mathcal{F}$. Moreover, if P is noise-free (i.e., $R(f^*) = 0$), the rate becomes n^{-1}. This is a fast rate.

More recently, Tsybakov (2004) describes intermediate situations using a margin assumption. This assumption adds a control on the behavior of the conditional probability function η at the level $\frac{1}{2}$ (see (10) below). Under this condition, Tsybakov (2004) gets minimax fast rates of convergence for classification with ERM estimators over a class $\mathcal{F}$ with controlled complexity (in terms of entropy). These rates depend on two parameters : the margin parameter and the complexity of the class of candidates f^* (see also Massart and Nédélec, 2006). Another study of the behavior of ERM is presented in Bartlett and Mendelson (2006).

It is well known, however, that minimizing (3) is computationally intractable for many non trivial classes of functions (Arora et al., 1997). It comes from the non convexity of the functional (3). It suggests that we must use a convex surrogate Φ for the loss. The main idea is to minimize an empirical Φ-risk

$$A_n^{\Phi}(f) = \frac{1}{n}\sum_{i=1}^{n} \Phi(Y_i f(X_i)),$$

over a class $\mathcal{F}$ of real-valued functions. Then $\hat{f}_n = \text{sign}(\hat{F}_n)$ where $\hat{F}_n \in \text{Arg}\min_{f\in\mathcal{F}} A_n^{\Phi}(f)$ has a small excess risk. Recently a number of methods have been proposed, such as boosting (Freund, 1995) or Support Vector Machines. The statistical consequences of choosing a convex surrogate is well treated by Zhang (2004) and Bartlett et al. (2006). In this paper it is proposed to use the hinge loss $\Phi(v) = (1-v)_+$ (where $(\cdot)_+$ denotes the positive part) as surrogate, that is, to focus on the SVM algorithm.

SVM was first proposed by Boser et al. (1992) for pattern recognition. It consists in minimizing a regularized empirical Φ-risk over a Reproducing Kernel Hilbert Space (RKHS for short in the sequel). Given a training set D_n, the SVM optimization problem without offset can be written:

$$\min_{f\in\mathcal{H}_K} \left(\frac{1}{n}\sum_{i=1}^{n} l(Y_i, f(X_i)) + \alpha_n \| f \|_K^2 \right), \tag{4}$$

where in the sequel:

1. The functional l is called the hinge loss and is now written $l(y, f(x)) = (1 - yf(x))_+$. The first term of the minimization (4) is then the empirical Φ-risk A_n^Φ for $\Phi(v) = (1-v)_+$.

2. The space $\mathcal{H}_K$ is a RKHS with reproducing kernel K. Under some mild conditions over K, it consists of continuous functions from $\mathcal{X}$ to $\mathbb{R}$ or $\mathbb{C}$ with the reproducing property:

$$\forall f \in \mathcal{H}_K, \forall x \in \mathcal{X}, f(x) = < K(x, \cdot), f >_{\mathcal{H}_K} .$$

   Recall that every positive definite kernel has an essentially unique RKHS (Aronszajn, 1950).

3. The sequence α_n is a decreasing sequence that depends on n. This smoothing parameter has to be determined explicitly. Such a problem will be studied in this work.

4. The norm $\|.\|_K$ is the norm associated to the inner product in the Hilbert space $\mathcal{H}_K$.

For a survey on this kernel method we refer to Cristianini and Shawe-Taylor (2000).

This algorithm is at the heart of many theoretical considerations. However, its good practical performances are not yet completely understood. The study of statistical consistency of the algorithm and approximation properties of kernels can be found in Steinwart (2001) or more recently in Steinwart (2005). Blanchard et al. (2006) propose a model selection point of view for SVM. Finally, several authors provide learning rates to the Bayes for SVM (Wu and Zhou, 2006; Wu et al., 2007; Steinwart and Scovel, 2007, 2005). In these papers, both approximation power of kernels and estimation results are presented. Wu and Zhou (2006) state slow rates (logarithmic with the sample size) for SVM using a Gaussian kernel with fixed width. It holds under no margin assumption for Bayes rule with a given regularity. Steinwart and Scovel (2007) give, under a margin assumption, fast rates for SVM using a decreasing width (which depends on the sample size). An additional geometric hypothesis over the joint distribution is necessary to get a control of the approximation using Gaussian kernels.

These results focus on SVM using Gaussian kernels. The goal of this work is to clarify both practical and theoretical performances of the algorithm using two different classes of kernels. In a first theoretical part, we consider a family of kernels generating Sobolev spaces as RKHS. It gives an alternative to the extensively studied Gaussian kernels. We quantify the approximation power of these kernels. It depends on the regularity of the Bayes prediction rule in terms of Besov space. Then under the margin assumption, we give learning rates of convergence for SVM using Sobolev spaces. It holds by choosing optimally the tuning parameter α_n in (4). This choice strongly depends on the regularity assumption over the Bayes and the margin assumption. As a result, it is non-adaptive. Then we turn out into more practical considerations. Following Lecué (2007a), we give a procedure to construct directly from the data a classifier with similar statistical performances. It uses a method called aggregation with exponential weights. Finally, we show practical performances of this aggregate and compare it with a similar classifier using Gaussian kernels and results of Steinwart and Scovel (2007).

The paper is organized as follows. In Section 2, we give statistical performances of SVM using Sobolev spaces. Section 3 presents the adaptive procedure of aggregation and show the performances of the data-dependent aggregate. This procedure does not damage the learning rates stated in Section 2. We show practical experiments in Section 4 and conclude in Section 5 with a discussion. Section 6 is devoted to the proofs.

2. Statistical Performances

As a regularization procedure, minimization (4) generates two types of errors: the estimation error and the approximation error. The use of a finite sample size produces the estimation error. The approximation error can be seen as the distance between the hypothesis space and the Bayes decision rule. It comes from the use of a RKHS of continuous functions in the minimization whereas the Bayes is not continuous. The first one is random and depends on the fluctuation of the training set. The second one is deterministic and depends on the size of the RKHS. We can see coarsely that these errors are antagonist. Theorem 7 gives a choice of the regularization parameter α_n that makes the trade-off between these two errors.

For the estimation error, we will state an oracle-type inequality of the form :

$$\mathbb{E}R_l(\hat{f}_n, f^*) \leq C \inf_{f \in \mathcal{H}_K} \left(R_l(f, f^*) + \alpha_n \|f\|_K^2 \right) + \varepsilon_n, \tag{5}$$

where $R_l(f, f^*) := \mathbb{E}_P l(Y, f(X)) - \mathbb{E}_P l(Y, f^*(X))$ is the excess l-risk of f. The term ε_n must be a residual term and satisfies:

$$\varepsilon_n \leq C' \inf_{f \in \mathcal{H}_K} \left(R_l(f, f^*) + \alpha_n \|f\|_K^2 \right),$$

where $C' > 0$. Inequality (5) deals with the estimation error. It depends on the complexity of the class of functions $\mathcal{H}_K$ and the difficulty of the problem.

Hence it remains to control the infimum in the right hand side (RHS for short) of (5). Steinwart and Scovel (2007) define the approximation error function as:

$$a(\alpha_n) := \inf_{f \in \mathcal{H}_K} \left(R_l(f, f^*) + \alpha_n \|f\|_K^2 \right). \tag{6}$$

This function represents the theoretical version of the empirical minimization (4). It depends on the chosen $\mathcal{H}_K$ and the behaviour of α_n as a function of n.

Using this approach, Steinwart and Scovel (2007) study the statistical performances of SVM minimization (4) with the parametric family of Gaussian kernels. For $\sigma \in \mathbb{R}$, we define the Gaussian kernel $K_\sigma(x,y) = \exp\left(-\sigma^2 \|x-y\|^2\right)$ on the closed unit ball of $\mathbb{R}^d$ (denoted $\mathcal{X}$). The parameter σ^{-1} is called the width of the Gaussian kernel. In this paper, under a margin assumption and a geometric assumption over the distribution, they state fast learning rates for SVM. These rates hold under some specific choices of tuning parameters recalled in Sect. 4. Following Lecué (2007a), we will use this result and more precisely these choices of tuning parameters to implement the aggregate using Gaussian kernels.

2.1 Sobolev Smooth Kernels

We propose to deal with other class of kernels than the Gaussian kernels. First we need to introduce some notations. Let us consider the set of complex-valued and integrable (resp. square-integrable) functions on $\mathbb{R}^d$ denoted as $L^1(\mathbb{R}^d)$ (resp. $L^2(\mathbb{R}^d)$). On this set, we define the Fourier transform of f to be:

$$\hat{f}(\omega) = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} f(t) e^{-i\omega.t} dt, \forall \omega \in \mathbb{R}^d,$$

where $x.y$ denotes the usual scalar product of $\mathbb{R}^d$ between two points $x,y \in \mathbb{R}^d$.

After the usual extension from $L^1(\mathbb{R}^d)$ to $L^2(\mathbb{R}^d)$ with Plancherel, this operator is an isometry on $L^2(\mathbb{R}^d)$. It allows us to define, for any $s \in \mathbb{R}^+$, the Sobolev space $\mathcal{W}_s^2$ (often called fractional Sobolev space) as the following subspace of $L^2(\mathbb{R}^d)$ (Malliavin, 1974):

$$\mathcal{W}_s^2 := \{ f \in L^2(\mathbb{R}^d) : \|f\|_s^2 = \int_{\mathbb{R}^d} |\hat{f}(\omega)|^2 (1+\|\omega\|^2)^s d\omega < \infty \}. \tag{7}$$

We refer to Triebel (1992) or Adams (1975) for a large study of this well-known functional space. With such a norm, $\mathcal{W}_s^2$ is a Hilbert space endowed with the inner product defined as:

$$< f,g >_s = \int_{\mathbb{R}^d} \hat{f}(\omega)\overline{\hat{g}(\omega)}(1+\|\omega\|^2)^s d\omega,$$

where $\bar{z}$ is the complex conjugate of z in $\mathbb{C}$. Moreover it is a Hilbert space of continuous functions for any $s > \frac{d}{2}$ (due to the embedding between $\mathcal{W}_s^2$ and $C(\mathbb{R}^d)$ for any $s > \frac{d}{2}$). It can be seen as a RKHS.

In this framework, a kernel is a symmetric and positive definite function $K : \mathbb{R}^d \times \mathbb{R}^d \mapsto \mathbb{C}$. For $r \in \mathbb{R}^+$, a kernel K_r will be called *Sobolev smooth kernel* with exponent $r > d$ if the associated RKHS $\mathcal{H}_{K_r}$ is such that

$$\mathcal{H}_{K_r} = \mathcal{W}_{\frac{r}{2}}^2,$$

where $\mathcal{W}_{\frac{r}{2}}^2$ is defined in (7). The restriction $r > d$ ensures that the RKHS consists of continuous functions from $\mathbb{R}^d$ to $\mathbb{C}$. Corollary 2 provides a way of constructing such a kernel.

We say that a kernel K is a *translation invariant kernel* (or RBF kernel), if for all $x,y \in \mathbb{R}^d$,

$$K(x,y) = \Phi(x-y) \tag{8}$$

for a given $\Phi : \mathbb{R}^d \mapsto \mathbb{C}$. Function Φ is often called RB function for Radial Basis function. The most popular example of translation invariant kernel is the Gaussian kernel $K_\sigma(x,y) = \exp(-\sigma^2\|x-y\|^2)$. This kernel is not a Sobolev smooth kernel (see below).

Under suitable assumptions on Φ, the following theorem gives a Fourier representation of a RKHS associated to a translation invariant kernel. The proof is given in Section 6.

Theorem 1 *Let $K : \mathbb{R}^d \times \mathbb{R}^d \mapsto \mathbb{C}$ be a translation invariant kernel where in* (8) *Φ belongs to $L^1(\mathbb{R}^d) \cap L^2(\mathbb{R}^d)$ and such that $\widehat{\Phi}$ is integrable. Then the RKHS associated to K can be written*

$$\mathcal{H}_K = \{ f \in L^2(\mathbb{R}^d) : \|f\|_K^2 = \frac{1}{(2\pi)^{d/2}} \int_S \frac{|\hat{f}(\omega)|^2}{\widehat{\Phi}(\omega)} d\omega < \infty \text{ and } \hat{f} = 0 \text{ on } \mathbb{R}^d \backslash S \}$$

with the inner product

$$< f,g >_K = \frac{1}{(2\pi)^{d/2}} \int_S \frac{\hat{f}(\omega)\overline{\hat{g}(\omega)}}{\widehat{\Phi}(\omega)} d\omega,$$

where $S := \{\omega \in \mathbb{R}^d : \widehat{\Phi}(\omega) \neq 0\}$ is the support of $\widehat{\Phi}$.

Sufficient conditions to have a Sobolev smooth kernel are:

Corollary 2 *Let K satisfying assumptions of Theorem 1. Suppose moreover that there exist constants $C, c > 0$ and a real number $s > \frac{d}{2}$ such that*

$$\widehat{\Phi}(\omega) = \frac{C}{(c + \|\omega\|^2)^s}, \forall \omega \in \mathbb{R}^d. \tag{9}$$

Then K is a Sobolev smooth kernel with exponent $r = 2s > d$.

In Section 5 we propose an example of Sobolev smooth kernel and use it into the SVM procedure.

Remark 3 (Gaussian kernels are not Sobolev smooth) *Theorem 1 can be used to define Gaussian kernels in terms of Fourier transform. Indeed, the Gaussian kernel defined above is a translation invariant kernel with RB function $\Phi(x) = \exp(-\sigma^2\|x\|^2)$. Its Fourier transform is given by*

$$\widehat{\Phi}(\omega) = \frac{1}{(\sqrt{2}\sigma)^d} \exp(-\frac{\|\omega\|^2}{4\sigma^2}).$$

Then Φ satisfies assumptions of Theorem 1. The Fourier representation of $\mathcal{H}_\sigma$ is given by:

$$\mathcal{H}_\sigma = \{ f \in L^2(\mathbb{R}^d) : \int_{\mathbb{R}^d} |\hat{f}(\omega)|^2 \sigma^d \exp(\frac{\|\omega\|^2}{4\sigma^2}) d\omega < \infty \}.$$

From definition (7)*, it is clear that $\mathcal{H}_\sigma$ is not a Sobolev space. This integral representation of a Gaussian RKHS illustrates the smoothness of functions $f \in \mathcal{H}_\sigma$. Indeed we can see trivially that $\mathcal{H}_\sigma \subset \mathcal{H}_{K_r}$ for any fixed $\sigma, r > 0$ (because the Fourier transform of Φ is rapidly decreasing in this case). Moreover the parameter σ can be seen as a regularization parameter : the fewer is σ, the smoother are the functions in $\mathcal{H}_\sigma$. More precisely, $\sigma < \sigma'$ entails $\mathcal{H}_\sigma \subset \mathcal{H}_{\sigma'}$.*

2.2 Approximation Efficiency of Sobolev Smooth Kernels

Here we are interested in approximation properties of $\mathcal{H}_{K_r}$. We aim at bounding the approximation function $a(\alpha_n)$ defined in (6) for the procedure (4). The best case appears when $f^* \in \mathcal{H}_K$. Then we get coarsely $a(\alpha_n) \leq C\alpha_n$ where C is an absolute constant. This case is not realizable considering a continuous RKHS since the Bayes classifier is not. In this paper, we get a control of the approximation function when f^* does not belong to the RKHS. Theorem 4 provides such a result using a Sobolev smooth kernel.

Theorem 4 *Consider the approximation function $a(\alpha_n)$ defined in* (6)*, with Sobolev smooth kernel K_r such that $r > 2s > 0$. Suppose P_X satisfies $\frac{dP_X}{dx} \leq C_0$.*

Then if $f^* \in \mathcal{B}^2_{s,\infty}(\mathbb{R}^d)$, we have:

$$a(\alpha_n) \leq C_0^{\frac{r-2s}{r-s}} \|f^*\|_{s2\infty}^{\frac{r}{r-s}} \alpha_n^{\frac{s}{r-s}},$$

where $\|.\|_{s2\infty}$ defines the norm in the Besov space $\mathcal{B}^2_{s,\infty}(\mathbb{R}^d)$.

The proof is detailed in Section 6 where we define explicitly Besov spaces $\mathcal{B}^2_{s,\infty}(\mathbb{R}^d)$.

Remark 5 *(*BAYES REGULARITY*) Here we get a control of the approximation function under an assumption on the smoothness of the Bayes classifier. Of course large values of s are not possible because* $f^*(x) = \text{sign}(2\eta(x)-1)$ *is not even continuous (except for the trivial case* $\eta(x) < \frac{1}{2}$ *a.s. or* $\eta(x) > \frac{1}{2}$*). More precisely, the Besov space* $\mathcal{B}^p_{s,q}(\mathbb{R}^d)$ *is included in the space of continuous functions for* $s > \frac{d}{p}$ *and* $q > 1$*. Here* $p = 2$ *then parameter s must satisfy* $s < \frac{d}{2}$ *to have* $f^* \in \mathcal{B}^2_{s,\infty}(\mathbb{R}^d)$*. In Remark 10 we give an example of Bayes rule verifying this smoothness assumption.*

Remark 6 *(*COMPARISON WITH STEINWART AND SCOVEL, 2007*) Steinwart and Scovel (2007) propose a same type of result using Gaussian kernels. Under a geometric assumption over the distribution, they get*

$$a(\alpha_n) \leq C\alpha_n^{\frac{\gamma}{\gamma+1}},$$

where γ *is the geometric noise exponent. Here we propose a same type of result under a regularity assumption over the possible* f^**. Theorem 17 in Section 6 shows that this result can be generalized to any other kernel, using interpolation spaces.*

2.3 Learning Rates

In this work, we restrict the class of considered distributions P. We add a control on the local slope of the conditional probability function η at the level $\frac{1}{2}$. This margin assumption (we often call $|\eta - \frac{1}{2}|$ the margin) is originally due to Mammen and Tsybakov (1999) for discriminant analysis. We will use throughout this paper the following formulation: we say that P has *margin parameter* $q > 0$ if there exists a constant $c_0 > 0$ such that

$$\mathbb{P}(|2\eta(X)-1| \leq t) \leq c_0 t^q, \tag{10}$$

for all sufficiently small t.

According to Boucheron et al. (2005), this hypothesis is equivalent to the low noise or margin assumption in Tsybakov (2004). Best situation for learning appears when the conditional probability makes a jump at the level $\frac{1}{2}$. Hence (10) holds true for any positive q. It corresponds to a margin parameter $q = +\infty$, that is, $\kappa = 1$ in the sense of Tsybakov (2004).

Finally, last step of modelling consists in clipping the solution of minimization (4). For any classifier $\hat{f}$, we hence define the *clipped version* $\hat{f}^C$ with values in $[-1,1]$ by

$$\hat{f}^C(x) = \begin{cases} -1 \text{ for } x : \hat{f}(x) < -1, \\ f(x) \text{ for } x : \hat{f}(x) \in [-1,1], \\ 1 \text{ for } x : \hat{f}(x) > 1. \end{cases}$$

This operation does not modify the classification property of $\hat{f}$ since $\text{sign}(\hat{f}) = \text{sign}(\hat{f}^C)$. It produces classifiers with bounded norm $\|.\|_\infty$. It appears in several works (Bartlett, 1998; Steinwart et al., 2007). We stress that the clip does not modify the algorithm. It is done after the training as a part of the theoretical study of the algorithm. We are now on time to state the main result of this section.

Theorem 7 *Let P be a distribution over $\mathbb{R}^d \times \{-1,1\}$ such that P_X satisfies $\frac{dP_X}{dx} \leq C_0$ and* (10) *holds for $q \in [0,+\infty]$. Let $s > 0$ and suppose $f^* \in \mathcal{B}^2_{s,\infty}(\mathbb{R}^d)$.*

Consider the SVM minimization (4) *with Sobolev smooth kernel K_r, with $r > 2s \vee d$, built on the i.i.d. sequence $(X_i,Y_i), i = 1 \dots n$ according to P.*

If we choose α_n such that

$$\alpha_n \sim n^{-\frac{r(r-s)(q+1)}{s(r(q+2)-d)+d(r-s)(q+1)}}, \tag{11}$$

then there exists a constant C which depends on r,s,d,c_0,q and C_0 such that

$$\mathbb{E}R(\hat{f}^C_n, f^*) \leq Cn^{-\gamma(q,s)},$$

where

$$\gamma(q,s) = \frac{rs(q+1)}{s(r(q+2)-d)+d(r-s)(q+1)}. \tag{12}$$

The proof of this theorem is given in Section 6.

Remark 8 *(*FAST RATES*) Rate* (12) *is a fast rate (i.e., faster than $n^{-\frac{1}{2}}$) if $\frac{rs(q+1)}{s(r(q+2)-d)+d(r-s)(q+1)} > \frac{1}{2}$. In particular, for $q = +\infty$, it corresponds to $s > \frac{rd}{r+d}$. The presence of fast rates depends on the regularity of the Bayes classifier. Unfortunately the behaviour of f^* (see Remark 4) entails $s < \frac{d}{2}$. As a result, $\frac{sr}{sr+d(r-s)} < \frac{1}{2}$ and fast rates can not be reached.*

Remark 9 *(*COMPARISON WITH STEINWART AND SCOVEL, 2007*) This theorem gives performances of SVM using a fixed kernel. On the contrary, according to Steinwart and Scovel (2007), the bandwidth of the kernel has to be chosen as a function of n. Nevertheless, rates of convergences are fast for sufficiently large geometric noise parameter. Here we cannot get fast rates for reasonable assumption over f^*.*

Remark 10 *(*OPTIMAL SMOOTHING PARAMETER*) Theorem 7 provides a particular choice of α_n to reach rates* (12)*. Other definitions for the sequence α_n give other rates of convergence. We only mention the best possible rates. It holds for a regularization parameter optimizing the statistical performances. Indeed, α_n in* (11) *makes the balance between the estimation error and the approximation error.*

Remark 11 (EXAMPLE) *Consider the one-dimensional case where $\mathcal{X} = \mathbb{R}$. Suppose f^* is such that:*

$$card\{x \in \mathbb{R} : f^* \text{ jumps at } x\} = N < \infty. \tag{13}$$

It means that the Bayes rule changes only a finite number of times over the real line. Using standard analysis, we get

$$\|f^*\|_{TV} = \int_{\mathbb{R}} |Df^*(x)|dx = 2N$$

where Df^* is the generalized derivative of f^*. Moreover, for any f, $|\hat{f}(\omega)| \leq \|f\|_{VT}/|\omega|$. Then f^* belongs to $\mathcal{W}_{s,2}$ only for $s < 1/2$. Finally, with basic properties of Besov spaces (Triebel, 1992), we have $\mathcal{W}_{s,2} = \mathcal{B}^2_{s,2} \subset \mathcal{B}^2_{s,\infty}$.

Consequently, f^* verifying (13) *belongs to $\mathcal{B}^2_{s,\infty}$ for any $s < \frac{1}{2}$. If we consider a margin parameter $q = +\infty$, we hence cannot reach the rate of convergence*

$$n^{-\frac{r}{3r-1}}$$

which corresponds to a regularity $s = \frac{1}{2}$ in the Besov space. Then the SVM using Sobolev smooth kernel H_{K_r} with $r > 1$ cannot learn with fast rate in this simple case.

3. Aggregation

Theorem 7 provides the optimal value of α_n to reach rates of convergence (12) in the context of Sobolev spaces. It holds under two ad-hoc assumptions: a margin assumption over the distribution and a regularity assumption over the Bayes rule. Hence the choice of the smoothing parameter depends on two unknown parameters: the margin parameter q and the exponent s in the Besov space. Consequently the classifier $\hat{f}_n$ of Theorem 7 cannot be constructed from the data. It is called non-adaptive.

The goal of this section is to overcome this difficulty. We propose a classifier that adapts automatically both to the margin and to regularity. In other words, we will build a decision rule from D_n which does not depend on the unknown parameters s and q. Moreover, Theorem 12 shows that this procedure of adaptation will not damage the learning rates of Theorem 7.

We use a technique called aggregation (Nemirovski, 1998; Yang, 2000). We apply the method presented in Lecué (2007a) to our framework of Sobolev smooth kernel. It consists of splitting the data into two parts : the first part in used to construct a family of classifiers. The second part is used to make a convex combination of these classifiers. We obtain an adaptive decision rule which mimics the best one over the family. Let us first describe the method.

Denote $D^1_{n_1}$ (resp. $D^2_{n_2}$) the first subsample of size n_1 (resp. second subsample of size n_2) with $n_1 + n_2 = n$. The choice of n_1 and n_2 will be discussed later. We construct a set of classifiers $(\hat{f}^{\alpha}_{n_1})_{\alpha \in \mathcal{G}(n_2)}$ defined by $\hat{f}^{\alpha}_{n_1} = sign\left(\hat{F}^{\alpha}_{n_1}\right)$ where

$$\hat{F}^{\alpha}_{n_1} := \arg\min_{f \in \mathcal{H}_{K_r}} \left(\frac{1}{n_1} \sum_{i=1}^{n_1} l(Y_i, f(X_i)) + \alpha \| f \|^2_K \right).$$

The grid $\mathcal{G}(n_2)$ is defined by

$$\mathcal{G}(n_2) := \left\{ \alpha_k = n_2^{-\phi_k} : \phi_k = \frac{1}{2} + k\Delta^{-1}, k = 0, \ldots, \lfloor \frac{(2r-d)\Delta}{2d} \rfloor \right\},$$

with $\Delta = n_2^b$ for some $b > 0$. We hence have $\left\lfloor \frac{(2r-d)\Delta}{2d} \right\rfloor + 1$ classifiers to aggregate.

The procedure of aggregation uses the second subsample $D^2_{n_2}$ to construct a convex combination with exponential weights. Namely, the aggregate $\tilde{f}_n$ is defined by

$$\tilde{f}_n = \sum_{\alpha \in \mathcal{G}(n_2)} \omega^{(n)}_{\alpha} \hat{f}^{\alpha}_{n_1}, \tag{14}$$

where

$$\omega^{(n)}_{\alpha} = \frac{\exp\left(\sum_{i=n_1+1}^{n} Y_i \hat{f}^{\alpha}_{n_1}(X_i)\right)}{\sum_{\alpha' \in \mathcal{G}(n_2)} \exp\left(\sum_{i=n_1+1}^{n} Y_i \hat{f}^{\alpha'}_{n_1}(X_i)\right)}.$$

We hence have the following result.

Theorem 12 *Consider the classifier $\tilde{f}_n$ defined in* (14) *where $n_2 = \lceil a\frac{n}{\log n} \rceil$ for $a > 0$. Let K a compact of $(0,\infty)^2$. Then there exists a constant C which depends on r,d,c_0,K,a,b,L and C_0 such that for all $(q,s) \in K$*

$$\sup_{P \in Q_{q,s}} \mathbb{E}R(\tilde{f}_n, f^*) \leq Cn^{-\gamma(q,s)},$$

where

$$\gamma(q,s) = \frac{rs(q+1)}{s(r(q+2)-d)+d(r-s)(q+1)}$$

and $Q_{q,s}$ is the set of distributions P satisfying $\frac{dP_X}{dx} < C_0$, (10) *with parameter q and such that $f^* \in \mathcal{B}^2_{s,\infty}(\mathbb{R}^d, L) = \{f \in \mathcal{B}^2_{s,\infty}(\mathbb{R}^d) : \|f\| \leq L\}$.*

Remark 13 *Same rates as in Theorem 7 are attained. Here we deal with an implementable classifier. In Section 5 we sum up practical performances of this aggregate.*

Remark 14 *Instead of aggregating a power of n classifiers, only $\log n$ classifiers are enough to obtain this result. Lecué (2007b) states an oracle inequality such as* (22) *without any restriction on the number of estimators to aggregate.*

Remark 15 *(*AVERAGE OF AGGREGATES*) This method supposes, for a given n_1 and n_2, an arbitrary choice for the subsample $D^1_{n_1}$ and $D^2_{n_2}$. However we can use different splits of the training set. We get an average of aggregates, namely*

$$\overline{f}_n = \frac{1}{M}\sum_{k=1}^{M} \tilde{f}_n^k.$$

It does not depend on a particular split. Each $\tilde{f}_n^k$ is defined in (14) *for the split number k. With (Lecué, 2007a, Theorem 2.4), this average satisfies the oracle inequality* (22)*. Then Theorem 12 holds for $\overline{f}_n$ for any family of M splits, for $M \leq C_n^{n_1}$.*

4. Practical Experiments

We now propose experiments illustrating performances of the aggregate of Section 3. We study SVM classifiers using both Sobolev spaces and Gaussian kernels. The aggregates were implemented in **R** using the free library *kernlab*. It contains implementations of support vector machines. For a description of this package for kernel-based learning methods in **R**, we refer to Karatzoglou et al. (2007). We use real world data sets from benchmark repository[1] used by Rätsch et al. (1998). We consider 9 data sets called "Banana", "Titanic", "Thyroid", "Diabetes", "Breast-Cancer", "Flare-solar", "Heart", "Image" and "Waveform". These data sets are explained in Table 1. For each data set, we have several realizations of training and test set. The dimension of the input space is denoted by d whereas the number of observations for the training set is n. It follows the notations used in the previous sections. On each realization, we train and test our classifiers. The results presented in Table 2,3,4 show the average test errors over these realizations and the standard deviations.

1. Data sets are available online at this address http://ida.first.fraunhofer.de/projects/bench/benchmarks.htm.

Table 1: Description of the data sets

4.1 SVM Using Sobolev Smooth Kernel

The first step is to pick up a Sobolev smooth kernel. Consider the following class of RBF kernels, with Radial Basis function Φ:

$$K(x,y) = \Phi(x-y) = \exp\left(-\sigma\|x-y\|\right), \forall \sigma \in \mathbb{R}. \tag{15}$$

For a given σ, this kernel is called a Laplacian kernel. It is clear that $\Phi \in L^1(\mathbb{R}^d) \cap L^2(\mathbb{R}^d)$. Recall the Fourier transform of $\Phi : \mathbb{R}^d \mapsto \mathbb{R}$ (see Williamson et al., 2001):

$$\widehat{\Phi}(\omega) = 2^{\frac{d}{2}} \pi^{-\frac{1}{2}} \Gamma(\frac{d}{2}+1) \frac{\sigma}{(\sigma^2 + \|\omega\|^2)^{\frac{d+1}{2}}}, \forall \omega \in \mathbb{R}^d,$$

where $\Gamma(x) = \int_{\mathbb{R}^+} e^{-t} t^{x-1} dt$ is the Gamma function.

With Corollary 2, for any fixed σ, the Laplacian kernel defined in (15) is a Sobolev smooth kernel with exponent $r = d+1$. It satisfies assumptions of Theorem 7 and can be used in the implementation of the algorithm.

It is worth noticing that the parameter σ is constant. If we take a significantly small value for σ, as $\sigma = n^{-u}$, $u > 0$, (9) holds for C and c depending on n. Thus Corollary 2 does not hold. To avoid this problem, we choose in our aggregation step using this class of kernels a constant $\sigma = 5$. In the sequel the Laplacian kernel used is precisely $K(x,y) = \exp(-5\|x-y\|)$.

Table 2 shows the first experiments. For each realization of training set, we use previous section to build

- the set of classifiers $(\hat{f}_{n_1}^{\alpha})$ for α belonging to $\mathcal{G}(n_2)$;
- exponential weights $\omega_{\alpha}^{(n)}$ to deduce aggregate $\tilde{f}_n$.

Recall the definition of $\mathcal{G}(n_2)$ in this case:

$$\mathcal{G}(n_2) := \left\{ \alpha_k = n_2^{-\phi_k} : \phi_k = \frac{1}{2} + k\Delta^{-1}, k = 0, \ldots, \lfloor \frac{(2r-d)\Delta}{2d} \rfloor \right\},$$

where $\Delta = n_2^b$. We take $b = 1$ in the construction. Instead of a step $\Delta = n_2^b$, it is possible to take only $\Delta = \log n_2$ (see Remark 14) . The value of b governs the size of the grid. The cardinal is

given in Table 2 for each data set. Note that growing b does not improve significantly the performances whereas it adds computing time. Indeed, whatever b, $\mathcal{G}(n_2)$ is contained in this case into $[n_2^{-\frac{d+1}{d}}, n_2^{-\frac{1}{2}}]$. This location is motivated by Theorem 7, namely equation (11).The value of b only deals with the distance between each point of $\mathcal{G}(n_2)$. It does not change the location of the grid.

Table 2 relates the average test errors and the standard deviations. We first collect the performances of the family of weak estimators $(\hat{f}_{n_1}^{\alpha}), \alpha \in \mathcal{G}(n_2)$. We mention in order the performances of the worst estimator, the mean over the family and the best over the family. It gives an idea of the estimators to aggregate. Then the performances of the aggregate using exponential weights are given in the last column.

Data Set	card$\mathcal{G}(n_2)$	max	mean	min	Laplace Aggregate

Waveform	56	14.51±0.70	14.16±0.67	13.78±0.65	14.12±0.72

Table 2: Performances using Laplacian kernel

Note that the amplitude in the family is not very important. It may be explain by its construction. Indeed, $\mathcal{G}(n_2)$ is motivated by Theorem 7, which gives the location of the grid (see above). This family has a mathematical justification. The test errors of the aggregate are located between the average over the family and the oracle of the family.

A temperature parameter usually appears in aggregation methods. It governs the variations of values $\omega_{\alpha}^{(n)}$, for $\alpha \in \mathcal{G}(n_2)$. In Table 2 the weak classifiers have almost the same performances. This could explain why no temperature parameter is needed here.

4.2 SVM Using Gaussian Kernels

Here we focus on the parametric class of Gaussian kernels $K_\sigma(x,y) = \exp\left(-\sigma^2\|x-y\|^2\right)$, for $\sigma \in \mathbb{R}$. We build an aggregate made of a convex combination of Gaussian SVM classifiers. In this case, the construction is not exactly the same. It comes from Steinwart and Scovel (2007). In this paper, they introduce a geometric noise assumption. This hypothesis deals with the concentration of the measure $|2\eta - 1|P_X$ near the decision boundary. It allows to control the approximation function (6). According to Steinwart and Scovel (2007), suppose that the probability distribution P has a geometric noise $\gamma > 0$ and assumption (10) holds with margin parameter $q > 0$. Then if we choose

$$\alpha_n = \begin{cases} n^{-\frac{\gamma+1}{2\gamma+1}} \text{ if } \gamma \leq \frac{q+2}{2q}, \\ n^{-\frac{2(\gamma+1)(q+1)}{2\gamma(q+2)+3q+4}}, \text{ otherwise} \end{cases}$$

the solution of (4) using a Gaussian kernel K_σ with $\sigma = \alpha_n^{-\frac{1}{(\gamma+1)d}}$ learns with rates

$$\begin{cases} n^{-\frac{\gamma}{2\gamma+1}+\varepsilon} \text{ if } \gamma \leq \frac{q+2}{2q}, \\ n^{-\frac{2\gamma(q+1)}{2\gamma(q+2)+3q+4}+\varepsilon} \text{ otherwise,} \end{cases}$$

for all $\varepsilon > 0$.

We can see that the variance of the Gaussian kernels is not fixed. It has to be chosen as a function of the geometric noise exponent. As a result, parameter σ must be considered in the aggregation procedure, as the smoothing parameter α. It gives a two-dimensional grid of Gaussian SVM of the following form (Lecué, 2007a):

$$\mathcal{N}(n_2) = \left\{ (\sigma_{n_2,\phi}, \alpha_{n_2,\psi}) = (n_2^{\phi/d}, n_2^{-\psi}) : (\phi,\psi) \in \mathcal{M}(n_2) \right\}$$

where

$$\mathcal{M}(n_2) = \left\{ (\phi_{n_2,p_1}, \psi_{n_2,p_2}) = \left(\frac{p_1}{2\Delta}, \frac{p_2}{\Delta} + \frac{1}{2} \right) : p_1 = 1,\dots,2\lfloor\Delta\rfloor; p_2 = 1,\dots,\lfloor\Delta/2\rfloor \right\},$$

for $\Delta = n_2^b$. Thus we have more classifiers to aggregate and needs more time to run. As a consequence, we choose constant $b = 0.5$ in our experiments. Such as the Sobolev case, the number of classifiers to aggregate is mentioned in Table 3 for each data set.

Table 3 relates the generalization performances of the classifiers over the test samples. We first give the performances of the family of Gaussian SVM (namely the worst, the mean and the oracle over the family). The performances of the aggregate using exponential weights are given in the last column.

Data Set	card$\mathcal{N}(n_2)$	max	mean	min	gaussian aggregate

Table 3: Performances using Gaussian kernels

In this case the generalization errors in the family are more disparate. It comes from a two-dimensional grid of parameters. The performances of the Gaussian aggregate, as above, are located between the average of weak estimators and the best among the family.

4.3 Comparison With Rätsch et al. (1998)

Table 4 combines the performances of the aggregates using Laplacian kernel and Gaussian kernels. The errors are comparable. Gaussian kernels and Laplacian kernel lead to similar performances. Then we mention the generalization errors of Rätsch et al. (1998).

Rätsch et al. (1998) proposes generalizations of the original Adaboost algorithm. However, extensive simulations are presented like experimental results for SVM using Gaussian kernels. The choice of the parameters (α_n, σ) are done by 5-fold-cross validation thanks to several training data sets. This approach has not any mathematical justification. Moreover their mathematical programming problems are distributed over 30 computers. We only use last column to have an idea of reasonable average test errors for these data sets.

Data Set	Laplace Aggregate	Gaussian Aggregate	Rätsch et al. (1998)

Waveform	14.12±0.72	15.04±0.79	9.88±0.83

Table 4: Comparison with Rätsch et al. (1998).

Table 4 illustrates good resistance of our aggregates when the dimension is not too large. Nevertheless, in the last columns, our estimators fail. This may have a theoretical explanation. In Theorem 7 and 12, a constant C appears in the upper bounds. This constant in front of the rates of convergence depends on the dimension of the input space. Increasing d grows this constant C and may affect the performances. Moreover, the choice of the parameters in Rätsch et al. (1998) are done with several training sets. In our approach, for each realization of a training set, we construct an adaptive classifier using n observations. The amount of information used is not the same. It may also explain this difference.

5. Conclusion

This paper gives some insights into SVM algorithm, from both theoretical and practical point of view. We have tackled several important questions such as its statistical performances, the role of the kernel and the choice of the tuning parameters.

The first part of the paper focuses on the statistical performances of the method. In this study, we consider Sobolev smooth kernels as an alternative to the Gaussian kernels. It allows us to bring out a functional class of Bayes rule (namely Besov spaces $\mathcal{B}^2_{s,\infty}$) ensuring good approximation properties for our hypothesis space. Explicit rates of convergence have been given depending on the margin and the regularity (Theorem 7). Nevertheless, this result was non-adaptive.

Then it has been necessary to consider the problem of adaptation. The aggregation method appeared suitable in this context to construct directly from the data a competitive decision rule: it has the same statistical performances as the non-adaptive classifier (Theorem 12). In this procedure, we use explicitly the theoretical part to choose the scale of tuning parameters. For completeness, we have finally implemented the method and gave practical performances over real benchmark data sets. These practical experiments are to be considered as preliminary. However it shows similar

performances for SVM using Gaussian or non-Gaussian kernel. Moreover it illustrates rather well the importance of constructing a classifier with some mathematical background.

6. Proofs

This section contains proofs of the results presented in this paper.

6.1 Proof of Theorem 1 and Corollary 2

We consider a translation invariant kernel $K : \mathbb{R}^d \times \mathbb{R}^d \mapsto \mathbb{C}$ with RB function Φ satisfying assumptions of Theorem 1. The following lemma will be useful.

Lemma 16 *For any $y \in \mathbb{R}^d$, consider the function $k_y : x \mapsto K(x,y)$ defined in $\mathbb{R}^d$. Then we have the following statements:*

1. $k_y(x) = \overline{\hat{g}_y(x)}$ *where* $g_y(\omega) = e^{i\omega.y}\widehat{\Phi}(\omega)$.
2. $\hat{k}_y(\omega) = e^{-i\omega.y}\widehat{\Phi}(\omega)$.

Proof

1. $\Phi \in L^2(\mathbb{R}^d)$ hence the inverse Fourier formula allows us to write :

$$\begin{aligned} k_y(x) = \Phi(x-y) &= \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{i\omega.(x-y)} \widehat{\Phi}(\omega) d\omega \\ &= \frac{1}{(2\pi)^{d/2}} \overline{\int_{\mathbb{R}^d} e^{-i\omega.x} e^{i\omega.y} \widehat{\Phi}(\omega) d\omega} \\ &= \frac{1}{(2\pi)^{d/2}} \overline{\int_{\mathbb{R}^d} e^{-i\omega.x} g_y(\omega) d\omega}. \end{aligned}$$

2. Now using 1. one gets

$$\hat{k}_y(\omega) = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-i\omega.x} k_y(x) dx = \frac{1}{(2\pi)^{d/2}} \overline{\int_{\mathbb{R}^d} e^{i\omega.x} \hat{g}_y(x) dx}.$$

Gathering with the inverse Fourier transform of $g_y \in L^2(\mathbb{R}^d)$, we have

$$\hat{k}_y(\omega) = \overline{g_y(\omega)} = e^{-i\omega.y}\widehat{\Phi}(\omega).$$

■

Proof (of Theorem 1)

We write

$$\mathcal{H}_0 = \{ f \in L^2(\mathbb{R}^d) : \int_S \frac{|\hat{f}(\omega)|^2}{\widehat{\Phi}(\omega)} d\omega < \infty \text{ and } \hat{f} = 0 \text{ on } S \},$$

with the corresponding norm

$$\|f\|_{\mathcal{H}_0} := \sqrt{\frac{1}{(2\pi)^{d/2}} \int_S \frac{|\hat{f}(\omega)|^2}{\widehat{\Phi}(\omega)} d\omega}.$$

We will show that $\mathcal{H}_0$ coincides with $\mathcal{H}_K$.

For a given $y \in \mathbb{R}^d$, from Lemma 16 it is clear that $\hat{k}_y(\omega) = 0$ for $\omega \in \mathbb{R}^d \backslash S$. Moreover using again Lemma 16:

$$\int_S \frac{|\hat{k}_y(\omega)|^2}{\widehat{\Phi}(\omega)} d\omega = \int_S \widehat{\Phi}(\omega) d\omega < \infty$$

since $\widehat{\Phi}$ is integrable. Then $k_y \in \mathcal{H}_0$ for any $y \in \mathbb{R}^d$. Now we have to establish that $\mathcal{H}_0$ is a Hilbert space. Following Matache and Matache (2002), we can show that, for any $f \in \mathcal{H}_0$:

$$\|\hat{f}\|_1 \leq \sqrt{(2\pi)^{d/2} \|\widehat{\Phi}\|_1} \|f\|_{\mathcal{H}_0} \text{ and } \|\hat{f}\|_2 \leq \sqrt{(2\pi)^{d/2} \|\Phi\|_1} \|f\|_{\mathcal{H}_0},$$

where $\|\cdot\|_1$ and $\|\cdot\|_2$ denote the norms in $L^1(\mathbb{R}^d)$ and $L^2(\mathbb{R}^d)$.

Indeed, by Cauchy-Schwarz,

$$\int_{\mathbb{R}^d} |\hat{f}(\omega)| d\omega \leq \sqrt{\frac{1}{(2\pi)^{d/2}} \int_S \frac{|\hat{f}(\omega)|^2}{\widehat{\Phi}(\omega)} d\omega} \sqrt{(2\pi)^{d/2} \int_S \widehat{\Phi}(\omega) d\omega}.$$

Moreover, since $\|\widehat{\Phi}\|_\infty \leq \|\Phi\|_1$,

$$\int_{\mathbb{R}^d} |\hat{f}(\omega)|^2 d\omega \leq \|\Phi\|_1 \int_S \frac{|\hat{f}(\omega|^2}{\widehat{\Phi}(\omega)} d\omega.$$

Then considering a Cauchy sequence $(f_n)_{n\in\mathbb{N}}$ in $\mathcal{H}_0$ endowed with $\|\cdot\|_{\mathcal{H}_0}$, $(\hat{f}_n)_{n\in\mathbb{N}}$ will be a Cauchy sequence in both $L^1(\mathbb{R}^d)$ and $L^2(\mathbb{R}^d)$. We conclude with Matache and Matache (2002) that $(f_n)_n$ is convergent in $\mathcal{H}_0$. Then $\mathcal{H}_0$ is complete and becomes a Hilbert space endowed with the following inner product:

$$< f, g >_{\mathcal{H}_0} = \frac{1}{(2\pi)^{d/2}} \int_S \frac{\hat{f}(\omega)\overline{\hat{g}(\omega)}}{\widehat{\Phi}(\omega)} d\omega.$$

Finally reproducing property holds. Indeed let $f \in \mathcal{H}_0$. Using again Lemma 16 :

$$f(x) = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{i\omega.x} \hat{f}(\omega) d\omega = \frac{1}{(2\pi)^{d/2}} \int_S \frac{\hat{f}(\omega)}{\widehat{\Phi}(\omega)} \overline{\hat{k}_x(\omega)} d\omega = < f, k_x >_{\mathcal{H}_0} .$$

We have already shown that $\forall x \in \mathbb{R}^d$, $k_x \in \mathcal{H}_0$. As a result, the unicity of the RKHS for a given kernel concludes the proof. ■

Proof (of Corollary 2)

First we have trivially that $\widehat{\Phi}$ is integrable since $s > \frac{1}{2}$. We can hence apply Theorem 1 to have

$$\mathcal{H}_K = \{ f \in L^2(\mathbb{R}^d) : \int_{\mathbb{R}^d} |\hat{f}(\omega)|^2 (c + \|\omega\|^2)^s d\omega < \infty \},$$

since the support of $\widehat{\Phi}$ is $\mathbb{R}^d$. This expression of the RKHS associated to K corresponds, up to a constant, to the Sobolev space $\mathcal{W}_s^2$ defined in (7). Then K is a Sobolev smooth kernel with exponent $r = 2s$. ■

6.2 Proof of Theorem 4

First introduce the notion of interpolation space (Bennett and Sharpley, 1988). We restrict ourselves to a description of the real interpolation method. Let $(B, \|.\|_B)$ be a Banach space and $\mathcal{H}$ a Hilbert space dense in B. The Peetre's functional for the couple $(B, \mathcal{H})$ is defined by, for $t > 0$,

$$P(f, t, B, \mathcal{H}) := \inf \left\{ \|f_0\|_B + t \|f_1\|_{\mathcal{H}}, f = f_0 + f_1 \text{ such that } f_0 \in B, f_1 \in \mathcal{H} \right\}.$$

For fixed $t > 0$, the functional P defines a norm in the Banach space B. It is therefore a simple way to define the interpolation space between B and $\mathcal{H}$ entirely in terms of this functional. Given $\theta \in]0,1[$ and $q \in [0, \infty]$, the space $(B, \mathcal{H})_{\theta,q}$ called *interpolation space between B and* $\mathcal{H}$ consists of all $f \in B$ such that

$$\|f\|_{\theta,q} := \begin{cases} \left(\int_0^{+\infty} t^{-\theta q} P(f, t, B, \mathcal{H})^q \frac{dt}{t} \right)^{\frac{1}{q}} \text{ if } q < \infty, \\ \sup_{t>0} \left\{ t^{-\theta} P(f, t, B, \mathcal{H}) \right\} \text{ if } q = \infty \end{cases}$$

is finite.

Here we are interested in the case $q = \infty$ and the following geometric explanation of interpolation space (Smale and Zhou, 2003, Theorem 3.1):

$$f \in (B, \mathcal{H})_{\theta,\infty} \Longrightarrow \inf_{g \in B_{\mathcal{H}}(R)} \|f - g\|_B \leq \|f\|_{\theta,\infty}^{\frac{1}{1-\theta}} \left(\frac{1}{R} \right)^{\frac{\theta}{1-\theta}}, \tag{16}$$

where $B_{\mathcal{H}}(R) := \left\{ f \in \mathcal{H} : \|f\|_{\mathcal{H}} \leq R \right\}$. Hence the interpolation space between $\mathcal{B}$ and $\mathcal{H}$ satisfies $\mathcal{H} \subset (\mathcal{B}, \mathcal{H})_{\theta,\infty} \subset \mathcal{B}$. To be more precise it consists of functions located at a polynomial decreasing distance in $\mathcal{B}$ from a ball in $\mathcal{H}$ of radius R as a function of R. It would be useful to control the approximation error function in our framework.

Theorem 17 *Consider $a(\alpha_n)$ defined in* (6). *Suppose the marginal of X is such that $\frac{dP_X}{dx} \leq C_0$. Then if $f^* \in (L^2(\mathbb{R}^d), \mathcal{H}_K)_{\theta,\infty}$ we have:*

$$a(\alpha_n) \leq \|f^*\|_{\theta,\infty}^{\frac{2}{2-\theta}} \alpha_n^{\frac{\theta}{2-\theta}}.$$

Proof By the lipschitz property of the hinge loss, we have clearly since $\frac{dP_X}{dx} \leq C_0$:

$$\begin{aligned} a(\alpha_n) &\leq \inf_{f \in \mathcal{H}_K} \left(\|f - f^*\|_{L^1(P_X)} + \alpha_n \|f\|_K^2 \right) \\ &\leq \inf_{R>0} \left(C_0 \inf_{f \in B_{\mathcal{H}_K}(R)} \|f - f^*\|_{L^2(\mathbb{R}^d)} + \alpha_n R^2 \right). \end{aligned}$$

Now from (16), it follows that if $f^* \in (L^2(\mathbb{R}^d), \mathcal{H}_K)_{\theta,\infty}$,

$$a(\alpha_n) \leq \inf_{R>0} \left(\|f^*\|_{\theta,\infty}^{\frac{1}{1-\theta}} \left(\frac{1}{R}\right)^{\frac{\theta}{1-\theta}} + \alpha_n R^2 \right).$$

Optimizing with respect to R leads to the conclusion. ■

Let introduce Besov spaces $\mathcal{B}^p_{s,q}(\mathbb{R}^d)$. A Besov space is a collection of functions with common smoothness, in terms of modulus of continuity. This is a large class of functional spaces, including in particular the Sobolev spaces defined in (7) ($\mathcal{W}^2_s = \mathcal{B}^2_{s,2}(\mathbb{R}^d)$ for any $s>0$) and the Hölder spaces ($H^s = \mathcal{B}^s_{\infty,\infty}(\mathbb{R}^d)$ for any $s>0$). For a large study, we refer to Triebel (1992).

Here we restrict ourselves to the spaces $\mathcal{B}^2_{s,\infty}(\mathbb{R}^d)$. For any $h \in \mathbb{R}^d$, we write I for the identity operator, T_h for the translation operator ($T_h(f,x) = f(x+h)$) and $\Delta_h^r := (T_h - I)^r$ for the difference operator. The modulus of continuity of order r of a function $f \in L^2(\mathbb{R}^d)$ is then

$$\omega_r(f,t)_2 = \sup_{|h|\leq t} \|\Delta_h^r(f)\|_{L^2(\mathbb{R}^d)}.$$

Then the Besov space $\mathcal{B}^2_{s,\infty}(\mathbb{R}^d)$ consists of all functions f such that the semi-norm

$$\|f\|_{s,\infty} = \sup_{t>0} t^{-s}\omega_r(f,t)_2$$

is finite.

If we add $\|f\|_{L^2(\mathbb{R}^d)}$ to this semi-norm, we obtain the usual norm of $\mathcal{B}^2_{s,\infty}(\mathbb{R}^d)$.

Lemma 18 *Let $s>0$ and $0<\theta<1$. Then,*

$$(L^2(\mathbb{R}^d), \mathcal{W}^2_s)_{\theta,\infty} = \mathcal{B}^2_{\theta s,\infty}(\mathbb{R}^d).$$

A proof is presented by Triebel (1978) in a more general framework.

Proof (of Theorem 4)

From the definition of Sobolev smooth kernels, we have $\mathcal{H}_{K_r} = \mathcal{W}^2_{\frac{r}{2}}$. Hence we obtain with Lemma 18:

$$(L^2(\mathbb{R}^d), \mathcal{H}_{K_r})_{\theta,\infty} = \mathcal{B}^2_{\frac{\theta r}{2},\infty}(\mathbb{R}^d).$$

Applying Theorem 17 with $\theta = \frac{2s}{r}$, this ends up the proof since P_X satisfies $\frac{dP_X}{dx} < C_0$. ■

6.3 Proof of Theorem 7

In order to control the generalization error, we have to state an inequality such as (5). We propose to use a stochastic oracle inequality from Steinwart et al. (2007). This result takes place under a margin assumption of the type (10) and a complexity assumption over the used RKHS.

We define the covering numbers of a subset A of a Banach space (E,d) as :

$$\mathcal{N}(A,\varepsilon,E) = \min\{n \geq 1 : \exists x_1, \dots x_n \in E \text{ such that } A \subset \cup_{i=1}^n B_d(x_i,\varepsilon)\}.$$

Furthermore, given a realization $T = \{(x_1, y_1), \dots (x_n, y_n)\}$ of the training set, we denote by $L^2(T_X)$ the space of all equivalence classes of functions $f : \mathcal{X} \mapsto \mathbb{R}$ such that the norm

$$\|f\|_{L^2(T_X)} := \left(\frac{1}{n} \sum_{i=1}^{n} f(x_i)^2 \right)^{1/2} \tag{17}$$

is finite. Then we can consider the behaviour of $\log \mathcal{N}(B_{\mathcal{H}_K}, \varepsilon, L^2(T_X))$ as a complexity measure for the used RKHS.

Proposition 19 (Steinwart and Scovel, 2007) *Let P be a distribution on $\mathcal{X} \times \{-1, 1\}$ and $\mathcal{H}_K$ a RKHS of continuous functions on $\mathcal{X}$. Suppose*

1. *There exists $q \in [0, +\infty]$ and $c_0 > 0$ such that*

$$\mathbb{P}(|2\eta(X) - 1| \leq t) \leq c_0 t^q, , \forall t > 0.$$

2. *There exist $a \geq 1, 0 < p < 1$ such that*

$$\sup_{T \in (\mathcal{X} \times \mathcal{Y})^n} \log \mathcal{N}\left(B_{\mathcal{H}_K}, \varepsilon, L^2(T_X)\right) \leq a \varepsilon^{-2p}, \forall \varepsilon > 0. \tag{18}$$

Then there exist constants $c \geq 1$, $\kappa, \kappa', \kappa'' > 0$ such that for all $x \geq 1$, the clipped version $\hat{f}_n^C$ of SVM classifier $\hat{f}_n$ satisfies, with probability larger than $1 - e^{-x}$,

$$\begin{aligned} R_l(\hat{f}_n^C, f^*) &\leq c \inf_{f \in \mathcal{H}_K} \left(\mathbb{E}_P (l(f) - l(f^*)) + \alpha_n \|f\|_K^2 \right) + \frac{\kappa}{n \alpha_n^p} \\ &+ \left(\frac{\kappa}{n \alpha_n^p} \right)^{\frac{q+1}{q+2-p}} + \frac{\kappa'}{n^{\frac{q+1}{q+2}}} + \frac{\kappa'' x}{n}. \end{aligned}$$

Proof (of Theorem 7)

The hinge loss $l(y, f(x)) = (1 - y f(x))_+$ satisfies, for all classifier $\hat{f}$ (Zhang, 2004):

$$R(\hat{f}, f^*) \leq R_l(\hat{f}, f^*). \tag{19}$$

Therefore, to control the excess risk of a classifier, it is sufficient to control the RHS of (19).

We apply Proposition 19 for the stochastic part and Theorem 4 for the approximation part of the analysis.

Recall a standard result for covering numbers of Sobolev spaces (Chen et al., 2004):

$$\log \mathcal{N}(B_{\mathcal{W}_r^2}, \varepsilon, C(\mathbb{R}^d)) \leq a \varepsilon^{-\frac{d}{r}}, \tag{20}$$

where constant $a := a(d)$. From (17) we have $\|f\|_{L^2(T_X)} \leq \|f\|_\infty$ for any $f \in C(\mathbb{R}^d)$, $T \in (\mathcal{X} \times \mathcal{Y})^n$. Then (20) holds true for $\log \mathcal{N}(B_{\mathcal{W}_r^2}, \varepsilon, L^2(T_X))$ uniformly over $T \in (\mathcal{X} \times \mathcal{Y})^n$. Gathering with $\mathcal{H}_{K_r} = \mathcal{W}_{r/2}^2$, the RKHS $\mathcal{H}_{K_r}$ satisfies (18) of Proposition 19 with $p = \frac{d}{r}$. Applying Proposition 19, there exist $c \geq 1$, $\kappa, \kappa', \kappa'' > 0$ such that, for all $x \geq 1$, with probability larger than $1 - e^{-x}$,

$$\begin{aligned} R_l(\hat{f}_n^C, f^*) &\leq c \inf_{f \in \mathcal{H}_K} \left(R_l(f, f^*) + \alpha_n \|f\|_K^2 \right) + \frac{\kappa}{n \alpha_n^{\frac{d}{r}}} \\ &+ \left(\frac{\kappa}{n \alpha_n^{\frac{d}{r}}} \right)^{\frac{q+1}{q+2-d/r}} + \frac{\kappa'}{n^{\frac{q+1}{q+2}}} + \frac{\kappa'' x}{n}. \end{aligned}$$

Since $f^* \in \mathcal{B}^2_{s,\infty}(\mathbb{R}^d)$, we get from Theorem 4 that with probability larger than $1-e^{-x}$,

$$R_l(\hat{f}_n^C, f^*) \leq cC_0^{\frac{r}{r-s}} \|f^*\|_{s,\infty}^{\frac{r}{r-s}} \alpha_n^{\frac{s}{r-s}} + \frac{\kappa}{n\alpha_n^{\frac{d}{r}}} + \left(\frac{\kappa}{n\alpha_n^{\frac{d}{r}}}\right)^{\frac{q+1}{q+2-d/r}} + \frac{\kappa'}{n\alpha_n^{\frac{d}{r}}} + \frac{\kappa'' x}{n}.$$

The choice of α_n in (11) optimizes the RHS. Integrating with respect to the training set, one leads to the conclusion. ■

6.4 Proof of Theorem 12

To prove Theorem 12, we use a general oracle inequality for aggregation. Let us first recall the general context of aggregation.

Suppose we have $M \geq 2$ differents classifiers $f_1, \ldots, f_M$ with values in $\{-1,1\}$. The method of aggregation consists in building a new classifier $\tilde{f}_n$ from D_n called aggregate which mimics the best among $f_1, \ldots f_M$. Our procedure is using exponential weights of the following form:

$$\omega_j^{(n)} = \frac{\exp\left(\sum_{i=1}^n Y_i f_j(X_i)\right)}{\sum_{k\in\{1\ldots M\}} \exp\left(\sum_{i=1}^n Y_i f_k(X_i)\right)}.$$

Then we define the following aggregate:

$$\tilde{f}_n = \sum_{j=1}^M \omega_j^{(n)} f_j. \tag{21}$$

Under the margin assumption (10), we have this oracle inequality:

Theorem 20 (Lecué, 2005) *Suppose* (10) *holds for some $q \in (0,+\infty)$. Assume we have at least a polynomial number of classifiers to aggregate (i.e., there exist $a \geq 1$, $b > 0$ such that $M \geq an^b$). Then the aggregate defined in* (21) *satisfies, for all integer $n \geq 1$,*

$$\mathbb{E}R(\tilde{f}_n, f^*) \leq (1+2\log^{-1/4} M)\left(2\min_{k\in\{1,\ldots M\}} R(f_k, f^*) + Cn^{-\frac{q+1}{q+2}} \log^{7/4} M\right), \tag{22}$$

where C depends on a, b and the constant c_0 appearing in (10)*.*

Proof (of Theorem 12)

Let $(q_0, s_0) \in K$ and consider $0 < q_{min} < q_{max} < +\infty$ and $0 < s_{min} < s_{max} < +\infty$ such that $K \subset [q_{min}, q_{max}] \times [s_{min}, s_{max}]$. We consider the function

$$\Phi(q,s) = \frac{r(r-s)(q+1)}{s(r(q+2)-d) + (r-s)(q+1)d}$$

defined on $[0,+\infty[\times[0,+\infty[$ with value on $[\frac{1}{2}, \frac{r}{d}]$. We denote by

$$k_0 \in \left\{0, \ldots, \left\lfloor \frac{(2r-d)\Delta}{2d} \right\rfloor - 1\right\}$$

the integer such that

$$\frac{1}{2}+k_0\Delta^{-1}\leq\Phi(q_0,s_0)\leq\frac{1}{2}+(k_0+1)\Delta^{-1}.$$

Since $q\mapsto\Phi(q,s)$ continuously increases on $\mathbb{R}^+$, for n greater than a constant depending on b, r, d and K, there exists $\overline{q}_0\in\left[\frac{q_{min}}{2},q_{max}\right]$ such that $\overline{q}_0\leq q_0$ and

$$\Phi(\overline{q}_0,s_0)=\frac{1}{2}+k_0\Delta^{-1}. \tag{23}$$

Now we can apply Theorem 20 for $\overline{q}_0$. Since $\Delta=n_2^b$, putting $M=\left\lfloor\frac{(2r-d)\Delta}{2d}\right\rfloor$ we have the following oracle inequality:

$$\mathbb{E}_{P^{\otimes n_2}}\left(R(\tilde{f}_n,f^*)|D_{n_1}^1\right)\leq(1+2\log^{-\frac{1}{4}}M)\left(2\min_{\alpha\in\mathcal{G}(n_2)}\left(R(\hat{f}_{n_1}^{\alpha},f^*)\right)+C_1n_2^{-\frac{\overline{q}_0+1}{\overline{q}_0+2}}\log^{7/4}M\right),$$

where C_1 depends on c_0, K and b. Hence we have, integrating with respect to $D_{n_1}^1$,

$$\mathbb{E}\left(R(\tilde{f}_n,f^*)\right)\leq C_2\left(\mathbb{E}R(\hat{f}_{n_1}^{\alpha_{k_0}},f^*)+n_2^{-\frac{\overline{q}_0+1}{\overline{q}_0+2}}\log^{7/4}n_2\right),$$

where $\alpha_{k_0}=m^{-\phi_{k_0}}=n_2^{-\Phi(\overline{q}_0,s_0)}$ with (23) and C_2 depends on K,b,r,d and c_0. Therefore we can apply Theorem 7 to the classifier $\hat{f}_{n_1}^{\alpha_k}$:

$$\mathbb{E}_{P^{\otimes n_1}}R(\hat{f}_{n_1}^{\alpha_{k_0}},f^*)\leq Cn_1^{-\frac{s_0}{r-s_0}\Phi(\overline{q}_0,s_0)},$$

where C depends on r,d and K. Remark that C does not depend on $\overline{q}_0$ and s_0 since $(\overline{q}_0,s_0)\in\left[\frac{q_{min}}{2},q_{max}\right]\times[s_{min},s_{max}]$. Moreover C is uniformly bounded over (q,s) belonging to a compact in Theorem 7.

Finally suppose P satisfies (10) for q_0. Hence we obtain:

$$\begin{aligned}\mathbb{E}\left(R(\tilde{f}_n,f^*)\right)&\leq C_3\left(n_1^{-\frac{s_0}{r-s_0}\Phi(\overline{q}_0,s_0)}+n_2^{-\frac{\overline{q}_0+1}{\overline{q}_0+2}}\log^{\frac{7}{4}}n_2\right)\\&\leq C_3\left(n^{-\frac{s_0}{r-s_0}\Phi(\overline{q}_0,s_0)}+n^{-\frac{\overline{q}_0+1}{\overline{q}_0+2}}\log^{\frac{11}{4}}n\right)\\&\leq C_3'n^{-\frac{s_0}{r-s_0}\Phi(\overline{q}_0,s_0)}.\end{aligned}$$

for $C_3:=C_3(K,b,c_0,r,C_0,d)$. We have $n\geq n_2\geq\frac{an}{\log n}$ and $n_1\geq n(\frac{2}{3}-\frac{a}{\log 3})$. Then for n greater than a constant depending on β_{min}, a, and b, there exists $C_3':=C_3'(K,b,c_0,r,C_0,d)$ such that

The construction of $\overline{q}_0$ and restrictions on r entail $\frac{s_0}{r-s_0}|\Phi(\overline{q}_0,s_0)-\Phi(q_0,s_0)|\leq\Delta^{-1}=n_2^{-b}$. We lead to the conclusion since the sequence $(n^{n_2^{-b}})_{n\in\mathbb{N}}$ is convergent. ■

Abstract

Existing template-independent web data extraction approaches adopt highly ineffective decoupled strategies—attempting to do data record detection and attribute labeling in two separate phases. In this paper, we propose an integrated web data extraction paradigm with hierarchical models. The proposed model is called Dynamic Hierarchical Markov Random Fields (DHMRFs). DHMRFs take structural uncertainty into consideration and define a joint distribution of both model structure and class labels. The joint distribution is an exponential family distribution. As a conditional model, DHMRFs relax the independence assumption as made in directed models. Since exact inference is intractable, a variational method is developed to learn the model's parameters and to find the MAP model structure and label assignments. We apply DHMRFs to a real-world web data extraction task. Experimental results show that: (1) integrated web data extraction models can achieve significant improvements on both record detection and attribute labeling compared to decoupled models; (2) in diverse web data extraction DHMRFs can potentially address the blocky artifact issue which is suffered by fixed-structured hierarchical models.

Keywords: conditional random fields, dynamic hierarchical Markov random fields, integrated web data extraction, statistical hierarchical modeling, blocky artifact issue

1. Introduction

The World Wide Web is a vast and rapidly growing repository of information. There are various kinds of objects, such as products, people, and conferences, embedded in webpages. Extracting object information is key to object-level search engines like *Libra* (http://libra.msra.cn/) and

Rexa (http://rexa.info). Recent work has shown that *template-independent* approaches to extracting meta-data for the same type of real-world objects are feasible and promising. However, existing approaches use highly ineffective decoupled strategies—attempting to do data record detection and attribute labeling in two separate phases. This paper is to first propose an integrated web data extraction paradigm with hierarchical Markov Random Fields, and then address the blocky artifact issue (Irving et al., 1997) with Dynamic Hierarchical Markov Random Fields.

A Motivating Example: we begin by illustrating the problem with an example, drawn from an actual application of product information extraction under our Windows Live Product Search project (http://products.live.com). The goal is to extract meta-data about real-world products from every product page on the Web. Specifically, for crawled webpages, we first use a classifier to select product pages and then extract the *Name*, *Image*, *Price*, and *Description* of each product from the identified product pages. Our statistical study on 51K randomly crawled webpages shows that about 12.6 percent are product pages. That is, there are about 1 billion product pages within a search index containing 9 billion crawled webpages. If only half of them are correctly extracted, we will have a huge collection of meta-data about real-world products that could be used for further knowledge discovery and data management tasks, such as comparison shopping and user intention detection.

However, how to extract product information from webpages generated by many (maybe tens of thousands of) different templates is non-trivial. One possible solution is that we first distinguish webpages generated by different templates, and then build an extractor for each template; this type of solution is *template-dependent*. Template-dependent methods are impractical for two reasons. First, accurately identifying webpages for each template is a far from trivial task because even webpages from the same website may be generated by dozens of templates. Second, even if we can distinguish webpages, the learning and maintenance of so many different extractors for different templates will require substantial efforts.

Fortunately, recent work (Lerman et al., 2004; Zhai and Liu, 2005; Zhu et al., 2005) has shown the feasibility and promise of *template-independent* meta-data extraction for the same type of objects. We can simply combine the existing techniques to build a template-independent extractor for product pages. Specifically, two types of webpages—*list pages* and *detail pages*[1]—are needed to be treated by existing extraction methods. List pages are webpages containing several structured data records, and detail pages are webpages only containing detailed information about a single object. Figure 1 illustrates these two types of pages. For list pages, we can first use the methods by Zhai and Liu (2005) Lerman et al. (2004) to detect data records and then use the model by Zhu et al. (2005) to label the data elements within the detected records. Similarly, for detail pages we can first use the methods by Song et al. (2004) to identify a main data block of a detail page, and then use the same model from Zhu et al. (2005) to do attribute labeling for the elements in the main block.

However, it is highly ineffective to use decoupled strategies—attempting to do data record detection and attribute labeling in two separate phases. The reasons for this are:

Error Propagation: as record detection and attribute labeling are two separate phases, the errors in record detection will be propagated to attribute labeling. Thus, the overall performance is limited and upper-bounded by that of record detection.

Lack of Semantics in Record Detection: human readers always take into account semantics of the text to understand webpages. For instance, in Figure 1(a), when claiming a block is a data record, we use the evidence that it contains a product's name, image, price, and description. Thus,

1. Our empirical study shows that about 0.35 of product pages are list pages and the rest are detail pages.

(a) A list page with two data records. The first record contains 7 elements and the second contains 8 elements.

(b) A detail page contains one product item.

Figure 1: A sample list page and a detail page.

more effective record detection algorithms should take into account the semantic labels of the text, but existing methods (Zhai and Liu, 2005; Lerman et al., 2004) do not consider them.

Lack of Mutual Interactions in Attribute Labeling: data records in the same page are strongly correlated. They always have a similar layout and the elements at the same position of different records always have similar features and semantic labels. For example, in Figure 1(a) the element on the top-left of each record is an image. Existing methods (Zhu et al., 2005) do not achieve these correlations because data records are labeled independently.

First-Order Markov Assumption: for webpages, especially detail pages, long-distance dependencies always exist between different attribute elements. This is because there are always many irrelevant elements or noise elements appearing between the attributes. For example, in Figure 1(b) there are several noise elements, such as "Add to Cart" and "Select Quantity", appearing between the price and description. However, plat models like 2D CRFs (Zhu et al., 2005) cannot incorporate long-distance dependencies because of their first-order Markov assumption.

To address the above problems, the first part of this paper is to propose an integrated web data extraction paradigm. Specifically, we take a vision-tree representation of webpages and define both record detection and attribute labeling as assigning semantic labels to the nodes on the trees. Then, we can define the integrated web data extraction that performs record detection and attribute labeling simultaneously. Based on the tree representation, we define a simple integrated web data extraction model—Hierarchical Conditional Random Fields (HCRFs), whose structures are determined by vision-trees.

However, for HCRFs, their structures may not be the most appropriate for web data extraction. This is because when constructing the vision-tree of each webpage, it is unaware of semantic labels. Thus, they cannot resolve all ambiguities. This will lead to those cases in which some closely related nodes may be separated significantly and only connected through a remote ancestor node on the tree. Due to the model's local Markov assumption, it will lose some useful dependencies and result in low accuracy. An extreme case is that the attributes of different objects are intertwined. Figure 2 shows an example where the two neighboring records on the webpage have their attributes intertwined on the corresponding tree. In this case, fixed-structured hierarchical models are incapable of reorganizing them correctly. This problem has been generally known as blocky artifact issue in image processing (Irving et al., 1997).

Thus, effective web data extraction models should have the capability to adapt their structures during the inference process. The second part of this paper is to generalize Hierarchical Conditional Random Fields to incorporate structural uncertainty. The general model is called Dynamic Hierarchical Markov Random Fields (DHMRFs). DHMRFs consist of two parts—structure model and class label model. Both parts are jointly defined as an exponential family distribution. Compared to the directed Dynamic Trees (Williams and Adams, 1999) which have been proposed in image processing to address the blocky artifact issue, our model representation is compact and parameter sharing is easy. This is because conditional probability tables (CPTs) are used in Dynamic Trees to represent transition from parent nodes to child nodes. If different CPTs are used for different nodes, it will easily lead to over-parameterization. Thus, layer-wise CPT sharing is always adopted. But in the scenario of web data, sharing CPTs can be difficult because the hierarchical structures are not as regular as the dyadic or quad trees in image processing. Here, different pages can have quite different depths, and nodes from different pages at the same depth can have very diverse semantics. In contrast, DHMRFs define probability distributions via a set of feature functions and weights. These feature functions depend much more on observations and their labels than on the depths of the nodes. Thus, the undirected model is more suitable for diverse web data extraction. Furthermore, as a conditional model (Lafferty et al., 2001), DHMRFs relax the conditional independence assumption among observations as made in directed models. Finally, instead of trees in which only parent-child dependencies are assumed, DHMRFs consider the triple-wise interactions among neighboring sibling variables and their parent. These triple-wise dependencies provide more flexibility in encoding useful features.

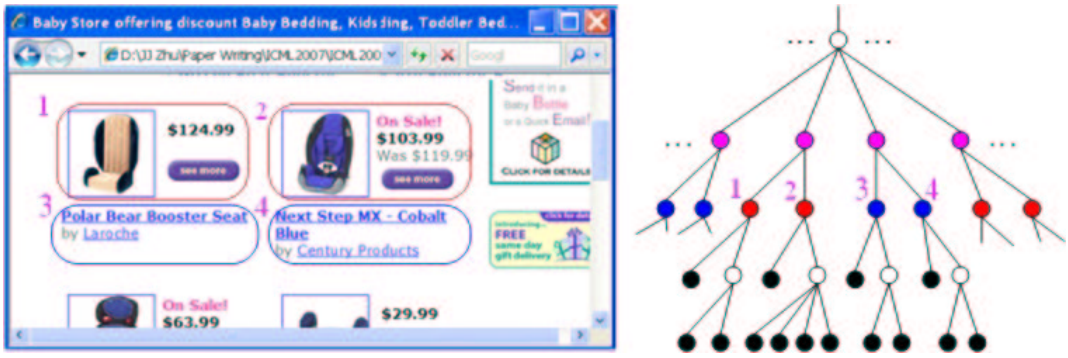

Figure 2: An intertwined example webpage. Blocks 1 and 3 present information of one product and blocks 2 and 4 present information of another product. But on the right tree, the information is not correctly grouped.

In undirected dynamic models, parameter estimation is generally intractable, especially when there are hidden variables—both structures and inner variables are hidden in our study. We develop a variational algorithm within the paradigm of contrastive divergence mean field learning (Welling and Hinton, 2001) to do parameter estimation and to find the MAP assignment of labels and the most likely model structures. The performance of our models is demonstrated on a web data extraction task—production information extraction. The results show that: (1) integrated web data extraction models can significantly improve the performance of both record detection and attribute labeling compared to decoupled methods; (2) Dynamic Hierarchical Markov Random Fields can (partially) avoid the blocky artifact issue and achieve high extraction accuracy without tedious manual labeling of inner nodes, which is required in the learning of the fixed-structured models; (3) integrated extraction models can generalize well to unseen templates. Note that the model is general and could be applied to other fields. We leave further examinations as future work.

The rest of the paper is organized as follows. In the next section, we discuss some background knowledge on which this work is based. Section 3 presents an integrated web data extraction paradigm and fixed-structured Hierarchical Conditional Random Fields. Section 4 describes Dynamic Hierarchical Markov Random Fields, including an approximate inference algorithm. Section 5 describes implementation details and experimental setup on the task of product information extraction. Section 6 and 7 presents evaluation results. Section 8 brings this paper to a conclusion and some future research directions are discussed. Finally, we give our acknowledgements.

2. Preliminary Background Knowledge

The background knowledge, on which the following work is based, is from web data extraction and statistical hierarchical modeling. We introduce these two fields in turn.

2.1 Web Data Extraction

Web data extraction is an information extraction (IE) task that identifies information of interest from webpages. The difference of web data extraction from traditional IE is that various types of

structural dependencies between HTML elements exist. For example, the HTML tag tree is itself hierarchical and each webpage is displayed as a two-dimensional image to readers. Leveraging the two-dimensional spatial information to extract web data has been studied (Zhu et al., 2005; Gatterbauer et al., 2007). This paper is to explore both hierarchical and two-dimensional spatial information for more effective web data extraction.

Wrapper learning approaches (Muslea et al., 2001; Kushmerick, 2000) are template-dependent. They take in some manually labeled webpages and learn some extraction rules (or wrappers). Since the learned wrappers can only be used to extract data from similar pages, maintaining the wrappers as web sites change will require substantial efforts. Furthermore, in wrapper learning users must provide explicit information about each template. So it will be expensive to train a system that extracts data from many web sites. The methods by Embley et al. (1999), Buttler et al. (2001), Chang and Lui (2001), Crescenzi et al. (2001) and Arasu and Garcia-Molina (2003) are also template-dependent, but they do not need labeled training data. They produce wrappers from a collection of similar webpages.

The methods by Zhai and Liu (2005), Lerman et al. (2004) and Gatterbauer et al. (2007) are template-independent. In work by Lerman et al. (2004), data on list pages are segmented using the information from their detail pages. The need of detail pages is a limitation because automatically identifying links that point to detail pages is non-trivial and there are also many pages that do not have detail pages behind them. Zhai and Liu (2005) proposed to detect data records using string matching and also some visual features to achieve better performance, but no semantics are considered. Like the work by Zhu et al. (2005), a general 2D visual model was proposed by Gatterbauer et al. (2007) to extract web tables. The data extracted by the methods of Zhai and Liu (2005), Lerman et al. (2004) and Gatterbauer et al. (2007) have no semantic labels. Our work (Zhu et al., 2005) is complementary to this and assigns semantic labels to the extracted data.

2.2 Statistical Hierarchical Modeling

Multi-scale or hierarchical statistical modeling has shown great promise in image labeling (Kato et al., 1993; Li et al., 2000; He et al., 2004; Kumar and Hebert, 2005) and human activity recognition (Liao et al., 2005). Based on whether data are observed at multiple scales, two scenarios exist in which hierarchical modeling is appropriate. First, data are observed at different spatial scales and a model is used to integrate information from the different scales. Second, data are observed only at the finest scale and a model is used to induce a particular process at that scale. The introduced intermediate processes or variables can incorporate more complex dependencies to help the target labeling. Another merit of hierarchical models is that they admit more efficient inference algorithms compared to flat models (Willsky, 2002).

Traditional hierarchical models always assume that model structures are fixed or can be constructed via some deterministic methods, such as sub-sampling of images (Li et al., 2000) and the minimum spanning tree algorithm (Quattoni et al., 2004) with a proper definition of distance. However, in many applications this assumption may not hold. For example, fixed models in image processing often lead to the blocky artifact issue, and the similar problem arises in web data extraction due to the diversity of web data. To address this problem some enhanced models have been proposed, such as the overlapping tree approach (Irving et al., 1997). Superior performance is achieved with the improvement of the descriptive component of the model. However, ultimate solutions should deal with the source of the blockiness—fixed model structures. Based on this intu-

ition, Dynamic Trees (Williams and Adams, 1999) have been proposed, which also consist of two parts—model of structures and model of class labels. However, the difference between DHMRFs and Dynamic Trees is that DHMRFs are defined as exponential family distributions and thus admit several advantages as discussed in the introduction.

Incorporating evidence at various scales was examined in a generative manner by Todorovic and Nechyba (2005). But our model is discriminative and it can relax the independence assumption among evidence as made in generative models. This is the key idea underlying Conditional Random Fields (Lafferty et al., 2001), which have shown great promise in information extraction (Culotta et al., 2006; Zhu et al., 2005). Modeling structural uncertainty has also been studied in relational learning (Getoor et al., 2001). Here, we focus on modeling the structural uncertainty within independently and identically distributed samples.

Finally, the work has partially appeared in the conference papers Zhu et al. (2006) and Zhu et al. (2007b).

3. Integrated Web Data Extraction

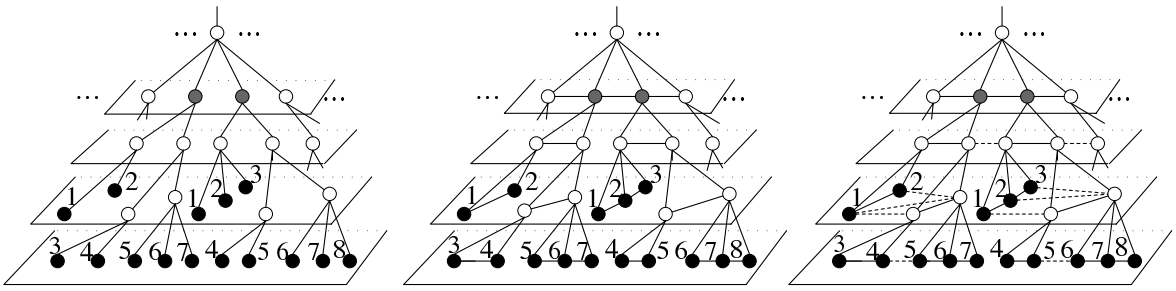
In this section, we formally define the integrated web data extraction and also propose Hierarchical Conditional Random Fields (HCRFs) to perform that task.

3.1 Vision-Tree Representation

For web data extraction, the first thing is to find a good representation format for webpages. Good representation can make the extraction task easier and improve extraction accuracy. In most previous work, tag-tree, which is a natural representation of the tag structure, is commonly used to represent a webpage. However, as Cai et al. (2004) pointed out, tag-trees tend to reveal presentation structure rather than content structure, and are often not accurate enough to discriminate different semantic portions in a webpage. Moreover, since authors use different styles to compose webpages, tag-trees are often complex and diverse. To overcome these difficulties, Cai et al. (2004) proposed a vision-based page segmentation (VIPS) approach. VIPS makes use of page layout features such as font, color, and size to construct a vision-tree for a page. It first extracts all suitable nodes from the tag-tree and then finds separators between these nodes. Here, separators denote horizontal or vertical lines in a webpage that visually do not cross any node. Based on these separators, the vision-tree of the webpage is constructed. Each node on this tree represents a data region in the webpage, which is called a block. The root block represents the whole page. Each inner block is the aggregation of all its child blocks. All leaf blocks are atomic units (i.e., elements) and form a flat segmentation of the webpage. Since vision-tree can effectively keep related content together while separating semantically different blocks from one another, we use it as our data representation format. Figure 3(a) is a vision-tree for the page in Figure 1(a), where empty circles denote inner blocks and filled circles denote leaf blocks (elements). For simplicity, we only show a sub-tree which contains the two data records in Figure 1(a). A detailed example was provided by Cai et al. (2004).

3.2 Record Detection and Attribute Labeling

Based on the definition of vision-tree, we now formally define the concepts of record detection and attribute labeling.



(a) (b) (c)

Figure 3: (a) Partial vision-tree of the webpage in Figure 1(a); (b) An HCRF model with linear-chain neighborhood between sibling nodes; (c) Another HCRF model with 2D neighborhood between sibling nodes and between nodes that share a grand-parent. Here, filled circles denote leaf blocks (elements) and the variables associated with them. Each filled circle corresponds to an element in the page in Figure 1(a) with the same number. Empty circles represent inner nodes and inner variables. The two gray nodes in each chart denote the roots of the sub-trees that correspond to the two data records in Figure 1(a).

Definition 3.1 (Record detection): Given a vision-tree, record detection is the task of locating the root of a minimal subtree that contains the content of a record. For a list page containing multiple records, all the records need to be identified.

For instance, for the vision-tree in Figure 3(a), the two blocks in gray are detected as data records. Note that as shown in Figure 2, given a particular vision-tree, we are not guaranteed to find the root nodes that correspond to data records. This is the very problem to be addressed by Dynamic Hierarchical Markov Random Fields.

Definition 3.2 (Attribute labeling): For each identified record, attribute labeling is the task of assigning attribute labels to the leaf blocks (elements) within the record.

We can build a complete model to extract both records and attributes by sequentially combining existing record detection and attribute labeling algorithms. However, as we have stated, this decoupled strategy is highly ineffective. Therefore, we propose an integrated approach that conducts simultaneous record extraction and attribute labeling.

3.3 Integrated Web Data Extraction

Based on the above definitions, both record detection and attribute labeling are the task of assigning labels to blocks of the vision-tree for a webpage. Therefore, we can define one probabilistic model to deal with both tasks. Formally, we define the integrated web data extraction as:

Definition 3.3 (Integrated Web Data Extraction): Given a vision-tree of a page, let $\mathrm{x} = \{x_0, x_1, \ldots, x_N\}$ be the features of all the blocks and each component x_i is a feature vector of one block, and let $\mathrm{y} = \{y_0, y_1, \ldots, y_N\}$ be one possible label assignment of the corresponding blocks. The goal of web data extraction is to find a label assignment $\mathrm{y}^\star$ that has the maximum posterior probability $\mathrm{y}^\star = \arg\max_{\mathrm{y}} p(\mathrm{y}|\mathrm{x})$, and extract data from this assignment.

3.4 Hierarchical Conditional Random Fields

In this section, we first introduce some basics of Conditional Random Fields and then propose Hierarchical Conditional Random Fields for integrated web data extraction.

3.4.1 CONDITIONAL RANDOM FIELDS

Conditional Random Fields (CRFs) (Lafferty et al., 2001) are Markov Random Fields that are globally conditioned on observations. Let $G = (V,E)$ be an undirected model over a set of random variables X and Y. X are variables over the observations to be labeled and Y are variables over the corresponding labels. The random variables Y could have a non-trivial structure, such as a linear-chain (Lafferty et al., 2001) and a 2D grid (Zhu et al., 2005). Each component Y_i has a label space or the set of possible labels $\mathcal{Y}_i$. The conditional distribution of the labels y (an instance of Y) given the observations x (an instance of X) has the form

$$p(\mathrm{y}|\mathrm{x}) = \frac{1}{Z(x)} \prod_{c \in \mathcal{C}} \phi(\mathrm{y}|_c, \mathrm{x}),$$

where $\mathcal{C}$ is the set of cliques in G; $\mathrm{y}|_c$ are the components of y associated with the clique c; ϕ is a potential function taking non-negative real values; $Z(\mathrm{x}) = \sum_{\mathrm{y}} \prod_{c \in \mathcal{C}} \phi(\mathrm{y}|_c, \mathrm{x})$ is the normalization factor or partition function in physics. The potential functions are usually expressed in terms of feature functions $f_k(\mathrm{y}|_c, \mathrm{x})$ and their weights λ_k:

$$\phi(\mathrm{y}|_c, \mathrm{x}) = \exp\Big\{ \sum_k \lambda_k f_k(\mathrm{y}|_c, \mathrm{x}) \Big\}.$$

Although functions f_k can take any real value, here we assume they are boolean and take either true or false.

3.4.2 HIERARCHICAL CONDITIONAL RANDOM FIELDS

Based on the vision-tree representation of the data, a Hierarchical Conditional Random Field (HCRF) model can be easily constructed. For the page in Figure 1(a) and its corresponding tree in Figure 3(a), an HCRF model is shown in Figure 3(b), where we also use empty circles to denote inner nodes and use filled circles to denote leaf nodes. For simplicity, only part of the model graph is presented. Each node on the graph is associated with a random variable Y_i. We will use nodes and variables exchangeably when there is no ambiguity. The observations that are globally conditioned on are omitted from this graph for simplicity. To make the model simple, we assume that the inner-layer interactions among sibling variables are sequential, that is, sibling variables are put into a sequence and only the relationships between neighboring variables are considered. Here, we use the position information and sequentialize the elements from left to right, top to bottom. For easy explanation and implementation, we assume that every inner node contains at least two children. Otherwise, we replace the parent with its single child. This assumption has no affect on the performance because the parent is identical to its child in this case.

The cliques of the graph in Figure 3(b) are its vertices, edges, and triangles. Let L be the number of layers indexed from 0 to $L-1$ starting from the root, and each layer $d (0 \le d < L)$ has N_d nodes. Let s_{il} be an indicator variable to denote the connectivity between node i and node l, where l is at the direct above layer of i. Let n_{ij} be an indicator variable to denote whether node i and node j are

adjacent to each other at the same layer. Then, $T = \cup_{d=1}^{L-1}\{(i,j,l) : 0 \le i,j < N_d, 0 \le l < N_{d-1}, n_{ij} = 1, s_{il} = 1, and\ s_{jl} = 1\}$ is the set of triangles in the graph G. Thus, $\mathcal{C} = V \cup E \cup T$ and the conditional probability is

$$p(\mathrm{y}|\mathrm{x}) = \frac{1}{Z(x)} \exp\Big\{ \sum_{v\in V}\sum_{k} \mu_k g_k(\mathrm{y}|_v, \mathrm{x}) + \sum_{e\in E}\sum_{k} \lambda_k f_k(\mathrm{y}|_e, \mathrm{x}) + \sum_{t\in T}\sum_{k} \gamma_k h_k(\mathrm{y}|_t, \mathrm{x}) \Big\}.$$

Note that we use the same notation Z to denote the normalization factor for both CRFs and HCRFs, although they are different. We will follow this notation when there is no ambiguity in the rest of the paper.

Figure 3(c) presents another slightly more complicated HCRF model. In this model, we consider the two-dimensional inner-layer dependency relationships between sibling nodes. Moreover, we also consider the two-dimensional interactions between nodes that share a common grant-parent on the tree. In Figure 3(c), dotted edges are introduced to encode additional dependencies compared to the model in Figure 3(b). The conditional probability $p(\mathrm{y}|\mathrm{x})$ is the same as that of the previous model but with the dotted edges included in E.

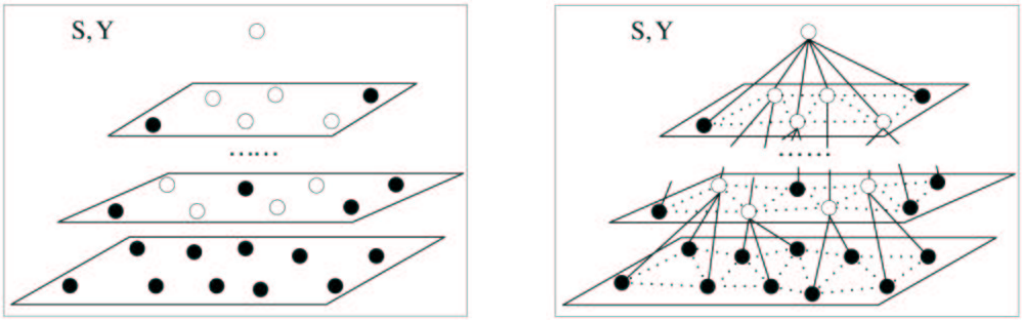
For the model in Figure 3(b), the graph is a chordal graph and its inference can be exactly and efficiently done with the junction tree algorithm (Cowell et al., 1999). In fact, the complexity of the junction tree algorithm is linear in terms of the number of maximum cliques (or triangles), which can be shown to be equivalent to the number of leaf nodes (or elements). For the model in Figure 3(c), however, no exact inference algorithm exists; we have to turn to approximate algorithms. Since the backbone (without dotted edges) of the model graph is the same as the previous model, whose inference can be exactly done, piecewise learning (Sutton and McCallum, 2005) should be a good method. The basic idea of piecewise learning is to partition the graph into a set of disjointed small pieces. For each piece, exact inference can be efficiently done. Then, a lower bound of the log-likelihood function can be derived as the combination of the local log-likelihoods on different pieces. To use piecewise learning, here, we take the backbone as one piece and take each additional edge (a dotted edge) as one piece. The method by Wainwright et al. (2002) could be another excellent approximate algorithm in our model. Unlike piecewise learning whose parameter estimation is still a maximization problem, the parameter estimation by Wainwright et al. (2002) becomes a constrained saddle point problem.

4. Dynamic Hierarchical Markov Random Fields

In this section, we present the detailed description of Dynamic Hierarchical Markov Random Fields. An approximate inference algorithm is developed to perform parameter estimation and to find the maximum a posterior model structure and label assignment.

4.1 Model Description

Suppose we are given a set of N vertices, and each vertex is associated with a set of observations. Also suppose the vertices are arranged in a layered manner. Then, hierarchical statistical modeling is a task to construct an appropriate hierarchical model structure and carry out inference about the labels of given observations. Determining the number of layers and the number of nodes at each layer is problem specific. We will give an example of web data extraction in the experiment section. Let S be random variables over hierarchical structures, X be variables over the observations to be labeled, and Y be variables over the corresponding labels. Each component Y_i is assumed to take



(a) (b)

Figure 4: (a) The initial setting of DHMRFs with a set of nodes that are arranged in multi-layers. Filled circles denote leaf nodes or elements and empty circles denote inner blocks of a webpage; (b) An instance of DHMRFs denoted by S and Y. Vertical edges are selected by posterior probabilities $p(\mathrm{s}|\mathrm{x})$. Dotted lines represent the 2D neighborhood system between nodes at the same layer.

values from a finite discrete label space $\mathcal{Y}_i$. Here, capitalized characters denote random variables and corresponding lower cases are their instances or configurations, for example, y is a label assignment and $y_i \in \mathcal{Y}_i$ is one component label. A state of the system is the pairing of a model structure and a label assignment, that is, (s,y). Given observations x, Dynamic Hierarchical Markov Random Fields (DHMRFs) define a conditional probability distribution $p(\mathrm{s},\mathrm{y}|\mathrm{x})$ of structure s and label assignment y. An example is shown in Figure 4, where the left graph is the initial setting of DHMRFs with a set of nodes that are arranged in multi-layers and the right is an instance of the dynamic model. Let the energy of the system being at the state (s,y) be $E(\mathrm{s},\mathrm{y},\mathrm{x})$, then the probability of the system being at this state is

$$p(\mathrm{s},\mathrm{y}|\mathrm{x}) = \frac{1}{Z(\mathrm{x})}\exp\{-E(\mathrm{s},\mathrm{y},\mathrm{x})\}.$$

This is a Boltzmann distribution with the temperature $T = 1$, and our model is one type of exponential random graph model (Robins et al., 2006). Since the system consists of two parts, the energy is also from two parts. We explain them as follows:

Structure Model: Let s_{il} be an indicator variable to denote the connectivity between node i and another node l, which is at the direct above level. s_{il} equals to 1 if node i connects to node l; otherwise it is 0. Here, leaf nodes can be at any level except the root node that is taken as a default node for an entire page. For leaf nodes, no child is allowed. We call the parent-child connection *vertical connection*. To retain the computational advantage of tree-structured models, each node is allowed to have only one parent in a particular structure s. We will use s_v to denote the set of vertical connections. With the aforementioned definitions of L and N_d, we get $\mathrm{s}_v = \cup_{d=1}^{L-1}\{s_{il} : 0 \leq i < N_d \text{ and } 0 \leq l < N_{d-1}\}$.

To consider the dependencies between the nodes at the same layer, *horizontal connection*s (i.e., connections between nodes at the same level) are incorporated in s. Let n_{ij} be an indicator variable to denote whether node i and node j are adjacent to each other. Similarly, n_{ij} equals to 1 if node

i connects to node j; otherwise, it is 0. Let's denote the set of horizontal connections by s_h, then $\mathrm{s}_h = \cup_{d=0}^{L-1}\{n_{ij} : 0 \le i, j < N_d \text{ and } i \neq j\}$. Here, we assume that the variables n_{ij} are independent of s_{il} and can be determined using some spatial ordering method. This assumption holds in applications such as web data extraction and image processing. As position information is encoded in each node, deterministic spatial ordering can decide the neighborhood system among a set of nodes. In theory, the horizontal neighborhood system can be arbitrary. We consider the 2D cases (Zhu et al., 2005), that is, each node is horizontally connected to all the nearest surrounding nodes in a 2D plane.

With the structure model, the first part of the energy when the system is at the state (s,y) is

$$E_1(\mathrm{s},\mathrm{y},\mathrm{x}) = \sum_k \mu_k \sum_{ijl} s_{il} s_{jl} n_{ij} g_k(i,j,l,\mathrm{x}),$$

where a triple (i,j,l) denotes a particular position in the dynamic model. A position can be a time interval in time series or a region of space in random fields. Here, i and j are two nodes at the same layer and l is a node at the direct above layer. g_k are feature functions defined on the three nodes at position (i,j,l), and μ_k are their weights.

Class Label Model: A sample s from the structure model defines a Hierarchical Conditional Random Field, which has been defined in Section 3.4.2. Let α_i^y be an indicator variable to denote the variable Y_i taking the class label y. Then, the second part of the energy when the system is at the state (s,y) is

$$E_2(\mathrm{s},\mathrm{y},\mathrm{x}) = \sum_k \lambda_k \sum_{ijl} s_{il} s_{jl} n_{ij} \sum_{y_i,y_j,y_l} \alpha_i^{y_i} \alpha_j^{y_j} \alpha_l^{y_l} f_k(y_i,y_j,y_l,\mathrm{x}),$$

where f_k are feature functions defined on the labels y_i, y_j, and y_l at position (i,j,l), and λ_k are their weights.

Although conditional models take observations as global conditions, when defining feature functions they need to know the "focused observations" at a particular position. For example, in linear-chain CRFs (Lafferty et al., 2001) the observation at time t is among the focused observations when defining feature functions related to the label y_t. In general, let t be a position and x_t be the set of focused observations at that position. The mapping function $\zeta : t \to \mathrm{x}_t$ defines the focused observations for each position. In generative models (Todorovic and Nechyba, 2005), the mapping function is defined to determine the observations generated by the states at a particular position. Moreover, an additional constraint $\forall t \neq s, \mathrm{x}_t \cap \mathrm{x}_s = \emptyset$ is also set due to their independence assumption that observations at different positions are conditionally independent given the states at those positions. In conditional models, however, there is no such constraint. The mapping function can be deterministic or stochastic. We assume it to be deterministic in this paper. Now, all feature functions take an additional argument ζ, that is, the feature functions are $g_k(i,j,l,\mathrm{x},\zeta)$ and $f_k(y_i,y_j,y_l,\mathrm{x},\zeta)$.

Taking E_1 and E_2 together, we get the joint distribution of s and y

$$p(\mathrm{s},\mathrm{y}|\mathrm{x}) = \frac{1}{Z(\mathrm{x})} \exp\left\{ \begin{array}{c} \sum_k \mu_k \sum_{ijl} s_{il} s_{jl} n_{ij} g_k(i,j,l,\mathrm{x},\zeta) + \\ \sum_k \lambda_k \sum_{ijl} s_{il} s_{jl} n_{ij} \sum_{y_i,y_j,y_l} \alpha_i^{y_i} \alpha_j^{y_j} \alpha_l^{y_l} f_k(y_i,y_j,y_l,\mathrm{x},\zeta) \end{array} \right\},$$

where $Z(\mathrm{x})$ is the normalization factor or partition function in physics. Note that although names are similar, Dynamic Hierarchical Markov Random Fields are quite different from Dynamic CRFs (Sutton et al., 2004), which are dynamic in terms of time, that is, they have repetitive model structure and parameters over time, and the structure at each time slice is fixed. Here, "Dynamic" means the model's structure is dynamically selected.

4.2 Parameter Estimation and Labeling

Let $\Theta = \{\mu_1, \mu_2, \ldots; \lambda_1, \lambda_2, \ldots\}$ denote the whole set of the model's parameters, and let $D = \{(\mathrm{x}^i, \mathrm{y}_e^i)\}_{i=1}^K$ denote the set of training data, where x^i is a sample and y_e^i are observed labels. We consider the general case with both hidden hierarchical structure s and hidden labels y_h. For example, in web data extraction only the labels of leaf nodes are observable and both the hierarchical structures and the labels of inner nodes are hidden. So the log-likelihood of the data is incomplete

$$L(\Theta) = \sum_{i=1}^{K} \log p(\mathrm{y}_e^i|\mathrm{x}^i) = \sum_{i=1}^{K} \log(\sum_{\mathrm{s},\mathrm{y}_h} p(\mathrm{s},\mathrm{y}_h,\mathrm{y}_e^i|\mathrm{x}^i)).$$

This function does not have a closed-form solution because of the marginalization taking place within the logarithm. In the following, we derive a lower bound of the log-likelihood, or equivalently an upper bound of the negative log-likelihood. Then, contrastive divergence learning (Hinton, 2002) is applied as an approximation.

Let $q(\mathrm{s},\mathrm{y}_h|\mathrm{y}_e,\mathrm{x})$ be an approximation of the true distribution $p(\mathrm{s},\mathrm{y}_h|\mathrm{y}_e,\mathrm{x})$. With a little abuse of notations, we will use $q(\mathrm{s},\mathrm{y}_h)$ to denote $q(\mathrm{s},\mathrm{y}_h|\mathrm{y}_e,\mathrm{x})$. We also ignore the summation operator in the log-likelihood during the following derivations, as there is no essential difference between one sample and a set of independently and identically distributed (IID) samples. The optimal approximation is the distribution that has the minimum Kullback-Leibler divergence between $q(\mathrm{s},\mathrm{y}_h)$ and $p(\mathrm{s},\mathrm{y}_h|\mathrm{y}_e,\mathrm{x})$. The KL divergence is defined as $KL(q||p) = \sum_{\mathrm{s},\mathrm{y}_h} q(\mathrm{s},\mathrm{y}_h) \log \frac{q(\mathrm{s},\mathrm{y}_h)}{p(\mathrm{s},\mathrm{y}_h|\mathrm{y}_e,\mathrm{x})}$.

Take $p(\mathrm{s},\mathrm{y}_h|\mathrm{y}_e,\mathrm{x}) = p(\mathrm{s},\mathrm{y}_h,\mathrm{y}_e|\mathrm{x})/p(\mathrm{y}_e|\mathrm{x})$ into the above equation and use the non-negativity of KL divergence, we get a lower bound of the log-likelihood

$$\log p(\mathrm{y}_e|\mathrm{x}) \geq \sum_{\mathrm{s},\mathrm{y}_h} q(\mathrm{s},\mathrm{y}_h)[\log p(\mathrm{s},\mathrm{y}_h,\mathrm{y}_e|\mathrm{x}) - \log q(\mathrm{s},\mathrm{y}_h)].$$

Equivalently, $\mathcal{L}(\Theta) \triangleq \sum_{\mathrm{s},\mathrm{y}_h} q(\mathrm{s},\mathrm{y}_h)[\log q(\mathrm{s},\mathrm{y}_h) - \log p(\mathrm{s},\mathrm{y}_h,\mathrm{y}_e|\mathrm{x})]$ is an upper bound of the negative log-likelihood $-L(\Theta)$. By analogy with statistical physics, the upper bound, which is actually a KL divergence, can be expressed as the difference of two free energies: $\mathcal{L}(\Theta) = F_0 - F_\infty$, where the first term is the free energy when we use data distribution with observable labels clamped to their values, and the second $F_\infty = -\log Z(\mathrm{x})$ is the free energy when we use model distribution with all variables free.

Now, the problem is to minimize the upper bound. The derivatives of $\mathcal{L}(\Theta)$ with respect to λ_k are

$$\begin{aligned}
\frac{\partial \mathcal{L}(\Theta)}{\partial \lambda_k} &= \frac{\partial}{\partial \lambda_k} \langle -\log p(\mathrm{s},\mathrm{y}_h,\mathrm{y}_e|\mathrm{x}) \rangle_{q(\mathrm{s},\mathrm{y}_h)} \\
&= -\sum_{ijl} \langle s_{il} s_{jl} n_{ij} \rangle_{q(\mathrm{s},\mathrm{y}_h)} \sum_{y_i,y_j,y_l} \langle \alpha_i^{y_i} \alpha_j^{y_j} \alpha_l^{y_l} \rangle_{q(\mathrm{s},\mathrm{y}_h)} f_k(y_i,y_j,y_l,\mathrm{x},\zeta) - \frac{\partial F_\infty}{\partial \lambda_k} \\
&= -\sum_{ijl} n_{ij} \langle s_{il} s_{jl} \rangle_{q(\mathrm{s},\mathrm{y}_h)} \sum_{y_i,y_j,y_l} \langle \alpha_i^{y_i} \alpha_j^{y_j} \alpha_l^{y_l} \rangle_{q(\mathrm{s},\mathrm{y}_h)} f_k(y_i,y_j,y_l,\mathrm{x},\zeta) - \frac{\partial F_\infty}{\partial \lambda_k}, \qquad (1)
\end{aligned}$$

where $\langle . \rangle_p$ is the expectation under the distribution p. The last equality holds because of the assumption that the neighborhood system between sibling nodes is determined independent of their parents.

Similarly, the derivatives of $\mathcal{L}(\Theta)$ with respect to μ_k are

$$\frac{\partial \mathcal{L}(\Theta)}{\partial \mu_k} = -\sum_{ijl} n_{ij} \langle s_{il} s_{jl} \rangle_{q(\mathrm{s},\mathrm{y}_h)} g_k(i,j,l,\mathrm{x},\zeta) - \frac{\partial F_\infty}{\partial \mu_k}. \tag{2}$$

In (1) and (2), the derivatives of the equilibrium free energy F_∞ are intractable in the case of Dynamic Hierarchical Markov Random Fields. However, by viewing the equilibrium distribution as the distribution of a Markov chain at time $t = \infty$ starting with data distribution, Markov chain Monte Carlo (MCMC) method can be used to reconstruct an approximation distribution $q_i(\mathrm{s},\mathrm{y}_h,\mathrm{y}_e)$ within several steps. This is the basic idea of contrastive divergence learning (Hinton, 2002). Now, the upper bound is approximated by

$$\begin{aligned}\mathcal{L}(\Theta) =& F_0 - F_\infty \\ \approx& F_0 - F_i = KL(q_0||p) - KL(q_i||p) \triangleq CF_i^{App},\end{aligned}$$

where $q_0 = q(\mathrm{s},\mathrm{y}_h)$ is optimized with observable labels clamped to their values, and $q_i(\mathrm{s},\mathrm{y}_h,\mathrm{y}_e)$ is optimized with all variables free starting with q_0. As shown by Hinton (2002), CF_i^{App}, known as contrastive divergence, is non-negative. But since $F_i \geq F_\infty$, there is no guarantee that it is still an upper bound. Some analyses of contrastive divergence learning (Yuille, 2004; Carreira-Perpinan and Hinton, 2005) have been carried out. In the sequel, we will set $i = 1$.

Now, the derivatives of CF_1^{App} with respect to the model's parameters are as in (1) and (2) but with the derivatives of F_∞ replaced by

$$-\sum_{ijl} n_{ij} \langle s_{il} s_{jl} \rangle_{q_1} \sum_{y_i y_j y_l} \langle \alpha_i^{y_i} \alpha_j^{y_j} \alpha_l^{y_l} \rangle_{q_1} f_k(y_i, y_j, y_l, \mathrm{x}, \zeta) \text{ and } -\sum_{ijl} n_{ij} \langle s_{il} s_{jl} \rangle_{q_1} g_k(i,j,l,\mathrm{x},\zeta)$$

respectively.

Generally, stochastic sampling is quite time demanding in constructing q_1. In contrast, the deterministic mean field variant (Welling and Hinton, 2001) is more efficient. An extension to the combination of a general deterministic variational approximation and contrastive divergence is studied by Welling and Sutton (2005). The learning procedure consists of two phases—wake phase and sleep phase. Wake phase is to optimize q_0 and sleep phase is to optimize q_1. We address the wake phase first.

Assume q_0 can be factorized as $q_0 = q(\mathrm{s},\mathrm{y}_h) = q(\mathrm{s})q(\mathrm{y}_h)$, and we get

$$KL(q_0||p) = -\langle \log p(\mathrm{s},\mathrm{y}_h,\mathrm{y}_e|\mathrm{x}) \rangle_{q_0} - H(q(\mathrm{s})) - H(q(\mathrm{y}_h)), \tag{3}$$

where $H(p) = -\langle \log p \rangle_p$ is the entropy of distribution p. To efficiently optimize q_0, more assumptions need to be made about the family of distributions of $q(\mathrm{s})$ and $q(\mathrm{y}_h)$. Here, we adopt the naïve mean field approximation. The basic idea underlying mean field theory (Jordan et al., 1999) is to make a distribution a factorized one by introducing additional independence assumptions. This factorized distribution leads to computational tractability. The simplest naïve mean field is to assume that interacted variables are mutually independent and the joint distribution is the product of single variable marginal probabilities.

Let μ_{il} be the probability of node i being connected to node l, and m_i^y be the probability of variable Y_i being at state y. As we assume variables n_{ij} are determined independent of s_{il}, the mean field distributions[2] are

$$q(\mathrm{s}) = \prod_{il} [\mu_{il}]^{s_{il}} \text{ and } q(\mathrm{y}_h) = \prod_{iy} [m_i^y]^{\alpha_i^y}.$$

Substitute the above distributions into (3) and keep $q(\mathrm{y}_h)$ fixed, then we get

$$KL(q_0||p) = -\langle \log p(\mathrm{s}, \mathrm{y}_h, \mathrm{y}_e|\mathrm{x}) \rangle_{q_0} - H(q(\mathrm{s})) + c,$$

where c is a constant. Let the derivative over μ_{il} equal zero, and we get

$$\mu_{il} \propto \exp \left\{ \begin{array}{c} \sum_k \mu_k s_{il} \sum_j \langle s_{jl} \rangle_{q(\mathrm{s})} n_{ij} g_k(i,j,l,\mathrm{x}) + \\ \sum_k \lambda_k s_{il} \sum_j \langle s_{jl} \rangle_{q(\mathrm{s})} n_{ij} \sum_{y_1,y_2,y_3} \langle \alpha_i^{y_1} \alpha_j^{y_2} \alpha_l^{y_3} \rangle_{q(\mathrm{y}_h)} f_k(y_1,y_2,y_3,\mathrm{x},\zeta) \end{array} \right\}. \tag{4}$$

Normalization will lead to the desired probabilities μ_{il}.

Similarly, keep $q(\mathrm{s})$ fixed and we get

$$KL(q_0||p) = -\langle \log p(\mathrm{s}, \mathrm{y}_h, \mathrm{y}_e|\mathrm{x}) \rangle_{q_0} - H(q(\mathrm{y}_h)) + c',$$

where c' is another constant. Let the derivative over m_i^y equal zero, and we get

$$m_i^y \propto \exp \sum_k \lambda_k \sum_{j l y_1 y_2} \left\{ \begin{array}{l} n_{ij} \langle s_{il} s_{jl} \rangle_{q(\mathrm{s})} \langle \alpha_j^{y_1} \alpha_l^{y_2} \rangle_{q(\mathrm{y}_h)} f_k(y,y_1,y_2,\mathrm{x},\zeta) + \\ n_{ij} \langle s_{jl} s_{il} \rangle_{q(\mathrm{s})} \langle \alpha_j^{y_1} \alpha_l^{y_2} \rangle_{q(\mathrm{y}_h)} f_k(y_1,y,y_2,\mathrm{x},\zeta) + \\ n_{jl} \langle s_{ji} s_{li} \rangle_{q(\mathrm{s})} \langle \alpha_j^{y_1} \alpha_l^{y_2} \rangle_{q(\mathrm{y}_h)} f_k(y_1,y_2,y,\mathrm{x},\zeta) \end{array} \right\}. \tag{5}$$

Note that since s_{il} and α_i^y are all indicator variables, their expectations are the marginal probabilities μ_{il} and m_i^y respectively. Also, because of the naïve mean field assumption of $q(\mathrm{s})$ and $q(\mathrm{y}_h)$, the expectations of the product of the indicator variables is the product of their corresponding marginal probabilities, that is, $\langle s_{il} s_{jl} \rangle_{q(\mathrm{s})} = \mu_{il}\mu_{jl}$, $\langle s_{ji} s_{li} \rangle_{q(\mathrm{s})} = \mu_{ji}\mu_{li}$, $\langle \alpha_j^{y_1} \alpha_l^{y_2} \rangle_{q(\mathrm{y}_h)} = m_j^{y_1} m_l^{y_2}$, and $\langle \alpha_i^{y_1} \alpha_j^{y_2} \alpha_l^{y_3} \rangle_{q(\mathrm{y}_h)} = m_i^{y_1} m_j^{y_2} m_l^{y_3}$.

Equations (4) and (5) are a set of coupled equations, also known as mean field equations. These equations are iteratively solved for a fixed point solution. Intuitively, parameters μ_{il} are updated by expected contributions from possible parents and neighbors, and similar for m_i^y. In (4) and (5), structure parameters μ_{il} depend on class label assignments, and m_i^y depend on expected structure connectivity. Thus, model structure selection is integrated with label assignment during the inference.

Now, we have presented a mean field approximation of the wake phase. To finish the sleep phase, the same mean field equations are enforced by coordinate descent alternating between observable variables Y_e and hidden variables S and Y_h. When first optimizing (5) for Y_e, the initial distribution of hidden variables are set as the optimal distribution at the end of wake phase. Then, take the optimal distribution of the former step as initial distribution of Y_e and optimize (4) and (5) to get an approximate distribution of hidden variables. For wake phase, initial distributions can be random and convergence is arrived at. But for sleep phase, a few steps are required to guarantee the improvement of CF_1^{App}.

2. $q(\mathrm{s}) = q(\mathrm{s_h}|\mathrm{s_v})q(\mathrm{s_v})$. Based on the assumption that $\mathrm{s_h}$ are deterministic and independent of $\mathrm{s_v}$, $q(\mathrm{s_h}|\mathrm{s_v})$ is an indicator function and takes all the probability one if $\mathrm{s_h}$ are the allowed connections.

Thus, all the terms in (1), (2), (4), and (5) can be calculated. The whole parameter estimation algorithm is as follows. First, apply (4) and (5) to iteratively compute the marginal probabilities of both wake and sleep phases. With the marginal probabilities, CF_1^{App} and its derivatives with respect to model parameters are calculated. Then, gradient-based optimization algorithms are applied to update model parameters. Here, we use the limited memory quasi-Newton method (Liu and Nocedal, 1989). The learning procedure is iterated until the relative change of CF_1^{App} is below some threshold. Although no guarantee exists that global optimization will be achieved, empirical studies show that this algorithm performs well.

For labeling a testing example, Equations (4) and (5) are iteratively solved with all variables free for a fixed point solution. At the end of convergence, the maximum a posterior model structure (a tree) is constructed from the probabilities μ_{il} by dynamic programming, and the most likely label assignments are found from the marginal probabilities m_i^y.

5. Implementation Details and Experimental Setup

Our experiments consist of two parts. The first part is to evaluate the performance of integrated web data extraction models compared with existing decoupled methods. The second part is to evaluate Dynamic Hierarchical Markov Random Fields (DHMRFs) compared with fixed-structured hierarchical models and Dynamic Trees (Williams and Adams, 1999). All the experiments are carried out on a real-world web data extraction task—production information extraction. In this section, we present the implementation details and the setup of our experiments. Results will be reported in the next two sections.

5.1 Features

As conditional models, DHMRFs and HCRFs can incorporate any useful feature for web data extraction. In this section, we present the types of features used in our experiments. As we shall note some of the features have been used in some existing extraction methods. However, they were mainly used as heuristic rules.

5.1.1 FEATURES OF ELEMENTS

For each element, we extract both content and visual features as listed in Table 1. All the features can be obtained through rendering a page. Previous work (Zhai and Liu, 2005; Zhu et al., 2005; Zhao et al., 2005; Gatterbauer et al., 2007) has shown the effectiveness of visual features for webpage analysis and information extraction.

5.1.2 FEATURES OF BLOCKS

The features of inner blocks are aggregations of their children's features. These features can be extracted via a bottom-up procedure starting from leaf nodes (or elements), such as the number of the children having a particular feature and the presence of a feature or a simultaneous presence of several features among the children. We also compute the following distances for each block to exploit the regularity of similar data records in a page.

Tree Distance Features: if two blocks are visually similar, usually their sub-trees on a vision-tree are also similar. We define the tree distance of two blocks as a measure of their structure similarity. The tree distance of two blocks is defined as the edit distance of their corresponding sub-

Name	Description
Content	The Content of a text element
Tag	The tag name of an element
Font Size	The font size of an element
Font Weight	The font weight of an element
Position	The coordinates of an element
Height	The height of an element's rectangle
Width	The width of an element's rectangle
Area	The area of an element's rectangle
Image URL	The source URL of an image element
Link URL	The action URL of an element if it exists
Image Alt-text	The alternative text of an image element

Table 1: The content and visual features of each element.

trees. Although the time-complexity of computing this distance could be high, we can substantially reduce the computation with some heuristics. For example, if the depth difference of two sub-trees is too large, they are not likely to be similar and this computation is not necessary. Once we have computed the tree distances, we can use some thresholds to define boolean-valued feature functions. For example, if the tree distance of two adjacent blocks is not more than 0.2, they are both likely to be data records.

Shape Distance and Type Distance Features: we also compute the shape distance and type distance (Zhao et al., 2005) of two blocks to exploit their similarity. For shape distance, we use the same definition of shape codes and the same calculation method as in the work (Zhao et al., 2005). To compute the type distance of two blocks, we define the following types for each element:

IMAGE: the element is an image.

JPEG IMAGE: the image element that is also a jpeg picture.

CODED IMAGE: the image element whose source URL contains at least three succeeding numbers, such as "/products/s_thumb/eb04iu_0190893_200t1.jpg".

TEXT: the element has text content.

LINK TEXT: the text element that contains an action URL.

DOLLAR TEXT: the text element that contains at least one dollar sign.

NOTE TEXT: the text element whose tag is "input", "select" or "option".

NULL: the default type of each element.

After defining each element's type code, a block's type code is defined as a sequence of the type codes of its children. As in the work by Zhao et al. (2005), multiple consecutive occurrences of each type are compressed to one occurrence. The edit distance of type codes is the type distance of two blocks.

Similar to the use of tree distance, we can easily incorporate shape distance and type distance by defining boolean-valued feature functions with pre-determined thresholds. Note that our model will not be sensitive to these thresholds because the defined feature functions are softened by learning a weight for each of them. Each feature function contributes its weight to the probability only when it is active. If a feature function is always active, it has no effect on the probability; and if a feature

Label Name	Semantic Meaning
Con_Image	Contains product's image
Con_Name	Contains product's name
Con_Price	Contains product's price
Con_Desc	Contains product's description
Con_ImgNam	Contains product's image and name
Con_NamPrc	Contains product's name and price
Con_ImgPrc	Contains product's image and price
Page Head	The head part of a Web page
Page Tail	The tail part of a Web page
Nav Bar	The navigation bar of a Web page
Data Region	Contains only similar data records
Data Record	Contains all the target attributes if exist
Info Block	Contains one or more data records and some additional information
Note Block	Contains no target attributes and are also not meaningful parts of a webpage

Table 2: Label spaces of inner variables for product information extraction.

function appears sparsely in the training set, smoothing techniques can be used to avoid over-fitting. Here, we use the spherical Gaussian prior to penalize the log-likelihood function during learning.

5.1.3 GLOBAL FEATURES

As described in the introduction, data records in the same webpage are always related. Based on work by Zhai and Liu (2005), we try to align the elements of two adjacent blocks in the same page and extract some global features to help attribute labeling.

For two neighboring blocks, we use the partial tree-alignment algorithm (Zhai and Liu, 2005) to align their elements. An alignment is discarded if most of the elements are not aligned. For successful alignments, the following feature is extracted.

Repeated elements are less informative: this feature is based on the observation that repeated elements in different records are more likely to be less useful, while important information such as the name of a product is not likely to repeat in the same webpage. For example, the "Add to cart" button appears in both data records as in Figure 1(a), but each record has a unique name. Currently, we just denote whether an element is repeated in different records. More complex measures like information entropy can be easily adopted. An example feature function can be defined as: if the element x_i repeatedly appears in the aligned records, it will be more likely to be labeled as Note or noise.

5.2 Label Spaces

For variables at leaf nodes, we are interested in deciding whether a leaf block (an element) is an attribute value of the object we want to extract. However, for variables at inner nodes, our interest shifts to the understanding of whether an inner block is a data record. So, we have two types of label spaces—leaf label space for variables at leaf nodes and inner label space for variables at inner nodes. The leaf label space consists of all the attribute names of the object we want to extract. In

product information extraction, the leaf label space consists of *Name*, *Image*, *Price*, *Description*, and *Note*. *Note* is used to describe the data we are not interested in.

The inner label space can be partitioned into an object-type independent part and an object-type dependent part. We explain how to define these two parts in turn:

Object-type Independent Labels: Since we want to extract data from webpages, the labels *Page Head*, *Page Tail*, *Nav Bar*, and *Info Block* are naturally needed to denote different parts of a webpage. The labels *Data Record* and *Data Region* are also required for detecting data records. The label *Note Block* is also required to denote blocks that do not contain any meaningful information, such as the attributes to be extracted and the head, tail or navigation bar of a webpage. All these labels are general to any web data extraction problem, and they are independent of any specific object type.

Object-type Dependent Labels: Between data record blocks and leaf blocks, there are intermediate blocks on a vision-tree. So, we must define some intermediate labels between *Data Record* and the labels in the leaf label space. These labels are object-type dependent because intermediate blocks contain some object specific attribute values. A natural method is to use the combinations of the attributes to define intermediate labels. Of course, if we use all the possible combinations, the label space could be too large. We can discard unimportant combinations by considering the co-occurrence frequencies of their corresponding attribute values in the training data. The object-type dependent labels in product information extraction are listed in Table 2 with the format Con_*.

5.3 Data Sets

We set up two general data sets with randomly crawled product webpages. The list data set (*LDST*) contains 771 list pages and the detail data set (*DDST*) contains 450 detail pages. All the pages are parsed by VIPS and are hierarchically labeled, that is, every block in the parsed vision-trees is labeled. We use 200 list pages and 150 detail pages to learn the parameters of different models. The remaining pages (571 list pages and 300 detail pages) are used for testing. For each product item, we want to extract four attributes—*Name*, *Image*, *Price*, and *Description*.

For the training data, the detail pages are from 61 web sites and the list pages are from 81 web sites. The number of web sites that are found in both list and detail training data is 39. Thus, in total the training pages are taken from 103 different web sites. Totally, 58 unique templates are presented in the list training pages and 61 unique templates are presented in the detail training pages. For testing data, Table 3 shows the number of unique web sites where the pages come from and the number of different templates presented in these data. For example, the pages in *LDST* are from 167 web sites, of which 78 are found in list training data and 52 are found in detail training data. The number of web sites that are found in both list and detail training data is 34. Similar interpretation applies to other numbers in the table. Thus, totally 71 list page web sites and 263 detail page web sites are not seen in the training data. For templates, 83 list page templates and 208 detail page templates are not seen the training data. For different templates, the number of documents varies. In *LDST*, most of the templates have 2 to 5 documents. In *DDST*, pages from different web sites typically have different templates and thus most templates have 1 document.

5.4 Evaluation Metrics

For data record detection, we use the standard *P*recision, *R*ecall and *F1* measure to evaluate the methods. A block is considered as a correctly detected data record if it contains all the appeared

Data Sets	*LDST*	*DDST*
#Web Site	167 (78/52/34)	268 (2/3/0)
#Template	140 (57/0/0)	212 (0/4/0)

Table 3: Statistics of the data sets.

attributes of one object, and does not contain any attributes of other objects. A correct data record could tolerate (miss or contain) some non-important information like "Add to Cart" button.

For attribute labeling, the performance on each attribute is evaluated by *P*recision (the percentage of returned elements that are correct), *R*ecall (the percentage of correct elements that are returned), and their harmonic mean *F1*. We also use two comprehensive evaluation criteria:

Block Instance Accuracy (Blk_IA): the percentage of data records of which the key attributes (*Name*, *Image*, and *Price*) are all correctly labeled.

Average F1 (Avg_F1): the average of F1 values of different attributes.

6. Evaluation of Integrated Web Data Extraction Models

In this section, we report the evaluation results of integrated web data extraction models compared with decoupled models. The results demonstrate that integrated extraction models can achieve significant improvements over decoupled models in both record detection and attribute labeling. We also show the generalization ability of the integrated extraction models.

6.1 Methods

We build the baseline methods by sequentially combining the record detection algorithm DEPTA (Zhai and Liu, 2005) and 2D CRFs (Zhu et al., 2005). For detail pages, which DEPTA cannot deal with, we first detect the main data block using the method by Song et al. (2004) and then use 2D CRFs to perform attribute labeling on the detected main block. For the integrated extraction model, a webpage is first segmented by VIPS to construct a vision-tree and then HCRFs are used to detect both records and attributes on the vision-tree. Note that all the HCRFs evaluated in this section are the model in Figure 3(b). The evaluation results of another HCRFs, which are slightly better, are presented in Section 7.

To see the effect of the global features in Section 5.1.3, we also evaluate an HCRF model that does not use these global features. We denote this model by H_NG (without global features). Similarly, we evaluate two 2D CRF models in the baseline methods. As in the work of Zhu et al. (2005), a basic 2D CRF model is set up with only the basic features (see Table 1) when labeling each detected data record. Another 2D CRF model is set up with both the basic features and the global features. We denote the basic model by 2D CRF and denote the other model by 2D_G. For 2D_G, we first cache all the detected records from one webpage and then extract the global features. As there is no tree structure here, the alignments are based on the elements' relative positions in each record.

To see the separate effect of our approach on record detection and attribute labeling, we first detect data records on the parsed vision-trees using the content features, tree distance, shape distance, and type distance features. Then, we use HCRFs to label the detected records. When doing

attribute labeling, we also evaluate two HCRF models with and without the global features. These two models are denoted by H_S and H_SNG respectively.

For all the HCRF models, we use 200 list pages and 150 detail pages together to learn their parameters. We use the same 200 list pages to train a 2D CRF model for extraction on list pages, and use the same 150 detail pages to train another 2D CRF model for extraction on detail pages. The reason for training two models for list and detail pages separately is that, for a 2D CRF model, the features and parameters for list and detail pages are quite different and a uniform model cannot work well. In the training stage, all of the algorithms converge quickly, within 20 iterations.

6.2 Results and Discussions

We compare our approach with DEPTA (Zhai and Liu, 2005) on *LDST* for data record detection. The running results of DEPTA on our data set are kindly provided by its authors. DEPTA has a similarity threshold, and it is set at 60% in this experiment. Some simple heuristics are also used in DEPTA to remove some noise records. For example, a data region that is far from the center or contains neither image nor dollar sign is removed.

6.2.1 RECORD DETECTION

The results of record detection are shown in Table 4. We can see that both HCRF and H_NG significantly outperform DEPTA in recall, improved by 8.1 points, and precision, improved by 7.5 points. The improvements come from two parts:

Advanced data representation and more features: in our model, we incorporate more features such as content features and shape distance and type distance features than DEPTA. We also adopt an advanced representation of webpages—vision-trees which have been shown to outperform tag-tree representation(Cai et al., 2004). As we can see from Table 4, H_SNG and H_S outperform DEPTA, and we gain about 2 points in precision, 7.3 points in recall, and 4.6 points in F1.

Incorporation of semantics during record detection: DEPTA just detects the blocks with regular patterns (i.e., regular tree structures) and does not take semantics into account. Thus, although some heuristics are used to remove some noise blocks, the results still contain blocks that are not data records or just parts of data records. In contrast, our approach integrates attribute labeling into block detection and can consider semantics during detecting data records. So, the blocks detected are of better quality and are more likely to be data records. For instance, a block containing a product's name, image, price and some descriptions is almost certain to be a data record, but a block containing only irrelevant information is unlikely to be a data record. The lower precisions of H_SNG and H_S demonstrate this. When not considering the semantics of the elements, H_SNG and H_S extract more noise blocks compared with H_NG or HCRF, so the precisions of record detection decrease by 5.5 points and the overall F1 measures decrease by 3.2 points.

6.2.2 ATTRIBUTE LABELING

As we can see from Table 5, our HCRF model significantly outperforms the baseline approach. On list pages, H_NG gains 18.7 points over 2D CRF in block instance accuracy and the achievements of HCRF are 13.9 points higher when compared with 2D CRF_G. On detail pages, our approach gains about 58 points over 2D CRF in block instance accuracy. The reasons for the better performance are:

Table 5: Attribute labeling results of different methods on both *LDST* and *DDST*, where *Desc* stands for *Description*.

Attribute labeling benefits from good quality records: one reason for this better performance is that attribute labeling can benefit from the good results of record detection. For example, if a detected record is not a data record or misses some important information such as *Name*, attribute labeling will fail to find the missed information or will find some incorrect information. So, H_SNG outperforms 2D CRF and H_S outperforms 2D_G. Of course the achievements of H_SNG and H_S may also come from the incorporation of long distance dependencies, which will be discussed later.

Global features help attribute labeling: another reason for the improvements in attribute labeling is the incorporation of the global features as in Section 5.1.3. From the results, we can see that when considering global features, attribute labeling is more accurate. For example, 3.4 points are gained in block instance accuracy by HCRF compared with H_NG, and H_S achieves 2.7 points in block instance accuracy compared with H_SNG. For the two baseline methods, compared with 2D CRF, which uses only the features of the elements in each detected record, more than 8 points are gained in block instance accuracy by 2D_G, which incorporates the global features.

HCRF models incorporate long distance dependencies: the third reason is the incorporation of long distance dependencies. From the results, we can see that hierarchical models could get

promising results while 2D CRFs perform poorly on detail pages. This is because, for a detected record, 2D CRFs put its elements in a two-dimensional grid and long distance interactions cannot be incorporated in the flat model, due to the first-order Markov assumption. In contrast, HCRF models can incorporate dependencies at various levels and thus incorporate long distance dependencies. For detail pages, as there is no record detection, H_SNG and H_S are not applicable here. There are no global features either, so we just list the results of HCRF and 2D CRF in Table 5.

The quite different performance of 2D CRFs on list and detail pages says the same thing about the effectiveness of long distance dependencies. For list pages, the inputs are data records, which always contain a small number of elements. In this case, 2D CRFs can effectively model the dependencies of the attributes and achieve reasonable accuracy. Note that the results on detail pages are achieved without any pre-processing to remove noise elements. Empirical studies show that some appropriate pre-processing can improve the performance significantly on detail pages.

6.3 Generalization Ability

We report some empirical results to show the generalization ability of the integrated web data extraction models. We randomly pick 37 templates from *LDST* and for each template we collect 5 webpages for training and 10 webpages for testing. We randomly select $N (N = 1,2,3,\cdots,37)$ templates together with their training pages as training data, and test the model on all the testing webpages of the 37 templates. For each N, we run the integrated HCRFs 10 times and take the average as the final results. Figure 5 shows the average F1 and block instance accuracy against different N. We can see that the integrated extraction models converge very quickly. As the number of templates increase in the training data, the extraction accuracy becomes higher and the variances become smaller. The strong generalization ability to unseen templates is mainly due to the very general and robust visual features we are using in our models. For different templates, although the low-level HTML codes or HTML tag trees are quite different, the visual layout and visual features they use are usually common. Thus, we can learn a robust model from a small set of templates and generalize well to unseen templates. Section 7.3 presents another set of results that show the generalization ability to unseen templates.

7. Evaluation of Dynamic Hierarchical Markov Random Fields

In this section, we report the evaluation results of Dynamic Hierarchical Markov Random Fields compared with fixed-structured hierarchical models and Dynamic Trees. Results show that DHMRFs can (at least partially) overcome the blocky artifact issue in diverse web data extraction. We also present some empirical studies about the learning algorithm of DHMRFs.

7.1 Models

We compare DHMRFs with HCRFs in both Figure 3(b) and 3(c), Dynamic Trees (D-Trees), and fixed-structured tree models (F-Trees). For HCRFs and F-Trees, all training pages are hierarchically labeled. The training is complete and exact message passing algorithms are used to learn their parameters and find MAP label assignments. For DHMRFs and D-Trees, labels of leaf nodes are kept the same and inner labels are hidden during learning. For the incomplete training, we apply the variational method developed in this paper for DHMRFs. Mean field approximation is also used for Dynamic Trees. For DHMRFs and HCRFs, the same set of feature functions are used for class

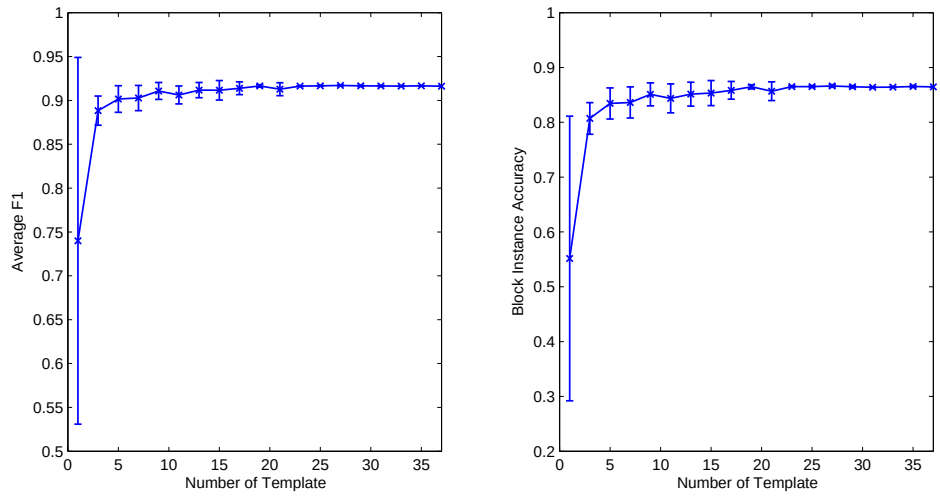

Figure 5: The left plot is the mean and variance of the Average F1 and the right plot is the mean and variance of the Block Instance Accuracy.

label assignment. We will use *HCRF* and *HCRF+* to denote the two HCRF models in Figure 3(b) and 3(c) respectively.

To apply DHMRFs and D-Trees, initial configuration of the model structure must be carried out first. Basically, we need to initially set the number of layers and the number of nodes at each layer. It may be different for different application domains to set the initial configuration. For image processing, it can be done via sub-sampling or wavelet filtering. For web data extraction, the data are represented as texts, images, buttons, and so on. These atomic information units are more expressive compared to image pixels. There is definitely no benefit to view a webpage as a collection of image pixels and then apply the methods in image processing. Here, we use the same number of layers (and the same number of nodes at each layer) in dynamic models as in the vision-trees. Note that additional nodes can be introduced. For DHMRFs feature functions can be easily defined to consider these nodes, and for D-Trees the *part-time-node-employment* prior (Adams and Williams, 1999) can be applied to get a sparse structure.

For D-Trees, two sets of parameters—conditional probability tables (CPTs) and affinities, need to be set. We keep the affinities fixed and learn the CPTs. To avoid over-parametrization, layer-wise CPT sharing is adopted in previous work. However, for heterogeneous web data, three-layer-wise sharing is better. That is, every three layers from the top down share one CPT. To incorporate evidence, we use the class-independent model (Storkey and Williams, 2003) with emission distributions set as the empirical frequencies in the training data set. CPTs are also initialized as frequencies. To avoid zero probabilities of unseen samples, Laplace's rule is used with pseudocount set at one. Our study shows that when the affinities are set as 0 for the natural parent, -1 for the nearest neighbors of the natural parent, and -3 for the null parent, better performance is achieved compared to previously used settings. The CPTs used in our experiments are achieved with 10 iterations.

7.2 Extraction Accuracy

Table 6 shows the extraction accuracy of different models. From the results, we can see that DHMRFs achieve the highest performance on both data sets. Compared to the fixed *HCRF*, on *LDST* about 3 points in Average F1 and about 5 points in Block Instance Accuracy are gained. Compared to the more complex *HCRF+*, more than 2 points in Average F1 and about 3 points in Block Instance Accuracy are achieved. More specifically, compared to *HCRF+*, more than 3 points are achieved in both precision and recall on *Name*, and more than 2 points are achieved on *Desc*. For *Image* and *Price* the improvements are smaller. This is because *Image* and *Price* are usually more distinctive than the other attributes. So both models perform quite well. On *DDST*, the improvements in *Name* are about 4 points in both precision and recall, and for *Description* the improvements are about 7 points in both precision and recall. Small improvements are achieved in *Image* and *Price* due to the same reason as in list pages.

The improvements demonstrate the merits of DHMRFs. First, DHMRFs can incorporate the two-dimensional neighborhood dependencies among the nodes at the same level, which have been shown to be useful (Zhu et al., 2005). The better performance of *HCRF+* compared to *HCRF* also shows the usefulness of two-dimensional neighborhood dependencies. By dynamically selecting connections between different nodes, DHMRFs can bring together the attributes of the same object (here, an object is a product item), and thus the correlation between these attributes can be strengthened. Second, DHMRFs can deal with webpages with intertwined attributes (Zhai and Liu, 2005). For these webpages, the attributes of different objects are intertwined in HTML tag trees. Unaware of semantic labels, the constructed vision-trees also have intertwined attributes. In these cases, fixed-structured HCRFs (both *HCRF* and *HCRF+*) cannot correctly detect data records by simply assigning labels to the nodes of a vision-tree. Instead, as structure selection is integrated with labeling in DHMRFs, the dynamic model can properly group the attributes of the same object, and at the same time separate the attributes of different objects with the help of semantic labels. The semantic labels have been shown to be helpful in detecting data records (i.e., groups of attributes) in previous experiments. Note that although intertwined cases are usually fewer than non-intertwined cases, they are not sparse samples in our model. This is because although their edge connections in HTML tag trees are somewhat different from non-intertwined ones, the visual features they share are almost the same. Thus, training samples with or without intertwined cases can teach a good model. In fact, to keep it fair for both dynamic models and fix-structured models, we only provide non-intertwined samples during training.

Compared to the fixed F-Trees, the worse performance of D-Trees is quite counter-intuitive. However, a close examination of the results reveals that the reason for the worse performance is due to the less discriminative power of D-Trees. As we have stated, for diverse web data CPT sharing can be difficult. Although empirical studies can find a good sharing method, we couldn't learn an optimal model with a limited set of training samples. Furthermore, its generative characteristic causes difficulty in encoding useful features. In this way, more uncertainty in structure selection couldn't be resolved than that in DHMRFs. This is evident if we look at the average log-likelihood of the MAP connections over all samples and all nodes. For D-Trees the average value is -0.4080, and for DHMRFs it is -0.3170. In terms of probability, they are equivalent to 0.6650 and 0.7283 respectively. The less discriminative power of D-Trees causes additional errors in constructing model structures even for the non-intertwined cases, and thus hurts the accuracy of record detection and attribute labeling. So, D-Trees perform worse than F-Trees, which can deal with the non-

intertwined cases well. The results also show that the directed tree models can perform well on our data sets, but are inferior to HCRFs.

7.3 Extraction Accuracy on Unseen Templates

For detail pages, since only a small number (i.e., 4) of templates in the testing data are seen in the training data, the results on webpages generated from unseen templates do not change much. Here, we only report the results on list pages. In total, *LDST* has 83 templates that are not seen in the training data. We select out all the pages with unseen templates, the total number being 190. Figure 6 shows the results of our models on these webpages. The overall performance is still very promising although it is lower than that on the whole set of webpages. Generally, the Dynamic Hierarchical Markov Random Fields always outperform all the other models. The integrated HCRFs outperform the sequential HCRFs, which take record detection and attribute labeling as two separate steps as described in Section 6.1. Dynamic Trees achieved the worst results due to the same reason of a less discriminative power in structure selection.

7.4 Fitness of Model Structure

Figure 7(a) compares the posterior probabilities of the MAP structures constructed by DHMRFs with those of the fixed structures. In terms of the number of nodes, the sizes of webpages change from 39 to 576 (average 166) in *LDST*, and the log posteriors change from -503.80 to -4.49 (average -50.7). In *DDST*, sizes range from 14 to 705 (average 131), and log posteriors range from -184.40 to -1.72 (average -42.47). Here, we only present the samples whose log posteriors are between -200 and 0 because most of the samples ($>$ 97%) fall into this interval. We can see that the MAP structures by DHMRFs always appear above the equal probability line. Thus, the structures found by the dynamic

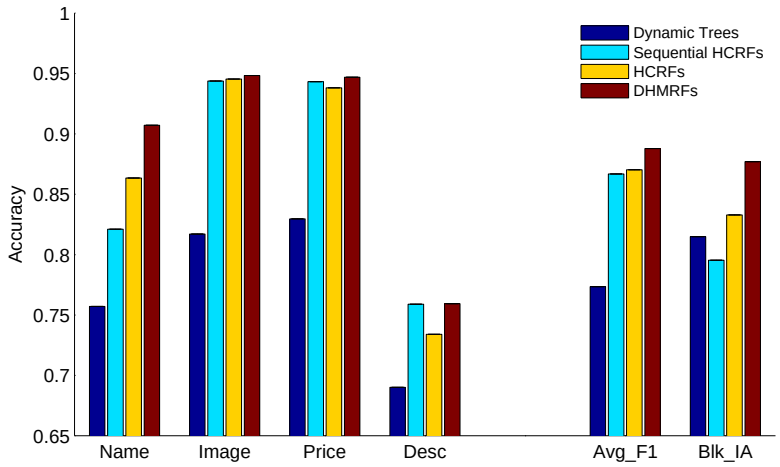

Figure 6: The performance of Dynamic Trees, Sequential HCRFs, HCRFs, and DHMRFs on the webpages whose templates are not presented in the training data. From left to right, the first four groups of the columns are the F1 of different attributes.

model have higher posterior probabilities. Another observation is that the distribution of samples from *DDST* is more disperse than that of the samples from *LDST*. The reason is that in list pages the attributes of an object always concentrate into small clusters, while they can scatter anywhere in detail pages.

7.5 Study about the Inference Algorithm

Figure 7(b) shows the change of average contrastive divergence with respect to iteration numbers in the learning of DHMRFs. To initialize the algorithm, at the wake phrase m_i^y are set to a uniform distribution plus a Gaussian noise with zero mean and variance 0.01, and μ_{il} are set to a random distribution. The model weights are initialized to zero. We can see that before 7 iterations average contrastive divergence decreases stably. And after 7, slight disturbances appear. But as for extraction accuracy, marginal changes occur (no more than 0.5 point in Block Instance Accuracy). Thus, the learning algorithm is quite stable. All the above results are achieved at iteration 7. The same initialization is used in labeling, and by running both learning and labeling many times, we observe that the algorithm is insensitive to the random initialization. Since the mean field equations are locally calculated and their update can typically converge within 5 iterations, both the learning and labeling are efficient.

8. Conclusions and Future Work

In this paper, we proposed an integrated web data extraction paradigm with hierarchical models. The proposed model is called Dynamic Hierarchical Markov Random Fields (DHMRFs), which take fixed-structured Hierarchical Conditional Random Fields (HCRFs) as a special case. DHMRFs incorporate structural uncertainty in a discriminative manner. By dynamically selecting connections

between variables, DHMRFs can potentially address the blocky artifact issue in diverse web data extraction. Compared to directed models, DHMRFs are compact in representation and powerful in encoding useful features. We develop a contrastive divergence learning algorithm to learn the parameters for DHMRFs. For the special case—HCRFs, parameter learning can be exactly performed with some assumption about the linearity of the neighborhood dependencies among sibling nodes, and without such an assumption piecewise learning can be applied to achieve a good approximation. We apply the models to a real-world web data extraction task. Experimental results show that: (1) integrated extraction models perform significantly better than decoupled methods on both record detection and attribute labeling; (2) DHMRFs can potentially address the blocky artifact issue in diverse web data extraction; (3) integrated extraction models can generalize well to unseen templates.

In our experiments, we apply a simple method to select labels for inner variables according to the co-occurrence frequency. Apparently, labels should not be selected independently and methods considering the correlations between different labels could be more desirable. We plan to try advanced methods in the future. It is also interesting to develop models that can automatically discover the number of layers and the number of nodes at each layer. Finally, extensive studies of the integrated extraction models in other complicated domains, like extracting researchers' information (Zhu et al., 2007a), is also to comprise our future work.

Abstract

In this paper we are concerned with reproducing kernel Hilbert spaces $\mathcal{H}_K$ of functions from an input space into a Hilbert space $\mathcal{Y}$, an environment appropriate for multi-task learning. The reproducing kernel K associated to $\mathcal{H}_K$ has its values as operators on $\mathcal{Y}$. Our primary goal here is to derive conditions which ensure that the kernel K is universal. This means that on every compact subset of the input space, every continuous function with values in $\mathcal{Y}$ can be uniformly approximated by sections of the kernel. We provide various characterizations of universal kernels and highlight them with several concrete examples of some practical importance. Our analysis uses basic principles of functional analysis and especially the useful notion of vector measures which we describe in sufficient detail to clarify our results.

Keywords: multi-task learning, multi-task kernels, universal approximation, vector-valued reproducing kernel Hilbert spaces

1. Introduction

The problem of studying representations and methods for learning vector-valued functions has received increasing attention in Machine Learning in the recent years. This problem is motivated by several applications in which it is required to estimate a vector-valued function from a set of input/output data. For example, one is frequently confronted with situations in which multiple supervised learning tasks must be learned simultaneously. This problem can be framed as that of learning a vector-valued function $f = (f_1, f_2, \ldots, f_n)$, where each of its components is a real-valued function and corresponds to a particular task. Often, these tasks are dependent on each other in

that they share some common underlying structure. By making use of this structure, each task is easier to learn. Empirical studies indicate that one can benefit significantly by learning the tasks simultaneously as opposed to learning them one by one in isolation (see, e.g., Evgeniou et al., 2005, and references therein).

In this paper, we build upon the recent work of Micchelli et al. (2006) by addressing the issue of universality of multi-task kernels. Multi-task kernels were recently discussed in Machine Learning context by Micchelli and Pontil (2005), however there is an extensive literature on multi-task kernels as there are important both in theory and practice (see Amodei, 1997; Burbea and Masani, 1984; Caponnetto and De Vito, 2006; Carmeli et al., 2006; Devinatz, 1960; Lowitzsh, 2005; Reisert and Burkhardt, 2007; Vazquez and Walter, 2003, and references therein for more information)

A multi-task kernel K is the reproducing kernel of a Hilbert space of functions from an input space $\mathcal{X}$ which takes values in a Hilbert space $\mathcal{Y}$. For example, in the discussion above, $\mathcal{Y} = \mathbb{R}^n$. Generally, the kernel K is defined on $\mathcal{X} \times \mathcal{X}$ and takes values as an *operator* from $\mathcal{Y}$ to itself.[1] When $\mathcal{Y}$ is n-dimensional, the kernel K takes values in the set of $n \times n$ matrix. The theory of reproducing kernel Hilbert spaces (RKHS) as described in Aronszajn (1950) for scalar-valued functions has extensions to any vector-valued $\mathcal{Y}$. Specifically, the RKHS is formed by taking the closure of the linear span of *kernel sections* $\{K(\cdot,x)y,\ x \in \mathcal{X},\ y \in \mathcal{Y}\}$, relative to the RKHS norm. We emphasize here that this fact is fundamentally tied to a norm induced by K and is generally non-constructive. Here, we are concerned with conditions on the kernel K which ensure that all continuous functions from $\mathcal{X}$ to $\mathcal{Y}$ can be uniformly approximated on any compact subset of $\mathcal{X}$ by the linear span of kernel sections.

As far as we are aware, the first paper which addresses this question in Machine Learning literature is Steinwart (2001). Steinwart uses the expression *universal kernel* and we follow that terminology here. The problem of identifying universal kernels was also discussed by Poggio et al. (2002). One of us was introduced to this problem in a lecture given at City University of Hong Kong by Zhou (2003). Subsequently, some aspects of this problem were treated in Micchelli et al. (2003) and Micchelli and Pontil (2004) and then in detail in Micchelli et al. (2006).

The question of identifying universal kernels has a practical basis. We wish to learn a *continuous* target function $f : \mathcal{X} \to \mathcal{Y}$ from a finite number of samples. The learning algorithm used for this purpose should be consistent. That is, as the samples size increases, the discrepancy between the target function and the function learned from the data should tend to zero. Kernel-based algorithms (Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004) generally use the representer theorem and learn a function in the linear span of kernel sections. Therefore, here we interpret consistency to mean that, for *any compact* subset $\mathcal{Z}$ of the input space $\mathcal{X}$ and every continuous target function $f : \mathcal{X} \to \mathcal{Y}$, the discrepancy between the target function and the learned function goes to zero uniformly on $\mathcal{Z}$ as the sample size goes to infinity. It is important to keep in mind that our input space is *not* assumed to be compact. However, we do assume that it is a Hausdorff topological space so that there is an abundance of compact subsets, for example any finite subset of the input space is compact.

Consistency in the sense we described above is important in order to study the statistical performance of learning algorithms based on RKHS. For example, Chen et al. (2004) and Steinwart et al. (2006) studied statistical analysis of soft margin SVM algorithms, Caponnetto and De Vito (2006) gave a detailed analysis of the regularized least-squares algorithm over vector-valued RKHS and

1. Sometimes, such a kernel is called operator-valued or matrix-valued kernel if $\mathcal{Y}$ is infinite of finite dimensional, respectively. However, for simplicity sake we adopt the terminology multi-task kernel throughout the paper.

proved universal consistency of this algorithm assuming that the kernel is universal and fulfills the additional condition that the operators $K(x,x)$ have finite trace. The results in these papers imply universal consistency of kernel-based learning algorithms when the considered kernel is universal. One more interesting application of universal kernels is described in Gretton et al. (2006).

This paper is organized as follows. In Section 2, we review the basic definition and properties of multi-task kernels, define the notion of universal kernel and describe some examples. In Section 3, we introduce the notion of feature map associated to a multi-task kernel and show its relevance to the question of universality. The main result in this section is Theorem 4, which establishes that the closure of the RKHS in the space of continuous functions is the same as the closure of the space generated by the feature map. The importance of this result is that universality of a kernel can be established directly by considering its features. In Section 4 we provide an alternate proof of Theorem 4 which uses the notion of vector measures and discuss ancillary results useful for several concrete examples of some practical importance highlighted in Section 5.

name	notation	information
input space	$\mathcal{X}$	a Hausdorff topological space
	$\mathcal{Z}$	compact subset of $\mathcal{X}$
	x,t,z	elements of $\mathcal{Z}$
	$\mathscr{B}(\mathcal{Z})$	Borel σ-algebra of $\mathcal{Z}$
	ν	signed scalar measure
	μ	vector measure, see Def. 8
	p,q	indices running from 1 to n
	i,j	indices running from 1 to m
output space	$\mathcal{Y}$	Hilbert space, with inner product $(\cdot,\cdot)_{\mathcal{Y}}$
	$\mathcal{B}_1$	unit ball centered at the origin, in $\mathcal{Y}$
feature space	$\mathcal{W}$	Hilbert space with inner product $\langle\cdot,\cdot\rangle_{\mathcal{W}}$
	$\mathcal{L}(\mathcal{Y},\mathcal{W})$	all bounded linear operators from $\mathcal{Y}$ into $\mathcal{W}$
	$\mathcal{L}(\mathcal{Y})$	all bounded linear operators from $\mathcal{Y}$ into itself
	A,B	elements of $\mathcal{L}(\mathcal{Y})$
	$\mathcal{L}_+(\mathcal{Y})\subseteq\mathcal{L}(\mathcal{Y})$	subset of positive linear operators
multi-task kernel	K	a function from $\mathcal{X}\times\mathcal{X}$ to $\mathcal{L}(\mathcal{Y})$, see Def. 1
	$\mathcal{H}_K$	reproducing kernel Hilbert space of K
feature representation	Φ	mapping from $\mathcal{X}$ to $\mathcal{L}(\mathcal{Y},\mathcal{W})$
	$\mathcal{C}(\mathcal{Z},\mathcal{Y})$	space of continuous $\mathcal{Y}$-valued functions on $\mathcal{Z}$
	ι	isometric mapping from $\mathcal{C}(\mathcal{Z},\mathcal{Y})$ to $\mathcal{C}(\mathcal{Z}\times\mathcal{B}_1)$
	$\mathcal{C}_K(\mathcal{Z},\mathcal{Y})$	subset of $\mathcal{C}(\mathcal{Z},\mathcal{Y})$ generated by K, see Eq. (2)
	$\mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y})$	subset of $\mathcal{C}(\mathcal{Z},\mathcal{Y})$ generated by Φ, see Eq. (9)

Table 1: Notation.

2. RKHS of Vector-Valued Functions

In this section, we review the theory of reproducing kernels for Hilbert spaces of vector-valued functions as in Micchelli and Pontil (2005) and introduce the notion of universal kernels.

We begin by introducing some notation. We let $\mathcal{Y}$ be a Hilbert space with inner product $(\cdot,\cdot)_{\mathcal{Y}}$ (we drop the subscript $\mathcal{Y}$ when confusion does not arise). The vector-valued functions will take values on $\mathcal{Y}$. We denote by $\mathcal{L}(\mathcal{Y})$ the space of all bounded linear operators from $\mathcal{Y}$ into itself, with the operator norm $\|A\| := \sup_{\|y\|=1} \|Ay\|$, $A \in \mathcal{L}(\mathcal{Y})$ and by $\mathcal{L}_+(\mathcal{Y})$ the set of all bounded, positive semi-definite linear operators, that is, $A \in \mathcal{L}_+(\mathcal{Y})$ provided that, for any $y \in \mathcal{Y}$, $(y,Ay) \geq 0$. We also denote, for any $A \in \mathcal{L}(\mathcal{Y})$, by A^* its adjoint. Finally, for every $m \in \mathbb{N}$, we define $\mathbb{N}_m = \{1,\ldots,m\}$. Table 1 summarizes the notation used in paper.

Definition 1 *We say that a function $K : \mathcal{X} \times \mathcal{X} \to \mathcal{L}(\mathcal{Y})$ is a multi-task kernel on $\mathcal{X}$ if $K(x,t)^* = K(t,x)$ for any $x,t \in \mathcal{X}$, and it is* positive semi-definite, *that is, for any $m \in \mathbb{N}$, $\{x_j : j \in \mathbb{N}_m\} \subseteq \mathcal{X}$ and $\{y_j : j \in \mathbb{N}_m\} \subseteq \mathcal{Y}$ there holds*

$$\sum_{i,j \in \mathbb{N}_m} (y_i, K(x_i,x_j)y_j) \geq 0. \tag{1}$$

For any $t \in \mathcal{X}$ and $y \in \mathcal{Y}$, we introduce the mapping $K_t y : \mathcal{X} \to \mathcal{Y}$ defined, for every $x \in \mathcal{X}$ by $(K_t y)(x) := K(x,t)y$. In the spirit of Moore-Aronszjain's theorem, there is a one-to-one correspondence between the kernel K with property (1) and an RKHS of functions $f : \mathcal{X} \to \mathcal{Y}$ (Aronszajn, 1950), see also Micchelli and Pontil (2005) and Carmeli et al. (2006).

Throughout this paper, we assume that the kernel K is *continuous* relative to the operator norm on $\mathcal{L}(\mathcal{Y})$. We now return to the formulation of the definition of universal kernel. For this purpose, we recall that $\mathcal{C}(\mathcal{Z},\mathcal{Y})$ is the Banach space of continuous $\mathcal{Y}$-valued continuous function on a compact subset $\mathcal{Z}$ of $\mathcal{X}$ with the *maximum norm*, defined by $\|f\|_{\infty,\mathcal{Z}} := \sup_{x \in \mathcal{Z}} \|f(x)\|_{\mathcal{Y}}$. We also define, for every multi-task kernel K, the subspace of $\mathcal{C}(\mathcal{Z},\mathcal{Y})$

$$\mathcal{C}_K(\mathcal{Z},\mathcal{Y}) := \overline{\text{span}}\{K_x y : x \in \mathcal{Z}, y \in \mathcal{Y}\}, \tag{2}$$

where the closure is relative to the norm in the space $\mathcal{C}(\mathcal{Z},\mathcal{Y})$.

Definition 2 *We say that a multi-task kernel K is a* universal kernel *if, for any compact subset $\mathcal{Z}$ of $\mathcal{X}$, $\mathcal{C}_K(\mathcal{Z},\mathcal{Y}) = \mathcal{C}(\mathcal{Z},\mathcal{Y})$.*

In the special case that $\mathcal{Y} = \mathbb{R}^n$, the kernel function K takes values as $n \times n$ matrices. The corresponding matrix elements can be identified by the formula

$$(K(x,t))_{pq} = \langle K_x e_p, K_t e_q \rangle_K, \ \ \forall x,t \in \mathcal{X},$$

where e_p, e_q are the standard coordinate basis in $\mathbb{R}^n$, for $p,q \in \mathbb{N}_n$.

In order to describe some of the examples of multi-task kernels below, it is useful to first present the following generalization of Schur product of scalar kernels to matrix-valued kernels. For this purpose, for any $i \in \mathbb{N}_m$ we let $y_i = (y_{1i}, y_{2i}, \ldots, y_{ni}) \in \mathbb{R}^n$, so that Equation (1) is equivalent to

$$\sum_{i,j \in \mathbb{N}_m} \sum_{p,q \in \mathbb{N}_n} y_{pi} (K(x_i,x_j))_{pq} y_{qj} \geq 0. \tag{3}$$

From the above observation, we conclude that K is a kernel if and only if $\big((K(x_i,x_j)_{p,q}\big)$ as the matrix with row index $(p,i) \in \mathbb{N}_n \times \mathbb{N}_m$ and column index $(q,j) \in \mathbb{N}_n \times \mathbb{N}_m$ is positive semi-definite. This fact makes possible, as long as the dimension of $\mathcal{Y}$ is finite, reducing the proof of some properties of operator-valued kernels to the proof of analogous properties of scalar-valued kernels; this process is illustrated by the following Proposition.

Proposition 3 *Let G and K be $n \times n$ multi-task kernels. Then, the element-wise product kernel $K \circ G : \mathcal{X} \times \mathcal{X} \to \mathbb{R}^n \times \mathbb{R}^n$ defined, for any $x,t \in \mathcal{X}$ and $p,q \in \mathbb{N}_n$, by $\big(K \circ G(x,t)\big)_{pq} := \big(K(x,t)\big)_{pq}\big(G(x,t)\big)_{pq}$ is an $n \times n$ multi-task kernel.*

Proof We have to check the positive semi-definiteness of $K \circ G$. To see this, for any $m \in \mathbb{N}$, $\{y_i \in \mathbb{R}^n : i \in \mathbb{N}_m\}$ and $\{x_i \in \mathcal{X} : i \in \mathbb{N}_m\}$ we observe that

$$\sum_{i,j \in \mathbb{N}_m} (y_i, K \circ G(x_i,x_j) y_j) = \sum_{p,i} \sum_{q,j} y_{pi} y_{qj} \big(K(x_i,x_j)\big)_{pq} \big(G(x_i,x_j)\big)_{pq}. \tag{4}$$

By inequality (3), it follows that the matrix $\big(\big(K(x_i,x_j)\big)_{pq}\big)$ is positive semi-definite as the matrix with (p,i) and (q,j) as row and column indices respectively, and so is $\big(\big(G(x_i,x_j)\big)_{pq}\big)$. Applying the Schur Lemma (Aronszajn, 1950) to these matrices implies that Equation (4) is nonnegative, and hence proves the assertion. ■

We now present some examples of multi-task kernels. They will be used in Section 5 to illustrate the general results in Sections 3 and 4.

The first example is adapted from Micchelli and Pontil (2005).

Example 1 *If, for every $j \in \mathbb{N}_m$ the function $G_j : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is a scalar kernel and $B_j \in \mathcal{L}_+(\mathcal{Y})$, then the function*

$$K(x,t) = \sum_{j \in \mathbb{N}_m} G_j(x,t) B_j, \quad \forall x,t \in \mathcal{X} \tag{5}$$

is a multi-task kernel.

The operators B_j model smoothness across the components of the vector-valued function. For example, in the context of multi-task learning (see, e.g., Evgeniou et al., 2005, and references therein), we set $\mathcal{Y} = \mathbb{R}^n$, hence B_j are $n \times n$ matrices. These matrices model the relationships across the tasks. Evgeniou et al. (2005) considered kernels of the form (5) with $m = 2$, B_1 a multiple of the identity matrix and B_2 a low rank matrix. A specific case for $\mathcal{X} = \mathbb{R}^d$ is

$$(K(x,t))_{p,q} = \lambda x \cdot t + (1-\lambda)\delta_{pq}(x \cdot t)^2, \quad p,q \in \mathbb{N}_n,$$

where $x \cdot t$ is the standard inner product in $\mathbb{R}^d$ and $\lambda \in [0,1]$. This kernel has an interesting interpretation. Using only the first term on the right hand side of the above equation ($\lambda = 1$) corresponds to learning all tasks as the same task, that is, all components of the vector-valued function $f = (f_1, \ldots, f_n)$ are the same function, which will be a linear function since the kernel G_1 is linear. Whereas, using only the second term ($\lambda = 0$) corresponds to learning independent tasks, that is, the components of the function f will be generally different functions. These functions will be quadratic since G_2 is a quadratic polynomial kernel. Thus, the above kernel combines two heterogeneous kernels to form a more flexible one. By choosing the parameter λ appropriately, the learning model can be tailored to the data at hand.

We note that if K is a diagonal matrix-valued kernel, then each component of a vector-valued function in the associated RKHS of K can be represented, independently of the other components, as a function in the RKHS of a scalar kernel. However, in general, a multi-task kernel will not be diagonal and, more importantly, *will not* be reduced to a diagonal one by linearly transforming the

output space. For example, the kernel in Equation (5) cannot be reduced to a diagonal kernel, unless all the matrices B_j, $j \in \mathbb{N}_m$ can all be simultaneously transformed into a diagonal matrix. Therefore, in general, the component functions share some underlying structure which is reflected by the choice of the kernel and cannot be treated as independent objects. This fact is further illustrated by the next example.

Example 2 *If $\mathcal{X}_0$ is a compact Hausdorff space, for $p \in \mathbb{N}_n$, T_p is a map from $\mathcal{X}$ from $\mathcal{X}_0$ (not necessary linear) and $G : \mathcal{X}_0 \times \mathcal{X}_0 \to \mathbb{R}$ is a scalar kernel, then*

$$K(x,t) := \Big(G(T_p x, T_q t)\Big)_{p,q=1}^n, \quad \forall x,t \in \mathcal{X}$$

is a matrix-valued kernel on $\mathcal{X}$.

A specific instance of the above example is described by Vazquez and Walter (2003) in the context of system identification. It corresponds to the choices that $\mathcal{X}_0 = \mathcal{X} = \mathbb{R}$ and $T_p(x) = x + \tau_p$, where $\tau_p \in \mathbb{R}$. In this case, the kernel K models "delays" between the components of the vector-valued function. Indeed, it is easy to verify that, for this choice, for all $f \in \mathcal{H}_K$ and $p \in \mathbb{N}_n$,

$$f_p(x) := (f(x), e_p) = h(x - \tau_p), \quad \forall x \in \mathcal{X}$$

where h is a scalar-valued function in the RKHS of kernel G.

Other choices of the map T_p are possible and provide interesting extensions of scalar kernels. For instance, the choice $K(x,t) := (e^{\sigma_{pq}\langle x,t\rangle} : p,q \in \mathbb{N}_n)$, where $\sigma = (\sigma_{pq})$ is a positive semi-definite matrix suggested by Example 2. Specifically, the eigenvalue decomposition of the matrix σ is given by $\sigma = \sum_{i=1}^n \lambda_i u_i u_i^T$ and, for any $x \in \mathcal{X}$ and $i \in \mathbb{N}_n$ the map $T_p^{(i)}$ is given by $T_p^{(i)} x := \sqrt{\lambda_i} u_{ip} x$. Therefore, we obtain that $K(x,t) = (\prod_{i=1}^n e^{\langle T_p^{(i)} x, T_q^{(i)} t\rangle} : p,q \in \mathbb{N}_n)$ and, so, by Proposition 3, we conclude that K is a matrix-valued kernel.

It is interesting to note, in passing, that, although one would expect the function

$$K(x,t) := \Big(e^{-\sigma_{pq}\|x-t\|^2}\Big)_{p,q=1}^n, \quad \forall x,t \in \mathcal{X} \tag{6}$$

to be a kernel over $\mathcal{X} = \mathbb{R}^d$, we will show later in Section 5 that this is not true, unless all entries of the matrix σ are the same.

Our next example called Hessian of Gaussian is motivated by the problem of learning gradients (Solak et al., 2002; Mukherjee and Zhou, 2006). In many applications, one wants to learn an unknown real-valued function $f(x)$, $x = (x^1, \ldots, x^d) \in \mathbb{R}^d$ and its gradient function $\nabla f = (\partial_1 f, \ldots, \partial_d f)$ where, for any $j \in \mathbb{N}_d$, $\partial_p f$ denotes the p-th partial derivative of f. Here the outputs y_{ip} denotes the observation of derivative of p-th derivative at sample x_i. Therefore, this problem is an appealing example of multi-task learning: learn the target function and its gradient function jointly.

To see why this problem is related with the Hessian of Gaussian, we adopt the Gaussian process (Rasmussen and Williams, 2006) viewpoint of kernel methods. In this perspective, kernels are interpreted as covariance functions of Gaussian prior probability distributions over suitable sets of functions. More specifically, the (unknown) target function f is usually assumed as the realizations of random variables indexed by its input vectors in a zero-mean Gaussian process. The Gaussian process can be fully specified by giving the covariance matrix for any finite set of zero-mean random

variables $\{f(x_i) : i \in \mathbb{N}_m\}$. The covariance between the functions corresponding to the inputs x_i and x_j can be defined by a given Mercer kernel, for example, the Gaussian kernel $G(x) = \exp(-\frac{\|x\|^2}{\sigma})$ with $\sigma > 0$, that is,

$$\operatorname{cov}(f(x_i), f(x_j)) = G(x_i - x_j).$$

Consequently, the covariance between $\partial_p f$ and $\partial_q f$ is given by

$$\operatorname{cov}(\partial_p f(x_i), \partial_q f(x_j)) = \partial_p \partial_q \operatorname{cov}(f(x_i), f(x_j)) = -\partial_p \partial_q G(x_i - x_j).$$

This suggests to us to use the Hessian of Gaussian to model the correlation of gradient function ∇f as we present in the following example.

Example 3 *We let $\mathcal{Y} = \mathcal{X} = \mathbb{R}^n$, and, for any $x = (x_p : p \in \mathbb{N}_n) \in \mathcal{X}$, $G(x) = \exp(-\frac{\|x\|^2}{\sigma})$ with $\sigma > 0$. Then, the Hessian matrix of G given by*

$$K(x,t) := (-(\partial_p \partial_q G)(x-t) : p,q \in \mathbb{N}_n) \ \ \forall x,t \in \mathcal{X}$$

is a matrix-valued kernel.

To illustrate our final example we let $L^2(\mathbb{R})$ be the Hilbert space of square integrable functions on $\mathbb{R}$ with the norm $\|h\|_{L^2}^2 := \int_{\mathbb{R}} h^2(x)dx$. Moreover, we denote by $W^1(\mathbb{R})$ the Sobolev space of order one, which is defined as the space of real-valued functions h on $\mathbb{R}$ whose norm

$$\|h\|_{W^1} := \left(\|h\|_{L^2}^2 + \|h'\|_{L^2}^2\right)^{\frac{1}{2}}$$

is finite.

Example 4 *Let $\mathcal{Y} = L^2(\mathbb{R})$, $\mathcal{X} = \mathbb{R}$ and consider the linear space of functions from $\mathbb{R}$ to $\mathcal{Y}$ which have finite norm*

$$\|f\|^2 = \int_{\mathbb{R}} \left(\|f(x,\cdot)\|_{W^1}^2 + \left\| \frac{\partial f(x,\cdot)}{\partial x} \right\|_{W^1}^2 \right) dx.$$

Then this is an RKHS with multi-task kernel given, for every $x,t \in \mathcal{X}$, by

$$(K(x,t)y)(r) = e^{-\pi|x-t|} \int_{\mathbb{R}} e^{-\pi|r-s|} y(s)ds, \ \ \forall y \in \mathcal{Y}, \ r \in \mathbb{R}.$$

This example may be appropriate to learn the heat distribution in a medium if we think of x as time. Another potential application extends the discussion following Example 1. Specifically, we consider the case that the input x represents both time and a task (e.g., the profile identifying a customer) and the output is the regression function associated to that task (e.g., the preference function of a customer, see Evgeniou et al., 2005, for more information). So, this example may be amenable for learning the dynamics of the tasks.

Further examples for the case that $\mathcal{Y} = L^2(\mathbb{R}^d)$ will be provided in Section 5. We also postpone to that section the proof of the claims in Examples 1-4 as well as the discussion about the universality of the kernels therein.

We end this section with some remarks. It is well known that universality of kernels is a main hypothesis in the proof of the consistency of kernel-based learning algorithms. Universal consistency of learning algorithms and their error analysis also rely on the capacity of the RKHS. In particular,

following the exact procedure for the scalar case in Cucker and Smale (2001), one sufficient condition for universal consistency of vector-valued (multi-task) learning algorithms is the compactness of the unit ball of vector-valued RKHS relative to the space of continuous vector-valued functions. Another alternate sufficient condition was proved in Caponnetto and De Vito (2006) for the regularized least-squares algorithm over vector-valued RKHS. There, it was assumed that, in addition to the universality of the kernel, the trace of the operators $K(x,x)$ is finite, for every $x \in \mathcal{X}$. Clearly, both conditions are fulfilled by the multi-task kernels presented above if the output space $\mathcal{Y}$ is finite dimensional, but they become non trivial in the infinite dimensional case. However, it is not clear to the authors whether either of these two conditions is necessary for universal consistency. We hope to come back to this problem in the future.

3. Universal Kernels by Features

In this section, we prove that a multi-task kernel is universal if and only if *its feature representation is universal*. To explain what we have in mind, we require some additional notation. We let $\mathcal{W}$ be a Hilbert space and $\mathcal{L}(\mathcal{Y},\mathcal{W})$ be the set of all bounded linear operators from $\mathcal{Y}$ to $\mathcal{W}$. A *feature representation* associated with a multi-task kernel K is a continuous function

$$\Phi : \mathcal{X} \to \mathcal{L}(\mathcal{Y},\mathcal{W})$$

such that, for every $x,t \in \mathcal{X}$

$$K(x,t) = \Phi^*(x)\Phi(t), \tag{7}$$

where, we recall, for each $x \in \mathcal{X}$, $\Phi^*(x)$ is the adjoint of $\Phi(x)$ and, therefore, it is in $\mathcal{L}(\mathcal{W},\mathcal{Y})$. Hence, from now on we call $\mathcal{W}$ the *feature space*. In the case that $\mathcal{Y} = \mathbb{R}$, the condition that $\Phi(x) \in \mathcal{L}(\mathcal{Y},\mathcal{W})$ can be merely viewed as saying that $\Phi(x)$ in an element of $\mathcal{W}$. Therefore, at least in this case we can rewrite Equation (7) as

$$K(x,t) = (\Phi(x),\Phi(t))_{\mathcal{W}}. \tag{8}$$

Another example of practical importance corresponds to the choice $\mathcal{W} = \mathbb{R}^k$ and $\mathcal{Y} = \mathbb{R}^n$, both finite dimensional Euclidean spaces. Here we can identify $\Phi(x)$ relative to standard basis of $\mathcal{W}$ and $\mathcal{Y}$ with the $k \times n$ matrix $\Phi(x) = (\Phi_{rp}(x) : r \in \mathbb{N}_k, p \in \mathbb{N}_n)$, where Φ_{rp} are scalar-valued continuous functions on $\mathcal{X}$. Therefore, according to (7) the matrix representation of the multi-task kernel K is, for each $x,t \in \mathcal{X}$,

$$(K(x,t))_{pq} = \sum_{r \in \mathbb{N}_k} \Phi_{rp}(x)\Phi_{rq}(t), \quad p,q \in \mathbb{N}_n.$$

Returning to the general case, we emphasize that we *assume* that the kernel K has the representation in Equation (7), although if it corresponds to a compact integral operator, such a representation will follow from the spectral theorem and Mercer Theorem (see, e.g., Micchelli et al., 2006).

Associated with a feature representation as described above is the following closed linear subspace of $\mathcal{C}(\mathcal{Z},\mathcal{Y})$

$$\mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y}) := \overline{\{\Phi^*(\cdot)w : w \in \mathcal{W}\}}, \tag{9}$$

where the closure is taken relative to the norm of $\mathcal{C}(\mathcal{Z},\mathcal{Y})$. The continuity of the functions $\Phi^*(\cdot)w$ follows from the assumed continuity of $K(\cdot,\cdot)$ by

$$\begin{aligned} \|\Phi^*(x)w - \Phi^*(t)w\|^2 &\le \|\Phi^*(x) - \Phi^*(t)\|^2 \|w\|^2_{\mathcal{W}} \\ &= \|(\Phi^*(x) - \Phi^*(t))(\Phi(x) - \Phi(t))\| \|w\|^2_{\mathcal{W}} \\ &= \|K(x,x) + K(t,t) - K(x,t) - K(t,x)\| \|w\|^2_{\mathcal{W}}. \end{aligned}$$

Our definition of the phrase "the feature representation is universal" means that $\mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y}) = \mathcal{C}(\mathcal{Z},\mathcal{Y})$ for every compact subset $\mathcal{Z}$ of the input space $\mathcal{X}$. The theorem below demonstrates, as we mentioned above, that the kernel K is universal if and only if its feature representation is universal. The content of Theorem 4 and of the other results of this Section (Lemmas 5, 6 and Proposition 7) are graphically represented by the diagram in Table 2

Theorem 4 *If K is a continuous multi-task kernel with feature representation Φ, then for every compact subset $\mathcal{Z}$ of $\mathcal{X}$, we have that $\mathcal{C}_K(\mathcal{Z},\mathcal{Y}) = \mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y})$.*

Proof The theorem follows straightforwardly from Lemmas 5, 6 and Proposition 7, which we present below.

■

As we know, the feature representation of a given kernel is not unique, therefore we conclude by Theorem 4 that if *some* feature representation of a multi-task kernel is universal then *every* feature representation is universal.

We shall give two different proofs of this general theorem. The first one will use a technique highlighted in Micchelli and Pontil (2005) and will be given in this section. The second proof will be given in the next section and uses the notion of *vector measure*. Both approaches adopt the point of view of Micchelli et al. (2006), in which Theorem 4 is proved in the special case that $\mathcal{Y} = \mathbb{R}$.

We now begin to explain in detail our first proof. We denote the unit ball in $\mathcal{Y}$ by $\mathcal{B}_1 := \{y : y \in \mathcal{Y}, \|y\| \leq 1\}$ and let $\mathcal{Z}$ be a prescribed compact subset of $\mathcal{X}$. Recall that $\mathcal{B}_1$ is not compact in the norm topology on $\mathcal{Y}$ *unless* $\mathcal{Y}$ is finite dimensional. But it is compact in the *weak topology* on $\mathcal{Y}$ since $\mathcal{Y}$ is a Hilbert space (see, e.g., Yosida, 1980). Remember that a basis for the open neighborhood of the origin in the weak topology is a set of the form $\{y : y \in \mathcal{Y}, |(y,y_i)| \leq 1, i \in \mathbb{N}_m\}$, where $y_1,\ldots,y_m$ are arbitrary vectors in $\mathcal{Y}$. We put on $\mathcal{B}_1$ the weak topology and conclude, by Tychonoff's theorem (see, e.g., Folland, 1999, p.136), that the set $\mathcal{Z}\times\mathcal{B}_1$ is also compact in the product topology.

The above observation allows us to associate $\mathcal{Y}$-valued functions defined on $\mathcal{Z}$ to scalar-valued functions defined on $\mathcal{Z}\times\mathcal{B}_1$. Specifically, we introduce the map $\iota : \mathcal{C}(\mathcal{Z},\mathcal{Y}) \to \mathcal{C}(\mathcal{Z}\times\mathcal{B}_1)$ which maps any function $f \in \mathcal{C}(\mathcal{Z},\mathcal{Y})$ to the function $\iota(f) \in \mathcal{C}(\mathcal{Z}\times\mathcal{B}_1)$ defined by the action

$$\iota(f) : (x,y) \mapsto (f(x),y)_\mathcal{Y}, \quad \forall (x,y) \in (\mathcal{Z}\times\mathcal{B}_1). \tag{10}$$

Consequently, it follows that the map ι is *isometric*, since

$$\sup_{x\in\mathcal{Z}} \|f(x)\|_\mathcal{Y} = \sup_{x\in\mathcal{Z}} \sup_{\|y\|\leq 1} |(f(x),y)_\mathcal{Y}| = \sup_{x\in\mathcal{Z}} \sup_{y\in\mathcal{B}_1} |\iota(f)(x,y)|,$$

where the first equality follows by Cauchy-Schwarz inequality. Moreover, we will denote by $\iota(\mathcal{C}(\mathcal{Z},\mathcal{Y}))$ the image of $\mathcal{C}(\mathcal{Z},\mathcal{Y})$ under the mapping ι. In particular, this space is a closed linear subspace of $\mathcal{C}(\mathcal{Z}\times\mathcal{B}_1)$ and, hence, a Banach space.

Similarly, to any multi-task kernel K on $\mathcal{Z}$ we associate a scalar kernel J on $\mathcal{Z}\times\mathcal{B}_1$ defined, for every $(x,y),(t,u) \in \mathcal{X}\times\mathcal{B}_1$, as

$$J((x,y),(t,u)) := (K(x,t)u,y). \tag{11}$$

Moreover, we denote by $\mathcal{C}_J(\mathcal{Z}\times\mathcal{B}_1)$ the closure in $\mathcal{C}(\mathcal{Z}\times\mathcal{B}_1)$ of the set of the sections of the kernel, $\{J((x,y),(\cdot,\cdot)) : (x,y) \in \mathcal{Z}\times\mathcal{B}_1\}$. It is important to realize that whenever K is a valid multi-task kernel, then J is a valid scalar kernel.

$$\begin{array}{ccc} \mathcal{C}_\Psi(\mathcal{Z}\times\mathcal{B}_1) & = & \mathcal{C}_J(\mathcal{Z}\times\mathcal{B}_1) \\ \iota\uparrow & & \uparrow\iota \\ \mathcal{C}_K(\mathcal{Z},\mathcal{Y}) & = & \mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y}) \end{array}$$

Table 2: The top equality is Proposition 7, the bottom equality is Theorem 4 and the left and right arrows are Lemma 5 and 6, respectively.

The lemma below relates the set $\mathcal{C}_K(\mathcal{Z},\mathcal{Y})$ to the corresponding set $\mathcal{C}_J(\mathcal{Z}\times\mathcal{B}_1)$ for the kernel J on $\mathcal{Z}\times\mathcal{B}_1$.

Lemma 5 *If $\mathcal{Z}$ is a compact subset of $\mathcal{X}$ and K is a continuous multi-task kernel then $\iota(\mathcal{C}_K(\mathcal{Z},\mathcal{Y})) = \mathcal{C}_J(\mathcal{Z}\times\mathcal{B}_1)$.*

Proof The assertion follows by Equation (11) and the continuity of the map ι. ■

In order to prove Theorem 4, we also need to provide a similar lemma for the set $\mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y})$. Before we state the lemma, we note that knowing the features of the multi-task kernel K leads us to the features for the scalar-kernel J associated to K. Specifically, for every $(x,y),(t,u)\in\mathcal{X}\times\mathcal{B}_1$, we have that

$$J((x,y),(t,u)) = (\Psi(x,y),\Psi(t,u))_{\mathcal{W}}, \tag{12}$$

where the continuous function $\Psi : \mathcal{X}\times\mathcal{B}_1 \to \mathcal{W}$ is defined as

$$\Psi(x,y) = \Phi(x)y, \quad x\in\mathcal{X}, y\in\mathcal{B}_1.$$

Thus, Equation (12) parallels Equation (8) except that $\mathcal{X}$ is replaced by $\mathcal{X}\times\mathcal{B}_1$. We also denote by $\mathcal{C}_\Psi(\mathcal{Z}\times\mathcal{B}_1) = \overline{\{(\Psi(\cdot),w)_{\mathcal{W}} : w\in\mathcal{W}\}}$, the closed linear subspace of $\mathcal{C}(\mathcal{Z}\times\mathcal{B}_1)$.

Lemma 6 *If $\mathcal{Z}$ is a compact subset of $\mathcal{X}$ and K is a continuous multi-task kernel with feature representation Φ then $\iota(\mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y})) = \mathcal{C}_\Psi(\mathcal{Z}\times\mathcal{B}_1)$.*

Proof The proof is immediate. Indeed, for each $x\in\mathcal{X}$, $w\in\mathcal{W}$, $y\in\mathcal{Y}$, we have that $(\Phi^*(x)w,y)_{\mathcal{Y}} = (w,\Phi(x)y)_{\mathcal{W}} = (\Psi(x,y),w)_{\mathcal{W}}$. ■

To complete the proof of Theorem 4, as illustrated in Table 2 it suffices to show that $\mathcal{C}_\Psi(\mathcal{Z}\times\mathcal{B}_1) = \mathcal{C}_J(\mathcal{Z}\times\mathcal{B}_1)$. To this end, we review some facts about signed measures and bounded linear functionals on continuous functions. Let Ω be any prescribed *compact* Hausdorff space and $\mathcal{C}(\Omega)$ be the space of all real-valued continuous functions with norm $\|\cdot\|_{\infty,\Omega}$. We also use the notation $\mathscr{B}(\Omega)$ to denote the Borel σ-algebra on Ω. Now, we recall the description of the dual space of $\mathcal{C}(\Omega)$. By the Riesz representation theorem, any linear functional L in the dual space of $\mathcal{C}(\Omega)$ is uniquely identified as a regular signed Borel measure ν on Ω (see, e.g., Folland 1999), that is,

$$L(g) = \int_\Omega g(x)d\nu(x), \quad \forall g\in\mathcal{C}(\Omega).$$

The variation of ν is given, for any $E \in \mathscr{B}(\Omega)$, by

$$|\nu|(E) := \sup\Big\{ \sum_{j\in\mathbb{N}} |\nu(A_j)| : \{A_j : j \in \mathbb{N}\} \text{ pairwise disjoint and } \cup_{j\in\mathbb{N}} A_j = E \Big\}.$$

Moreover, we have that $\|L\| = \|\nu\|$, where $\|\nu\| = |\nu|(\Omega)$ and $\|L\|$ is the operator norm of L defined by $\|L\| = \sup_{\|g\|_{\infty,\Omega}=1} |L(g)|$. Recall that a Borel measure ν is *regular* if, for any $E \in \mathscr{B}(\mathcal{X})$,

$$\nu(E) = \inf\big\{\nu(U) : E \subseteq U, U \text{ open}\big\} = \sup\big\{\nu(\bar{U}) : \bar{U} \subseteq E, \bar{U} \text{ compact}\big\}.$$

In particular, every finite Borel measure on Ω is regular, see Folland (1999, p.217). We denote by $\mathcal{M}(\Omega)$ the space of all regular signed measures on Ω with total variation norm. We emphasize here that the Riesz representation theorem stated above requires the compactness of the underlying space Ω.

As mentioned above, $\mathcal{Z} \times \mathcal{B}_1$ is compact relative to the weak topology if $\mathcal{Z}$ is compact. This enables us to use the Riesz representation theorem on the underlying space $\Omega = \mathcal{Z} \times \mathcal{B}_1$ to show the following proposition.

Proposition 7 *For any compact set $\mathcal{Z} \subseteq \mathcal{X}$, and any continuous multi-task kernel K with feature representation Φ, we have that $\mathcal{C}_\Psi(\mathcal{Z} \times \mathcal{B}_1) = \mathcal{C}_J(\mathcal{Z} \times \mathcal{B}_1)$.*

Proof For any compact set $\mathcal{Z} \subseteq \mathcal{X}$, recall that $\mathcal{Z} \times \mathcal{B}_1$ is compact if $\mathcal{B}_1$ is endowed with the weak topology of $\mathcal{Y}$. Hence, the result follows by applying Theorem 4 in Micchelli et al. (2006) to the scalar kernel J on the set $\mathcal{Z} \times \mathcal{B}_1$ with the feature representation given by Equation (12). However, for the convenience of the reader we review the steps of the argument used to prove that theorem. The basic idea is the observation that two closed subspaces of a Banach space are equal if and only if whenever a continuous linear functional vanishes on either one of the subspaces, it must also vanish on the other one. This is a consequence of the Hahn-Banach Theorem (see, e.g., Lax, 2002). In the case at hand, we know by the Riesz Representation Theorem that all continuous linear functionals L on $\mathcal{C}(\mathcal{Z} \times \mathcal{B}_1)$ are given by a regular signed Borel measure ν, that is for every $F \in \mathcal{C}(\mathcal{Z} \times \mathcal{B}_1)$, we have that

$$L(F) = \int_{\mathcal{Z}\times\mathcal{B}_1} F(x,y) d\nu(x,y).$$

Now, suppose that L vanishes on $\mathcal{C}_J(\mathcal{Z} \times \mathcal{B}_1)$, then we conclude, by (12), that

$$0 = \int_{\mathcal{Z}\times\mathcal{B}_1} \int_{\mathcal{Z}\times\mathcal{B}_1} (\Psi(x,y), \Psi(t,u))_{\mathcal{W}} d\nu(x,y) d\nu(t,u).$$

Also, since K is assumed to be continuous relative to the operator norm and $\mathcal{Z}$ is compact we have that $\|\Psi(x,y)\|_{\mathcal{W}}^2 = \|\Psi(x)y\|_{\mathcal{W}}^2 = (K(x,x)y,y) \leq \sup_{x\in\mathcal{Z}} \|K(x,x)\| < \infty$. This together with the equation

$$\left\| \int_{\mathcal{Z}\times\mathcal{B}_1} \Psi(x,y) d\nu(x,y) \right\|_{\mathcal{W}} \leq \int_{\mathcal{Z}\times\mathcal{B}_1} \|\Psi(x,y) d\nu(x,y)\| \, d\nu(x,y) \leq \sup_x \|K(x,x)\| |\nu|(\mathcal{Z}\times\mathcal{B}_1)$$

imply that the integrand $\int_{\mathcal{Z}\times\mathcal{B}_1} \Psi(x,y) d\nu(x,y)$ exists. Consequently, it follows that

$$\int_{\mathcal{Z}\times\mathcal{B}_1} \int_{\mathcal{Z}\times\mathcal{B}_1} (\Psi(x,y), \Psi(t,u))_{\mathcal{W}} d\nu(x,y) d\nu(t,u) = \left\| \int_{\mathcal{Z}\times\mathcal{B}_1} \Psi(x,y) d\nu(x,y) \right\|_{\mathcal{W}}^2 \tag{13}$$

and, so, we conclude that

$$\int_{\mathcal{Z}\times\mathcal{B}_1} \Psi(x,y)d\nu(x,y) = 0. \tag{14}$$

The proof of Equation (13) and the interpretation of the $\mathcal{W}$-valued integral appearing in Equation (14) is explained in detail in Micchelli et al. (2006). So, we conclude that L vanishes on $\mathcal{C}_\Psi(\mathcal{Z}\times\mathcal{B}_1)$.

Conversely, if L vanishes on $\mathcal{C}_\Psi(\mathcal{Z}\times\mathcal{B}_1)$ then, for any $x\in\mathcal{Z}, y\in\mathcal{B}_1$, we have that

$$\int_{\mathcal{Z}\times\mathcal{B}_1} J((x,y),(t,u))d\nu(t,u) = \left(\Psi(x,y), \int_{\mathcal{Z}\times\mathcal{B}_1} \Psi(t,u)\nu(t,u)\right) = 0$$

that is, L vanishes on $\mathcal{C}_J(\mathcal{Z}\times\mathcal{B}_1)$. ■

4. Further Perspectives for Universality

In this section, we provide an alternate proof of Theorem 4 using the notion of vector measure and also highlight the notion of the annihilator of a set, a useful tool for our examples of multi-task kernels in Section 5.

At first glance, the reduction of the question of when a multi-task kernel is universal to the scalar case, as explained in Section 3, seems compelling. However, there are several reasons to explore alternate approaches to this problem. Firstly, from a practical point of view, if we view multi-task learning as a scalar problem we may loose the ability to understand cross task interactions. Secondly, only one tool to resolve a problem may limit the possibility of success. Finally, as we demonstrated in Section 3 universality of multi-task kernels concerns density in the subspace $\mathcal{C}_J(\mathcal{Z}\times\mathcal{B}_1)$, not the full space $\mathcal{C}(\mathcal{Z}\times\mathcal{B}_1)$, an issue heretofore not considered. Therefore, we cannot directly employ the methods of the scalar case as presented in (Micchelli et al., 2003) to the multi-task case.

As we shall see in this section, the concept of vector measure allows us to directly confront the set $\mathcal{C}(\mathcal{Z},\mathcal{Y})$ rather than following a circuitous path to $\mathcal{C}_J(\mathcal{Z}\times\mathcal{B}_1)$. However, the basic principle which we employ is the same, namely, two closed linear subspaces of a Banach space are equal if and only if whenever a bounded linear functional vanishes on one of them, it also vanishes on the other one. Thus, to implement this principle we are led to consider the dual space of $\mathcal{C}(\mathcal{Z},\mathcal{Y})$. We remark, in passing, that this space also arose in the context of the feature space perspective for learning the kernel, see Micchelli and Pontil (2005a). For a description of the dual space of $\mathcal{C}(\mathcal{Z},\mathcal{Y})$, we need the notion of vector measures and in this regard rely upon the information about them in Diestel and Uhl, Jr. (1977).

To introduce our first definition, recall that throughout this paper $\mathcal{X}$ denotes a Hausdorff space, $\mathcal{Z}\subseteq\mathcal{X}$ any compact subset of $\mathcal{X}$ and $\mathscr{B}(\mathcal{Z})$ the Borel σ-algebra of $\mathcal{Z}$.

Definition 8 *A map $\mu:\mathscr{B}(\mathcal{Z})\to\mathcal{Y}$ is called a Borel vector measure if μ is countably additive, that is, $\mu(\cup_{j=1}^\infty E_j) = \sum_{j=1}^\infty \mu(E_j)$ in the norm of $\mathcal{Y}$, for all sequences $\{E_j : j\in\mathbb{N}\}$ of pairwise disjoint sets in $\mathscr{B}(\mathcal{Z})$*

It is important to note that the definition of vector measure given in Diestel and Uhl, Jr. (1977) only requires it to be finitely additive. For our purpose here, we only use countably additive measures and thus do not require the more general setting used in Diestel and Uhl, Jr. (1977).

For any vector measure μ, the variation of μ is defined, for any $E \in \mathscr{B}(\mathcal{Z})$, by the equation

$$|\mu|(E) := \sup\left\{ \sum_{j\in\mathbb{N}} \|\mu(A_j)\| : \{A_j : j \in \mathbb{N}\} \text{ pairwise disjoint and } \cup_{j\in\mathbb{N}} A_j = E \right\}.$$

In our terminology we conclude from (Diestel and Uhl, Jr., 1977, p.3) that μ is a vector measure if and only if the corresponding variation $|\mu|$ is a scalar measure as explained in Section 3. Whenever $|\mu|(\mathcal{Z}) < \infty$, we call μ a vector measure of *bounded variation* on $\mathcal{Z}$. Moreover, we say that a Borel vector measure μ on $\mathcal{Z}$ is *regular* if its variation measure $|\mu|$ is regular as defined in Section 3. We denote by $\mathcal{M}(\mathcal{Z},\mathcal{Y})$ the Banach space of all vector measures with bounded variation and norm $\|\mu\| := |\mu|(\mathcal{Z})$.

For any scalar measure $\nu \in \mathcal{M}(\mathcal{Z}\times\mathcal{B}_1)$, we define a $\mathcal{Y}$-valued function on $\mathscr{B}(\mathcal{Z})$, by the equation

$$\mu(E) := \int_{E\times\mathcal{B}_1} y d\nu(x,y), \qquad \forall E \in \mathscr{B}(\mathcal{Z}). \tag{15}$$

Let us confirm that μ is indeed a vector measure. For this purpose, choose any sequence of pairwise disjoint subsets $\{E_j : j \in \mathbb{N}\} \subseteq \mathscr{B}(\mathcal{Z})$, and observe that

$$\sum_{j\in\mathbb{N}} \|\mu(E_j)\|_{\mathcal{Y}} \leq \sum_{j\in\mathbb{N}} \Big| \int_{E_j}\int_{\mathcal{B}_1} d\nu(x,y)\Big| \leq |\nu|(\mathcal{Z}\times\mathcal{B}_1),$$

which implies that $|\mu|(\mathcal{Z})$ is finite and, hence, μ is a regular vector measure. This observation suggests that we define, for any $f \in \mathcal{C}(\mathcal{Z},\mathcal{Y})$, the integral of f relative to μ as

$$\int_{\mathcal{Z}} (f(x), d\mu(x)) := \int_{\mathcal{Z}}\int_{\mathcal{B}_1} (f(x), y) d\nu(x,y). \tag{16}$$

Alternatively, by the standard techniques of measure theory, for any vector measure $\mu \in \mathcal{M}(\mathcal{Z},\mathcal{Y})$ the integral $\int_{\mathcal{Z}} (f(x), d\mu(x))$ is well-defined.

One of our goals below is to show that given any vector measure μ, there corresponds a scalar measure ν such that Equation (16) still holds. Before doing so, let us point out a useful property about the integral appearing in the left hand side of Equation (16). Specifically, for any $y \in \mathcal{Y}$, we associate to any $\mu \in \mathcal{M}(\mathcal{Z},\mathcal{Y})$, a scalar measure μ_y defined, for any $E \in \mathscr{B}(\mathcal{Z})$, by the equation $\mu_y(E) := (y, \mu(E))$. Therefore, we conclude, for any $f \in \mathcal{C}(\mathcal{Z})$, that

$$\int_{\mathcal{Z}} (y f(x), d\mu(x)) = \int_{\mathcal{Z}} f(x) d\mu_y(x).$$

To prepare for our description of the dual space of $\mathcal{C}(\mathcal{Z},\mathcal{Y})$, we introduce, for each $f \in \mathcal{C}(\mathcal{Z},\mathcal{Y})$, a linear functional L_μ defined by,

$$L_\mu f := \int_{\mathcal{Z}} (f(x), d\mu(x)). \tag{17}$$

Then, we have the following useful lemmas, see the appendix for their proofs.

Lemma 9 *If $\mu \in \mathcal{M}(\mathcal{Z},\mathcal{Y})$ then $L_\mu \in \mathcal{C}^*(\mathcal{Z},\mathcal{Y})$ and $\|L_\mu\| = \|\mu\|$.*

Lemma 10 *(Dinculeanu-Singer) For any compact set $\mathcal{Z} \subseteq \mathcal{X}$, the map $\mu \mapsto L_\mu$ is an isomorphism from $\mathcal{M}(\mathcal{Z},\mathcal{Y})$ to $C^*(\mathcal{Z},\mathcal{Y})$.*

Lemma 10 is a vector-valued form of the Riesz representation theorem called *Dinculeanu-Singer theorem*, (see, e.g., Diestel and Uhl, Jr., 1977, p.182). For completeness, we provide a self-contained proof in the appendix.

It is interesting to remark that, for any $\mu \in \mathcal{M}(\mathcal{Z},\mathcal{Y})$ we have established in the proof of Lemma 10 that there exists a regular scalar measure ν on $\mathcal{Z} \times \mathcal{B}_1$ such that

$$L_\mu f = \int_{\mathcal{Z}\times\mathcal{B}_1} (f(x),y) d\nu(x,y).$$

Since we established the isometry between $\mathcal{C}^*(\mathcal{Z},\mathcal{Y})$ and $\mathcal{M}(\mathcal{Z},\mathcal{Y})$, it follows that, for every regular vector measure there corresponds a scalar measure on $\mathcal{Z} \times \mathcal{B}_1$ for which Equation (15) holds true.

In order to provide our alternate proof of Theorem 4, we need to attend to one further issue. Specifically, we need to define the integral $\int_{\mathcal{Z}} K(t,x)(d\mu(x))$ as an element in $\mathcal{Y}$. For this purpose, for any $\mu \in \mathcal{M}(\mathcal{Z},\mathcal{Y})$ and $t \in \mathcal{Z}$ we define a linear functional L_t on $\mathcal{Y}$ at $y \in \mathcal{Y}$ as

$$L_t y := \int_{\mathcal{Z}} (K(x,t)y, d\mu(x)).$$

Since its norm has the property $\|L_t\| \leq \big(\sup_{x\in\mathcal{Z}} \|K(x,t)\|\big)\|\mu\|$, by the Riesz representation lemma, we conclude that there exists a unique element $\bar{y}$ in $\mathcal{Y}$ such that

$$\int_{\mathcal{Z}} (K(x,t)y, d\mu(x)) = (\bar{y}, y).$$

It is this vector $\bar{y}$ which we denote by the integral $\int_{\mathcal{Z}} K(t,x)(d\mu(x))$.

Similarly, we define the integral $\int_{\mathcal{Z}} \Phi(x)(d\mu(x))$ as an element in $\mathcal{W}$. To do this, we note that $\|\Phi(x)\| = \|\Phi^*(x)\|$ and $\|\Phi^*(x)y\|^2 = \langle K(x,x)y, y\rangle$. Hence, we conclude that there exists a constant κ such that, for all $x \in \mathcal{X}$, $\|\Phi(x)\| \leq \|K(x,x)\|^{\frac{1}{2}} \leq \kappa$. Consequently, the linear functional L on $\mathcal{W}$ defined, for any $w \in \mathcal{W}$, by

$$L(w) := \int_{\mathcal{Z}} \Big(\Phi^*(x)w, d\mu(x)\Big)$$

satisfies the inequality $\|L\| \leq \kappa\|\mu\|$. Hence, we conclude that there exists a unique element $\bar{w} \in \mathcal{W}$ such that $L(w) = (\bar{w}, w)$ for any $w \in \mathcal{W}$. Now, we denote $\bar{w}$ by $\int_{\mathcal{Z}} \Phi(x)(d\mu(x))$ which means that

$$\Big(\int_{\mathcal{Z}} \Phi(x)(d\mu(x)), w\Big)_{\mathcal{W}} = \int_{\mathcal{Z}} \Big(\Phi^*(x)w, d\mu(x)\Big). \tag{18}$$

We have now assembled all the necessary properties of vector measures to provide an alternate proof of Theorem 4.

Alternate Proof of Theorem 4. We see from the feature representation (7) that

$$\int_{\mathcal{Z}} K(t,x)(d\mu(x)) = \int_{\mathcal{Z}} \Phi^*(t)\Phi(x)(d\mu(x)) = \Phi^*(t)\Big(\int_{\mathcal{Z}} \Phi(x)(d\mu(x))\Big), \quad \forall t \in \mathcal{Z}.$$

From this equation, we easily see that if $\int_{\mathcal{Z}} \Phi(x)(d\mu(x)) = 0$ then, for every $t \in \mathcal{Z}$, $\int_{\mathcal{Z}} K(t,x)(d\mu(x)) = 0$. On the other hand, applying (18) with the choice $w = \int_{\mathcal{Z}} \Phi(x)(d\mu(x))$ we get

$$\int_{\mathcal{Z}} \left(\Phi^*(t) \int_{\mathcal{Z}} \Phi(x)(d\mu(x)), d\mu(t) \right) = \left\| \int_{\mathcal{Z}} \Phi(x)(d\mu(x)) \right\|_{\mathcal{W}}^2.$$

Therefore, if, for any $t \in \mathcal{Z}$, $\int_{\mathcal{Z}} K(t,x)(d\mu(x)) = 0$ then $\int_{\mathcal{Z}} \Phi(x)(d\mu(x)) = 0$, or equivalently, by Equation (18),

$$\int_{\mathcal{Z}} (\Phi^*(x)w, d\mu(x)) = 0, \quad \forall w \in \mathcal{W}.$$

Consequently, a linear functional vanishes on $\mathcal{C}_K(\mathcal{Z},\mathcal{Y})$ if and only if it vanishes on $\mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y})$ and thus, we obtained that $\mathcal{C}_K(\mathcal{Z},\mathcal{Y}) = \mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y})$. ■

We end this section with a review of our approach to the question of universality of multi-task kernels. The principal tool we employ is a notion of functional analysis referred to as the *annihilator* set. Recall the notion of the annihilator of a set $\mathcal{V}$ which is defined by

$$\mathcal{V}^\perp := \left\{ \mu \in \mathcal{M}(\mathcal{Z},\mathcal{Y}) \ : \ \int_{\mathcal{Z}} (v(x), d\mu(x)) = 0, \forall v \in \mathcal{V} \right\}.$$

Notice that the annihilator of the closed linear span of $\mathcal{V}$ is the same as that of $\mathcal{V}$. Consequently, by applying the basic principle stated at the beginning of this section , we conclude that the linear span of $\mathcal{V}$ is dense in $\mathcal{C}(\mathcal{Z},\mathcal{Y})$, that is, $\overline{\text{span}}(\mathcal{V}) = \mathcal{C}(\mathcal{Z},\mathcal{Y})$ if and only if the annihilator $\mathcal{V}^\perp = \{0\}$. Hence, applying this observation to the set of kernel sections $K(\mathcal{Z}) := \{K(\cdot,x)y : \ x \in \mathcal{Z}, \ y \in \mathcal{Y}\}$ or to the set of its corresponding feature sections $\Phi(\mathcal{Z}) := \{\Phi^*(\cdot)w : w \in \mathcal{W}\}$, we obtain from Lemma 10 and Theorem 4, the summary of our main result.

Theorem 11 *Let $\mathcal{Z}$ be a compact subset of $\mathcal{X}$, K a continuous multi-task kernel, and Φ its feature representation. Then, the following statements are equivalent.*

1. $\mathcal{C}_K(\mathcal{Z},\mathcal{Y}) = \mathcal{C}(\mathcal{Z},\mathcal{Y})$.
2. $\mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y}) = \mathcal{C}(\mathcal{Z},\mathcal{Y})$.
3. $K(\mathcal{Z})^\perp = \left\{ \mu \in \mathcal{M}(\mathcal{Z},\mathcal{Y}) \ : \ \int_{\mathcal{Z}} K(t,x)(d\mu(x)) = 0, \ \forall t \in \mathcal{Z} \right\} = \{0\}$.
4. $\Phi(\mathcal{Z})^\perp = \left\{ \mu \in \mathcal{M}(\mathcal{Z},\mathcal{Y}) \ : \ \int_{\mathcal{Z}} \Phi(x)(d\mu(x)) = 0 \right\} = \{0\}$.

5. Universal Kernels

In this section, we prove the universality of some kernels, based on Theorem 11 developed above. Specifically, the examples highlighted in Section 2 will be discussed in detail.

Kernel's universality is a main hypothesis in the proof of consistency of learning algorithms. Universal consistency of the regularized least-squares algorithm over vector-valued RKHS was proved in Caponnetto and De Vito (2006); there, it was assumed that, in addition to universality of the kernel, the trace of the operators $K(x,x)$ is finite. In particular, this extra condition on the kernel holds, for the Example 1 highlighted in Section 2, when the operators B_j are trace class, and does not hold for Example 4. It is not clear to the authors whether the finite trace condition is necessary for consistency.

5.1 Product of Scalar Kernels and Operators

Our first example is produced by coupling a scalar kernel with an operator in $\mathcal{L}_+(\mathcal{Y})$. Given a scalar kernel G on $\mathcal{X}$ and an operator $B \in \mathcal{L}_+(\mathcal{Y})$, we define the function $K : \mathcal{X} \times \mathcal{X} \to \mathcal{L}(\mathcal{Y})$ by

$$K(x,t) = G(x,t)B, \quad \forall x,t \in \mathcal{X}. \tag{19}$$

For any $\{x_j \in \mathcal{X} : j \in \mathbb{N}_m\}$ and $\{y_j \in \mathcal{Y} : j \in \mathbb{N}_m\}$, we know that $(G(x_i,x_j))_{i,j\in\mathbb{N}_m}$ and $((By_i,y_j))_{i,j\in\mathbb{N}_m}$ are positive semi-definite. Applying Schur's lemma implies that the matrix $(G(x_i,x_j)(By_i,y_j))_{i,j\in\mathbb{N}_m}$ is positive semi-definite and hence, K is positive semi-definite. Moreover, $K^*(x,t) = K(x,t) = K(t,x)$ for any $x,t \in \mathcal{X}$. Therefore, we conclude by Definition 1 that K is a multi-task kernel.

Our goal below is to use the feature representation of the scalar kernel G to introduce the corresponding one for kernel K. To this end, we first let $\mathcal{W}$ be a Hilbert space and $\phi : \mathcal{X} \to \mathcal{W}$ a feature map of the scalar kernel G, so that

$$G(x,t) = (\phi(x),\phi(t))_{\mathcal{W}}, \qquad \forall x,t \in \mathcal{X}.$$

Then, we introduce the *tensor vector space* $\mathcal{W} \bigotimes \mathcal{Y}$. Algebraically, this vector space is spanned by elements of the form $w \otimes y$ with $w \in \mathcal{W}, y \in \mathcal{Y}$. For any $w_1 \otimes y_1, w_2 \otimes y_2 \in \mathcal{W} \bigotimes \mathcal{Y}$ and $c \in \mathbb{R}$, there holds the multi-linear relation

$$cw \otimes y = w \otimes cy = c(w \otimes y), \quad (w_1 + w_2) \otimes y = w_1 \otimes y + w_2 \otimes y,$$

and

$$w \otimes (y_1 + y_2) = w \otimes y_1 + w \otimes y_2.$$

We can turn the tensor space into an inner product space by defining, for any $w_1 \otimes y_1, w_2 \otimes y_2 \in \mathcal{W} \bigotimes \mathcal{Y}$,

$$\langle w_1 \otimes y_1, w_2 \otimes y_2 \rangle = (w_1,w_2)_{\mathcal{W}}(y_1,y_2)_{\mathcal{Y}}$$

and extending by linearity. Finally, taking the completion under this inner product, the vector space $\mathcal{W} \bigotimes \mathcal{Y}$ becomes a Hilbert space. Furthermore, if $\mathcal{W}$ and $\mathcal{Y}$ have orthonormal bases $\{w_i : i \in \mathbb{N}\}$ and $\{y_i : i \in \mathbb{N}\}$ respectively, then $\mathcal{W} \bigotimes \mathcal{Y}$ is exactly the Hilbert space spanned by the orthonormal basis $\{w_i \otimes y_j : i,j \in \mathbb{N}\}$ under the inner product defined above. For instance, if $\mathcal{W} = \mathbb{R}^k$ and $\mathcal{Y} = \mathbb{R}^n$, then $\mathcal{W} \bigotimes \mathcal{Y} = \mathbb{R}^{kn}$.

The above tensor product suggests that we define the map $\Phi : \mathcal{X} \to \mathcal{L}(\mathcal{Y}, \mathcal{W} \otimes \mathcal{Y})$ of kernel K by

$$\Phi(x)y := \phi(x) \otimes \sqrt{B}y, \qquad \forall x \in \mathcal{X},\ y \in \mathcal{Y},$$

and it follows that $\Phi^* : \mathcal{X} \to \mathcal{L}(\mathcal{W} \otimes \mathcal{Y}, \mathcal{Y})$ is given by

$$\Phi^*(x)(w \otimes y) := (\phi(x),w)_{\mathcal{W}}\sqrt{B}y, \quad \forall x \in \mathcal{X}, w \in \mathcal{W}, \text{ and } y \in \mathcal{Y}. \tag{20}$$

From the above observation, it is easy to check, for any $x,t \in \mathcal{X}$ and $y,u \in \mathcal{Y}$, that $(K(x,t)y,u) = \langle \Phi(x)y, \Phi(t)u \rangle$. Therefore, we conclude that Φ is a feature map for the multi-task kernel K.

Finally, we say that an operator $B \in \mathcal{L}_+(\mathcal{Y})$ is *positive definite* if (By,y) is positive whenever y is nonzero. We are now ready to present the result on universality of kernel K.

Theorem 12 *Let $G : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a continuous scalar kernel, $B \in \mathcal{L}_+(\mathcal{Y})$ and K be defined by Equation (19). Then, K is a multi-task universal kernel if and only if the scalar kernel G is universal and the operator B is positive definite.*

Proof By Theorem 11 and the feature representation (20), we only need to show that $\Phi(\mathcal{Z})^\perp = \{0\}$ if and only if G is universal and the operator B is positive definite.

We begin with the sufficiency. Suppose that there exists a nonzero vector measure μ such that, for any $w \otimes y \in \mathcal{W} \otimes \mathcal{Y}$, there holds

$$\int_{\mathcal{Z}} (\Phi^*(x)(w \otimes y), d\mu(x)) = \int_{\mathcal{Z}} (\phi(x), w)_{\mathcal{W}} (\sqrt{B}y, d\mu(x)) = 0. \tag{21}$$

Here, with a little abuse of notation we interpret, for a fixed $y \in \mathcal{Y}$, $(\sqrt{B}y, d\mu(x))$ as a scalar measure defined, for any $E \in \mathscr{B}(\mathcal{Z})$, by

$$\int_E (\sqrt{B}y, d\mu(x)) = (\sqrt{B}y, \mu(E)).$$

Since $\mu \in \mathcal{M}(\mathcal{Z}, \mathcal{Y})$, $(\sqrt{B}y, d\mu(x))$ is a regular signed scalar measure. Therefore, we see from (21) that $(\sqrt{B}y, d\mu(x)) \in \phi(\mathcal{Z})^\perp$ for any $y \in \mathcal{Y}$. Remember that G is universal if and only if $\phi(\mathcal{Z})^\perp = \{0\}$, and thus we conclude from (21) that $(\sqrt{B}y, d\mu(x)) = 0$ for any $y \in \mathcal{Y}$. It follows that $(\sqrt{B}y, \mu(E)) = 0$ for any $y \in \mathcal{Y}$ and $E \in \mathscr{B}(\mathcal{Z})$. Thus, for any fixed set E taking the choice $y = \sqrt{B}\mu(E)$ implies that $(B\mu(E), \mu(E)) = 0$. Since E is arbitrary, this means $\mu = 0$ and thus finishes the proof for the sufficiency.

To prove the necessity, suppose first that G is not universal and hence, we know that, for some compact subset $\mathcal{Z}$ of $\mathcal{X}$, there exists a nonzero scalar measure $\nu \in \mathcal{M}(\mathcal{Z})$ such that $\nu \in \phi(\mathcal{Z})^\perp$, that is, $\int_{\mathcal{Z}} (\phi(x), w) d\nu(x) = 0$ for any $w \in \mathcal{W}$. This suggests to us to choose, for a nonzero $y_0 \in \mathcal{Y}$, the nonzero vector measure $\mu = y_0\nu$ defined by $\mu(E) := y_0\nu(E)$ for any $E \in \mathscr{B}(\mathcal{Z})$. Hence, the integral in Equation (21) equals

$$\int_{\mathcal{Z}} (\Phi^*(x)(w \otimes y), d\mu(x)) = (\sqrt{B}y, y_0) \int_{\mathcal{Z}} (\phi(x), w)_{\mathcal{W}} d\nu(x) = 0.$$

Therefore, we conclude that there exists a nonzero vector measure $\mu \in \Phi(\mathcal{Z})^\perp$, which implies that K is not universal.

If B is not positive definite, namely, there exists a nonzero element $y_1 \in \mathcal{Y}$ such that $(By_1, y_1) = 0$. However, we observe that $\|\sqrt{B}y_1\|^2 = (By_1, y_1)$ which implies that $\sqrt{B}y_1 = 0$. This suggests to us to choose a nonzero vector measure $\mu = y_1\nu$ with some nonzero scalar measure ν. Therefore, we conclude, for any $w \in \mathcal{W}$ and $y \in \mathcal{Y}$, that

$$\begin{aligned} \int_{\mathcal{Z}} (\Phi^*(x)(w \otimes y), d\mu(x)) &= (\sqrt{B}y, y_1) \int_{\mathcal{Z}} (\phi(x), w)_{\mathcal{W}} d\nu(x) \\ &= (y, \sqrt{B}y_1) \int_{\mathcal{Z}} (\phi(x), w)_{\mathcal{W}} d\nu(x) = 0, \end{aligned}$$

which implies that the nonzero vector measure $\mu \in \Phi(\mathcal{Z})^\perp$. This finishes the proof of the theorem. ■

In the special case $\mathcal{Y} = \mathbb{R}^n$, the operator B is an $n \times n$ positive semi-definite matrix. Then, Theorem 12 tells us that the matrix-valued kernel $K(x,t) := G(x,t)B$ is universal if and only if G is universal and the matrix B is of full rank.

We now proceed further and consider kernels produced by a finite combination of scalar kernels and operators. Specifically, we consider, for any $j \in \mathbb{N}_m$, that $G_j : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a scalar kernel and $B_j \in \mathcal{L}_+(\mathcal{Y})$. We are interested in the kernel defined, for any $x,t \in \mathcal{X}$, by

$$K(x,t) := \sum_{j\in\mathbb{N}_m} G_j(x,t)B_j.$$

Suppose also, for each scalar kernel G_j, that there exists a Hilbert feature space $\mathcal{W}_j$ and a feature map $\phi_j : \mathcal{X} \to \mathcal{W}_j$.

To explain the associated feature map of kernel K, we need to define its feature space. For this purpose, let H_j be a Hilbert space with inner products $(\cdot,\cdot)_j$ for $j \in \mathbb{N}_m$ and we introduce the *direct sum Hilbert space* $\oplus_{j\in\mathbb{N}_m} H_j$ as follows. The elements in this space are of the form $(h_1,\ldots,h_m)$ with $h_j \in H_j$, and its inner product is defined, for any $(h_1,\ldots,h_m),(h'_1,\ldots,h'_m) \in \oplus_{j\in\mathbb{N}_m} H_j$, by

$$\langle (h_1,\ldots,h_m),(h'_1,\ldots,h'_m)\rangle := \sum_{j\in\mathbb{N}_m} (h_j,h'_j)_j.$$

This observation suggests to us to define the feature space of kernel K by the direct sum Hilbert space $\mathcal{W} := \oplus_{j\in\mathbb{N}_m}(\mathcal{W}_j \otimes \mathcal{Y})$, and its the map $\Phi : \mathcal{X} \to \mathcal{L}(\mathcal{Y},\mathcal{W})$, for any $x \in \mathcal{X}$ and $y \in \mathcal{Y}$, by

$$\Phi(x)y := (\phi_1(x) \otimes \sqrt{B_1}\, y, \ldots, \phi_m(x) \otimes \sqrt{B_m}\, y). \tag{22}$$

Hence, its adjoint operator $\Phi^* : \mathcal{X} \to \mathcal{L}(\oplus_{j\in\mathbb{N}_m}(\mathcal{W}_j \otimes \mathcal{Y}),\mathcal{Y})$ is given, for any $(w_1 \otimes y_1,\ldots,w_m \otimes y_m) \in \oplus_{j\in\mathbb{N}_m}(\mathcal{W}_j \otimes \mathcal{Y})$, by

$$\Phi^*(x)((w_1 \otimes y_1,\ldots,w_m \otimes y_m)) := \sum_{j\in\mathbb{N}_m} (\phi_j(x),w_j)_{\mathcal{W}_j} \sqrt{B_j}\, y_j.$$

Using the above observation, it is easy to see that, for any $x,t \in \mathcal{X}$, $K(x,t) = \Phi^*(x)\Phi(t)$. Thus K is a multi-task kernel and Φ is a feature map of K.

We are now in a position to state the result about the universality of the kernel K.

Theorem 13 *Suppose that $G_j : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is a continuous scalar universal kernel, and $B_j \in \mathcal{L}_+(\mathcal{Y})$ for $j \in \mathbb{N}_m$. Then, $K(x,t) := \sum_{j\in\mathbb{N}_m} G_j(x,t)B_j$ is universal if and only if $\sum_{j\in\mathbb{N}_m} B_j$ is positive definite.*

Proof Following Theorem 11, we need to prove that $\Phi(\mathcal{Z})^\perp = \{0\}$ for any compact set $\mathcal{Z}$ if and only if $\sum_{j\in\mathbb{N}_m} B_j$ is positive definite. To see this, observe that $\mu \in \Phi(\mathcal{Z})^\perp$ implies, for any $(w_1 \otimes y_1,\ldots,w_m \otimes y_m) \in \oplus_{j\in\mathbb{N}_m}(\mathcal{W}_j \otimes \mathcal{Y})$, that

$$\int_{\mathcal{Z}} \sum_{j\in\mathbb{N}_m} (\phi_j(x),w_j)_{\mathcal{W}_j}(\sqrt{B_j}\, y_j, d\mu(x)) = 0.$$

Since $w_j \in \mathcal{W}_j$ is arbitrary, the above equation is equivalent to

$$\int_{\mathcal{Z}} (\phi_j(x),w_j)_{\mathcal{W}_j}(\sqrt{B_j}\, y_j, d\mu(x)) = 0, \ \ \forall w_j \in \mathcal{W}_j, y_j \in \mathcal{Y} \text{ and } j \in \mathbb{N}_m, \tag{23}$$

which implies that $(\sqrt{B_j}\, y_j, d\mu(x)) \in \phi(\mathcal{Z})^\perp$ for any $j \in \mathbb{N}_m$. Recall that G_j is universal if and only if $\phi(\mathcal{Z})^\perp = \{0\}$. Therefore, Equation (23) holds true if and only if

$$(\mu(E), \sqrt{B_j}\, y_j) = (\sqrt{B_j}\mu(E), y_j) = 0, \quad \forall E \in \mathscr{B}(\mathcal{Z}), \ \ y_j \in \mathcal{Y}, j \in \mathbb{N}_m. \tag{24}$$

To move on to the next step, we will show that Equation (24) is true if and only if

$$(\mu(E), B_j\mu(E)) = 0, \quad \forall E \in \mathscr{B}(\mathcal{Z}), j \in \mathbb{N}_m. \tag{25}$$

To see this, we observe, for any $j \in \mathbb{N}_m$, that $\|\sqrt{B_j}\mu(E)\|^2 = (\mu(E), B_j\mu(E))$. Hence, Equation (25) implies Equation (24). Conversely, applying Equation (24) with the choice $y_j = \mu(E)$ directly yields Equation (25).

Moreover, we know, for any $y \in \mathcal{Y}$ and $j \in \mathbb{N}_m$, that $(B_j y, y)$ is nonnegative. Therefore, Equation (25) is equivalent to that

$$\big((\sum_{j\in\mathbb{N}_m} B_j)\mu(E), \mu(E)\big) = 0, \quad \forall E \in \mathscr{B}(\mathcal{Z}). \tag{26}$$

Therefore, we conclude that $\mu \in \Phi(\mathcal{Z})^\perp$ if and only if the above equation holds true.

Obviously, by Equation (26), we see that if $\sum_{j\in\mathbb{N}_m} B_j$ is positive definite then $\mu = 0$. This means that kernel K is universal. Suppose that $\sum_{j\in\mathbb{N}_m} B_j$ is not positive definite, that is, there exists a nonzero $y_0 \in \mathcal{Y}$ such that $\|\big(\sum_{j\in\mathbb{N}_m} B_j\big)^{\frac{1}{2}} y_0\|^2 := \big((\sum_{j\in\mathbb{N}_m} B_j)y_0, y_0\big) = 0$. Hence, choosing a nonzero vector measure $\mu := y_0\nu$, with ν a nonzero scalar measure, implies that Equation (26) holds true and, thus kernel K is not universal. This finishes the proof of the theorem. ■

Now we are in a position to analyze Examples 1 and 4 given in the Section 2. Since the function K considered in Example 1 is in the form of (22), we conclude that it is a multi-task kernel.

We now discuss a class of kernels which includes that presented in Example 4. To this end, we use the notation $\mathbb{Z}_+ = \{0\} \cup \mathbb{N}$ and, for any smooth function $f : \mathbb{R}^m \to \mathbb{R}$ and index $\alpha = (\alpha_1, \ldots, \alpha_m) \in \mathbb{Z}_+^m$, we denote the α-th partial derivative by $\partial^\alpha f(x) := \frac{\partial^{|\alpha|} f(x)}{\partial^{\alpha_1} x_1 \ldots \partial^{\alpha_m} x_m}$. Then, recall that the Sobolev space W^k with integer order k is the space of real valued functions with norm defined by

$$\|f\|_{W^k}^2 := \sum_{|\alpha|\le k} \int_{\mathbb{R}^m} |\partial^\alpha f(x)|^2 dx, \tag{27}$$

where $|\alpha| = \sum_{j\in\mathbb{N}_m} \alpha_j$, see Stein (1970). This space can be extended to any fractional index $s > 0$. To see this, we need the Fourier transform defined, for any $f \in L^1(\mathbb{R}^m)$, as

$$\hat{f}(\xi) := \int_{\mathbb{R}^m} e^{-2\pi i\langle x,\xi\rangle} f(x) dx, \qquad \forall \xi \in \mathbb{R}^m,$$

see Stein (1970). It has a natural extension to $L^2(\mathbb{R}^m)$ satisfying the Plancherel formula $\|f\|_{L^2(\mathbb{R}^m)} = \|\hat{f}\|_{L^2(\mathbb{R}^m)}$. In particular, we observe, for any $\alpha = (\alpha_1, \ldots, \alpha_m) \in \mathbb{Z}_+^m$ and $\xi = (\xi_1, \ldots, \xi_m) \in \mathbb{R}^m$, that $\widehat{\partial^\alpha f}(\xi) = \hat{f}(\xi)(2\pi i\xi_1)^{\alpha_1} \ldots (2\pi i\xi_m)^{\alpha_m}$. Hence, by Plancherel formula, we see, for any $f \in W^k$ with $k \in \mathbb{N}$, that its norm $\|f\|_{W^k}$ is equivalent to

$$\Big(\int_{\mathbb{R}^m} (1 + 4\pi\|\xi\|^2)^k |\hat{f}(\xi)|^2 d\xi\Big)^{\frac{1}{2}}.$$

This observation suggests to us to introduce fractional Sobolev space W^s (see, e.g., Stein, 1970) with any order $s > 0$ with norm defined, for any function f, by

$$\|f\|_{W^s}^2 := \int_{\mathbb{R}^m} (1 + 4\pi^2\|\xi\|^2)^s |\hat{f}(\xi)|^2 d\xi.$$

Finally, we need the Sobolev embedding lemma which states that, for any $s > \frac{m}{2}$, there exists an absolute constant c such that, for any $f \in W^s$ and any $x \in \mathbb{R}^m$, there holds

$$|f(x)| \leq c\|f\|_{W^s},$$

(see, e.g., Folland, 1999; Stein, 1970).

The next result extends Example 4 to multivariate functions.

Proposition 14 *Let $\mathcal{Y} = L^2(\mathbb{R}^d)$, $\mathcal{X} = \mathbb{R}$ and $\mathcal{H}$ be the space of real-valued functions with norm*

$$\|f\|^2 := \int_{\mathbb{R}} \Big[\Big\| f(x,\cdot) \Big\|^2_{W^{\frac{d+1}{2}}} + \Big\| \frac{\partial f}{\partial x}(x,\cdot) \Big\|^2_{W^{\frac{d+1}{2}}} \Big] dx.$$

Then this is an RKHS with universal multi-task kernel given, for every $x,t \in \mathcal{X}$ by

$$(K(x,t)y)(r) = e^{-\pi|x-t|} \int_{\mathbb{R}^d} e^{-\pi\|r-s\|} y(s) ds, \;\; \forall y \in \mathcal{Y}, \; r \in \mathbb{R}^d. \tag{28}$$

Proof For any fixed $t \in \mathbb{R}^d$, it follows from the Sobolev embedding lemma that

$$|f(x,t)| \leq c\|f(\cdot,t)\|_{W^1}.$$

Combining this with the definition of Sobolev space W^1 given by Equation (27), we have that

$$\begin{aligned} \|f(x)\|^2_{\mathcal{Y}} &\leq c^2 \int_{\mathbb{R}^d} \|f(\cdot,t)\|^2_{W^1} dt \\ &= c^2 \int_{\mathbb{R}^d} \Big(\int_{\mathbb{R}} |f(x,t)|^2 + |\frac{\partial f}{\partial x}(x,t)|^2 dt \Big) dx \leq c^2 \|f\|^2. \end{aligned}$$

Since, for any $y \in \mathcal{B}_1$ and $x \in \mathbb{R}$, $|(y, f(x))_{\mathcal{Y}}| \leq \|y\|_{\mathcal{Y}} \|f(x)\|_{\mathcal{Y}} \leq \|f(x)\|_{\mathcal{Y}}$, by the above equation there exists a constant c' such that, for any $y \in \mathcal{B}_1, x \in \mathbb{R}$ and $f \in \mathcal{H}$,

$$|(y, f(x))_{\mathcal{Y}}| \leq c'\|f\|.$$

Hence, by the Riesz representation lemma, $\mathcal{H}$ is an RKHS (Micchelli and Pontil, 2005).

Next, we confirm Equation (28) is the kernel associated to $\mathcal{H}$. To this end, it suffices to show that the reproducing property holds, that is, for any $f \in \mathcal{H}$, $y \in \mathcal{Y}$ and $x \in \mathcal{X}$

$$(y, f(x))_{\mathcal{Y}} = \langle K_x y, f \rangle, \tag{29}$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product in $\mathcal{H}$.

By the Plancherel formula, we observe that the left-hand side of Equation (29) equals

$$\int_{\mathbb{R}^d} \hat{y}(\tau) \Big[\overline{\int_{\mathbb{R}} e^{2\pi i \langle x,\xi \rangle} \hat{f}(\xi,\tau) d\xi} \Big] d\tau = \int_{\mathbb{R}^d} \int_{\mathbb{R}} \hat{y}(\tau) e^{-2\pi i \langle x,\xi \rangle} \overline{\hat{f}(\xi,\tau)} d\xi d\tau.$$

On the other hand, note that $K_x y(x') := K(x',x)y \in \mathcal{Y}$, and consider its Fourier transform

$$(\widehat{K}(\cdot,x)y)(\xi,\tau) = \int_{\mathbb{R}^d} \int_{\mathbb{R}} e^{-2\pi i \langle x',\xi \rangle} e^{-2\pi i \langle r,\tau \rangle} (K(x',x)y)(r) dr dx'.$$

Using Equation (28) and the Plancherel formula, the integral on the right hand of the above equation is equal to

$$\frac{e^{-2\pi i\langle x,\xi\rangle}}{(1+4\pi^2|\xi|^2)}\frac{\hat{y}(\tau)}{(1+4\pi^2\|\tau\|^2)^{\frac{d+1}{2}}}. \tag{30}$$

However, the right-hand side of Equation (29) is identical to

$$\int_{\mathbb{R}^d}\int_{\mathbb{R}}(\widehat{K}(\cdot,x)y)(\xi,\tau)\overline{\hat{f}(\xi,\tau)}(1+4\pi^2|\xi|^2)(1+4\pi^2\|\tau\|^2)^{\frac{d+1}{2}}d\tau d\xi.$$

Putting (30) into the above equation, we immediately know that the reproducing property (29) holds true. This verifies that K is the reproducing kernel of the Hilbert space $\mathcal{H}$.

To prove the universality of this kernel, let $\mathcal{Z}$ be any prescribed compact subset of $\mathcal{X}$, we define the Laplace kernel, for any $x,t\in\mathbb{R}$, by $G(x,t):=e^{-|x-t|}$ and the operator $B:L^2(\mathbb{R}^d)\to L^2(\mathbb{R}^d)$ by

$$Bg(r):=\int_{\mathbb{R}^d}e^{-\|r-s\|}g(s)ds,\ \ \forall\, r\in\mathbb{R}^d.$$

Then, $K(x,t)=e^{-|x-t|}B$ and moreover

$$\widehat{Bg}(\tau)=c_d\frac{\hat{g}(\tau)}{(1+4\pi^2\|\tau\|^2)^{\frac{d+1}{2}}}. \tag{31}$$

By Theorem 12, it now suffices to prove that G is universal and B is positive definite. To this end, note that there exists c_d such that

$$G(x,t)=c_d\int_{\mathbb{R}}\frac{e^{-2\pi i\langle x-t,\xi\rangle}}{1+4\pi^2|\xi|^2}d\xi.$$

Since the weight function $\frac{1}{1+4\pi^2|\xi|^2}$ is positive, G is universal according to Micchelli et al. (2003).

To show the positive definiteness of B, we obtain from Equation (31) and the Plancherel formula that

$$(Bg,g)=c_d\int_{\mathbb{R}^d}\frac{|\hat{g}(\tau)|^2d\tau}{(1+4\pi^2\|\tau\|^2)^{\frac{d+1}{2}}}.$$

From this observation, the assertion follows. ■

We now discuss continuous parameterized multi-task kernels. For this purpose, let Ω be a locally compact Hausdorff space and, for any $\omega\in\Omega$, $B(\omega)$ be an $n\times n$ positive semi-definite matrix. We are interested in the kernel of the following form

$$K(x,t)=\int_{\Omega}G(\omega)(x,t)B(\omega)dp(\omega),\quad \forall x,t\in\mathcal{X}, \tag{32}$$

where p is a measure on Ω. We investigate this kernel in the case that, for any $\omega\in\Omega$, $G(\omega)$ is a scalar kernel with a feature representation given, for any $x,t\in\mathcal{X}$, by the formula $G(\omega)(x,t)=\langle\phi_\omega(x),\phi_\omega(t)\rangle_{\mathcal{W}}$. Now, we introduce the Hilbert space $\widetilde{\mathcal{W}}=L^2(\Omega,\mathcal{W}\otimes\mathcal{Y},p)$ with norm defined, for any $f:\Omega\to\mathcal{W}\otimes\mathcal{Y}$, by

$$\|f\|^2_{\widetilde{\mathcal{W}}}:=\int_{\Omega}\|f(\omega)\|^2_{\mathcal{W}\otimes\mathcal{Y}}dp(\omega).$$

Next, we define a map $\Phi : \mathcal{X} \to \mathcal{L}(\mathcal{Y}, L^2(\Omega, \mathcal{W} \otimes \mathcal{Y}, p))$, for any $x \in \mathcal{X}$ and $\omega \in \Omega$, by

$$\Phi(x)y(\omega) := \phi_\omega(x) \otimes (\sqrt{B(\omega)}y).$$

By an argument similar to that used just before Theorem 13, we conclude that K is a multi-task kernel and has the feature map Φ with feature space $\widetilde{\mathcal{W}}$.

We are ready to present a sufficient condition on the universality of K.

Theorem 15 *Let p be a measure on Ω and for every ω in the support of p, let $G(\omega)$ be a continuous universal kernel and $B(\omega)$ a positive definite operator. Then, the multi-task kernel K defined by Equation (32) is universal.*

Proof Following Theorem 11, for a compact set $\mathcal{Z} \subseteq \mathcal{X}$ suppose that there exists a vector measure μ such that

$$\int_{\mathcal{Z}} \phi_\omega(x) \otimes \sqrt{B(\omega)}(d\mu(x)) = 0.$$

Therefore, there exists a $\omega_0 \in \text{support}(p)$ satisfying $\int_{\mathcal{Z}} \phi_{\omega_0}(x) \otimes \sqrt{B(\omega_0)}\big(d\mu(x)\big) = 0$. Equivalently, $\int_{\mathcal{Z}} \phi_{\omega_0}(x)\big(\sqrt{B(\omega_0)}d\mu(x), y\big) = 0$ for any $y \in \mathcal{Y}$. Since we assume $G(\omega_0)$ is universal, appealing to the feature characterization in the scalar case (Micchelli et al., 2006) implies that the scalar measure $(\sqrt{B(\omega_0)}d\mu(x), y) = 0$. Consequently, we obtain that $\mu \equiv 0$ since $y \in \mathcal{Y}$ is arbitrary. This completes the proof of this theorem. ■

Next we offer a concrete example of the above theorem.

Example 5 *Suppose the measure p over $[0,\infty)$ does not concentrate on zero and $B(\omega)$ be a positive definite $n \times n$ matrix for each $\omega \in (0,\infty)$. Then the kernel $K(x,t) = \int_0^\infty e^{-\omega\|x-t\|^2} B(\omega)dp(\omega)$ is a multi-task universal kernel.*

Further specializing this example, we choose the measure p to be the Lebesgue measure on $[0,\infty)$ and choose $B(\omega)$ in the following manner. Let A be $n \times n$ symmetric matrices. For every $\omega > 0$, we define the (i,j)-th entry of the matrix $B(\omega)$ as $e^{-\omega A_{ij}}$, $i, j \in \mathbb{N}_n$. Recall that a matrix A is *conditionally negative semi-definite* if, for any $c_i \in \mathbb{R}, i \in \mathbb{N}_n$ with $\sum_{i\in\mathbb{N}_n} c_i = 0$, then the quadratic form satisfies $\sum_{i,j\in\mathbb{N}_n} c_i A_{ij} c_j \leq 0$. A well-known theorem of I. J. Schoenberg (see, e.g., Micchelli, 1986) state that $B(\omega)$ is positive semi-definite for all $\omega > 0$ if and only if A is conditionally negative semi-definite. Moreover, if the elements of the conditionally negative semi-definite matrix A satisfy, for any $i, j \in \mathbb{N}_n$, the inequalities $A_{ij} > \frac{1}{2}(A_{ii} + A_{jj})$ and $A_{ii} > 0$, then $B(\omega)$ is positive definite (Micchelli, 1986). With this choice of A, the universal kernel in Example 5 becomes

$$\Big(K(x,t)\Big)_{ij} = \frac{1}{\|x-t\|^2 + A_{ij}}, \quad \forall i, j \in \mathbb{N}_n.$$

5.2 Transformation Kernels

In this subsection we explore matrix-valued kernels produced by transforming scalar kernels. To introduce this type of kernels, let $\mathcal{Y} = \mathbb{R}^n$, $\widetilde{\mathcal{X}}$ be a Hausdorff space and T_p be a map from $\mathcal{X}$ to

$\widetilde{\mathcal{X}}$ (not necessary linear) for $p \in \mathbb{N}_n$. Then, given a continuous scalar kernel $G : \widetilde{\mathcal{X}} \times \widetilde{\mathcal{X}} \to \mathbb{R}$, we consider the matrix-valued kernel on $\mathcal{X}$ defined by

$$K(x,t) := \Big(G(T_p x, T_q t)\Big)_{p,q=1}^{n}, \ \ \forall x,t \in \mathcal{X}. \tag{33}$$

Proposition 16 *Let G be a scalar kernel and K be defined by (33). Then, K is a matrix-valued kernel.*

Proof For any $m \in \mathbb{N}$, $\{y_i : y_i \in \mathbb{R}^n, i \in \mathbb{N}_m\}$ and $\{x_i : x_i \in \widetilde{\mathcal{X}}, i \in \mathbb{N}_m\}$ then

$$\sum_{i,j \in \mathbb{N}_m} (y_i, K(x_i,x_j) y_j) = \sum_{p,i} \sum_{q,j} y_{pi} y_{qj} G(T_p x_i, T_q x_j).$$

Since G is a scalar reproducing kernel on $\mathcal{Z}$, the last term of the above equality is nonnegative, and hence K is positive semi-definite matrix-valued kernel. This completes the proof of the assertion. ■

We turn our attention to the characterization of the universality of K defined by Equation (33). To this end, we assume that the scalar kernel G has a feature map $\phi : \widetilde{\mathcal{X}} \to \mathcal{W}$ and define the mapping $\Phi(x) : \mathbb{R}^n \to \mathcal{W}$, for any $y = (y_1, \ldots, y_n) \in \mathbb{R}^n$, by $\Phi(x)y = \sum_{p \in \mathbb{N}_n} y_p \phi(T_p x)$. Its adjoint operator $\Phi(x)^* : \mathcal{W} \to \mathbb{R}^n$ is given, for any $w \in \mathcal{W}$, as $\Phi^*(x)w = (\langle \phi(T_1 x), w \rangle_{\mathcal{W}}, \ldots, \langle \phi(T_n x), w \rangle_{\mathcal{W}})$. Then, for any $x,t \in \mathcal{X}$, the kernel $K(x,t) = \Phi^*(x)\Phi(t)$ and thus, we conclude that $\mathcal{W}$ is the feature space of K and Φ is its feature map.

We also need some further notation and definitions. For a map $T : \mathcal{X} \to \widetilde{\mathcal{X}}$, we denote its range space by $T\mathcal{X} := \{Tx : x \in \mathcal{X}\}$ and $T^{-1}(E) := \{x : Tx \in E\}$ for any $E \subset \widetilde{\mathcal{X}}$. In addition, we say that T is continuous if $T^{-1}(U)$ is open whenever U is a open set in $\widetilde{\mathcal{X}}$. Finally, for any scalar Borel measure ν on $\mathcal{X}$ and a continuous map T from $\mathcal{X}$ to $\widetilde{\mathcal{X}}$, we introduce the *image measure* $\nu \circ T^{-1}$ on $\widetilde{\mathcal{X}}$ defined, for any $E \in \mathscr{B}(\widetilde{\mathcal{X}})$, by $(\nu \circ T^{-1})(E) := \nu(\{x \in \mathcal{X} : Tx \in E\})$.

We are ready to state the result about universality of the kernel K in Equation (33).

Proposition 17 *Let G be a scalar universal kernel, $T_p : \mathcal{X} \to \widetilde{\mathcal{X}}$ be continuous for each $p \in \mathbb{N}_n$ and define the kernel K by Equation (33). Then K is universal if and only the sets $T_q\mathcal{X}$, $q \in \mathbb{N}_n$, are pairwise disjoint and T_q is one-to-one for each $q \in \mathbb{N}_n$.*

Proof Following Theorem 11, for any compact set $\mathcal{Z} \subseteq \mathcal{X}$, it suffices to verify the equation $\Phi(\mathcal{Z})^\perp = \{0\}$. Before doing so, we recall that, by Lemma 10 and the remark which followed it, for any vector measure $\mu \in \mathcal{M}(\mathcal{Z}, \mathbb{R}^n)$, there exists a scalar regular measure $\nu \in \mathcal{M}(\mathcal{Z} \times \mathcal{B}_1)$ such that

$$d\mu(t) = \Big(\int_{\mathcal{B}_1} y_1 d\nu(t,y), \ldots, \int_{\mathcal{B}_1} y_n d\nu(t,y) \Big).$$

Hence, any vector measure μ can be represented as $\mu = (\mu_1, \ldots, \mu_n)$ where each μ_i is a scalar measure. Then, $\mu \in \Phi(\mathcal{Z})^\perp$ can be rewritten as

$$\sum_{q \in \mathbb{N}_n} \int_{\mathcal{Z}} \phi(T_q t) d\mu_q(t) = 0.$$

Equivalently, if $\widetilde{\mathcal{Z}} := \cup_{q \in \mathbb{N}_n} T_q \mathcal{Z}$ we conclude that

$$\int_{\widetilde{\mathcal{Z}}} \phi(z) d\Big(\sum_{q \in \mathbb{N}_n} \mu_q \circ T_q^{-1} \Big)(z) = 0.$$

Since T_q is continuous for any $q \in \mathbb{N}_n$, the range space $T_q\mathcal{Z}$ is compact and so is $\widetilde{\mathcal{Z}}$. Recall from Micchelli et al. (2006) that the scalar kernel G is universal on $\widetilde{\mathcal{Z}}$ if and only if its feature map ϕ is universal on $\widetilde{\mathcal{Z}}$. Therefore, the above equation is reduced to the form

$$\sum_{q\in\mathbb{N}_n} \mu_q \circ T_q^{-1} = 0.$$

Consequently, we conclude that K is universal if and only if

$$\big\{(\mu_1,\ldots,\mu_n) : \sum_{q\in\mathbb{N}_n} \mu_q \circ T_q^{-1} = 0\big\} = \big\{0\big\}. \tag{34}$$

With the above derivation, we can now prove the necessity. Suppose that $\{T_q\mathcal{X} : q \in \mathbb{N}_n\}$ is not pairwise disjoint. Without loss of generality, we assume that $T_1\mathcal{X} \cap T_2\mathcal{X} \neq \emptyset$. That means there exists $x_1, x_2 \in \mathcal{X}$ such that $T_1x_1 = T_2x_2 = z_0$. Let $\mu_q \equiv 0$ for $q \geq 3$, and denote by $\delta_{x=x'}$ the point distribution at $x' \in \mathcal{X}$. Then, choosing $\mu_1 = \delta_{x=x_1}$, and $\mu_2 = -\delta_{x=x_2}$ implies that Equation (34) holds true. By Theorem 11 in Section 4, we know that K is not universal. This completes the first assertion.

Now suppose that there is a map, for example T_p, which is not one-to-one. This implies that there exists $x_1, x_2 \in \mathcal{X}$, $x_1 \neq x_2$, such that $T_px_1 = T_px_2$. Hence, if we let $\mu_q = 0$ for any $q \neq p$ and $\mu_p = \delta_{x=x_1} - \delta_{x=x_2}$ then $\sum_{q\in\mathbb{N}_n} \mu_q \circ T_q^{-1} = 0$,. But $\mu_p \neq 0$, hence, by Theorem 11, K is not universal. This completes the our assertion.

Finally, we prove the sufficiency. Since $\mu_q \circ T_q^{-1}$ only lives on $T_q\mathcal{X}$ and $\{T_q\mathcal{X} : q \in \mathbb{N}_n\}$ is pairwise disjoint, then $\sum_{q\in\mathbb{N}_n} \mu_q \circ T_q^{-1} = 0$ is equivalent to $\mu_q \circ T_q^{-1} = 0$ for each $q \in \mathbb{N}_n$. However, since T_q is one-to-one, $E = T_q^{-1}(T_q(E))$ for each Borel set $E \in \mathscr{B}(\mathcal{X})$. This means that $\mu_q(E) = \mu_q \circ T_q^{-1}(T_q(E)) = 0$ for any $E \in \mathscr{B}(\mathcal{X})$. This concludes the proof of the proposition. ■

We end this subsection with detailed proofs of our claims about the examples presented in Section 2. Indeed, we already proved the positive semi-definiteness of the kernel in Example 2 by Proposition 16. Below, we prove the claim that the function K given by Equation (6) is not a kernel in general.

Proposition 18 *Let $\sigma_{pq} > 0$ and $\sigma_{pq} = \sigma_{qp}$ for any $p,q \in \mathbb{N}_n$. Then, the matrix-valued function defined by*

$$K(x,t) := \left(e^{-\sigma_{pq}\|x-y\|^2}\right)_{p,q=1}^{n}, \ \ \forall x,t \in \mathcal{X}$$

is a multi-task kernel if and only if for some constant σ, $\sigma_{pq} = \sigma$ for any $p,q \in \mathbb{N}_n$.

Proof When $\left(\sigma_{pq}\right)_{p,q=1}^{n}$ is a constant matrix then K is positive semi-definite. Conversely, suppose K is a multi-task kernel which means, for any $m \in \mathbb{N}$ and $x_i \in \mathcal{X}$ with $i \in \mathbb{N}_m$, that the double-indexed $nm \times nm$ matrix

$$\left(G((i,p),(j,q)) = e^{-\sigma_{pq}\|x_i-x_j\|^2}\right)_{(i,p),(j,q)\in\mathbb{N}_m\times\mathbb{N}_n} \tag{35}$$

is positive semi-definite.

We choose any distinct positive integers p_0 and q_0. In Equation (35), we specify any m,n with $m \geq n$ such that $p_0, q_0 \in \mathbb{N}_m$, $x_1,\ldots,x_n$ with $x_{p_0} \neq x_{q_0}$ and set $c = \|x_{p_0} - x_{q_0}\|^2$. Therefore, we

conclude that the matrix

$$\begin{pmatrix} 1 & 1 & \exp\{-c\sigma_{p_0p_0}\} & \exp\{-c\sigma_{p_0q_0}\} \\ 1 & 1 & \exp\{-c\sigma_{q_0p_0}\} & \exp\{-c\sigma_{q_0q_0}\} \\ \exp\{-c\sigma_{p_0p_0}\} & \exp\{-c\sigma_{p_0q_0}\} & 1 & 1 \\ \exp\{-c\sigma_{q_0p_0}\} & \exp\{-c\sigma_{q_0q_0}\} & 1 & 1 \end{pmatrix}$$

is positive semi-definite. Consequently, the determinant of its 3×3 sub-matrix in the upper right hand corner, which equals $-\left[\exp\{-c\sigma_{p_0p_0}\}-\exp\{-c\sigma_{q_0p_0}\}\right]^2$, is nonnegative. Therefore, we conclude that $\sigma_{p_0p_0}=\sigma_{q_0p_0}$. ■

5.3 Hessian of Gaussian Kernels

In this subsection we consider the universal example of the Hessian of scalar Gaussian kernels (Example 3 in Section 2). To introduce this type of kernels, we let $\mathcal{X}=\mathcal{Y}=\mathbb{R}^n$ and G be a Gaussian kernel with deviation σ, that is, for any $x\in\mathbb{R}^n$, $G(x)=e^{-\|x\|^2/\sigma}$ with $\sigma>0$. Then, the Hessian matrix of the kernel G is

$$K(x,t):=\Big(-(\partial_p\partial_q G)(x-t)\Big)_{p,q=1}^{n}\quad\forall x,t\in\mathbb{R}^n. \tag{36}$$

and so alternatively, K has the form

$$K(x,t)=4\pi\big(2\pi\sigma\big)^{n/2}\int_{\mathbb{R}^n}e^{2\pi i\langle x-t,\xi\rangle}\xi\xi^T e^{-\sigma\|\xi\|^2}d\xi. \tag{37}$$

Corollary 19 *Let $n\geq 1$ and $K:\mathbb{R}^n\times\mathbb{R}^n\to\mathbb{R}^{n\times n}$ be defined by (36). Then, K is a matrix-valued kernel which is universal if and only if $n=1$.*

Proof The fact that K is positive semi-definite directly follows from the observation, for any $m\in\mathbb{N}$, $\{y_i:y_i\in\mathbb{R}^n,i\in\mathbb{N}_m\}$ and $\{x_i:x_i\in\mathcal{X},i\in\mathbb{N}_m\}$, that

$$\sum_{i,j,\in\mathbb{N}_m}(y_i,K(x_i,x_j)y_j)=4\pi\big(2\pi\sigma\big)^{n/2}\int_{\mathbb{R}^n}\left|\sum_{i\in\mathbb{N}_m}\langle y_i,\xi\rangle e^{2\pi i\langle x_i,\xi\rangle}\right|^2 e^{-\sigma\|\xi\|^2}d\xi.$$

In order to prove the universality of K, we follow Theorem 11. For this purpose, we assume that $\mathcal{Z}$ is a compact subset of $\mathcal{X}$ and $\mu\in\mathcal{K}(\mathcal{Z})^\perp$, that is,

$$\int_{\mathcal{Z}}K(x,t)(d\mu(t))=0\quad\forall x\in\mathcal{Z}. \tag{38}$$

By Equation (37), this equation is equivalent to

$$\int_{\mathbb{R}^n}e^{2\pi i\langle x,\xi\rangle}\xi e^{-\sigma\|\xi\|^2}\int_{\mathcal{Z}}e^{-2\pi i\langle t,\xi\rangle}(\xi,d\mu(t))d\xi=0,\ \ \forall x\in\mathcal{Z},$$

which implies, by integrating both sides of this equation with respect to $x\in\mathbb{R}^n$, that

$$\int_{\mathbb{R}^n}e^{-\sigma\|\xi\|^2}\left|\int_{\mathcal{Z}}e^{-2\pi i\langle t,\xi\rangle}(\xi,d\mu(t))\right|^2 d\xi=0.$$

Consequently, Equation (38) is identical to the equation

$$\int_{\mathcal{Z}} e^{-2\pi i\langle t,\xi\rangle}(\xi, d\mu(t)) = 0, \qquad \forall \xi \in \mathbb{R}^n.$$

If $n = 1$, the above equation means that

$$\int_{\mathcal{Z}} e^{-2\pi i t\xi} d\mu(t) = 0, \qquad \forall \xi \in \mathbb{R}.$$

Taking the k-th derivative with respect to ξ of both sides of this equation and set $\xi = 0$, we have, for every $k \in \mathbb{N}$, that

$$\int_{\mathcal{Z}} t^k d\mu(t) = 0.$$

Since polynomials are dense in $\mathcal{C}(\mathcal{Z})$, we conclude from the above equation that $\mu = 0$. Hence, by Theorem 11, the kernel K is universal when $n = 1$.

If $n \geq 2$, we choose $\mu_q = 0$ for $q \geq 3$ and $d\mu_1(t) = dt_1(\delta_{t_2=1} - \delta_{t_2=-1})\prod_{p=3}^n \delta_{t_p=0}$ and $d\mu_2(t) = (\delta_{t_1=-1} - \delta_{t_1=1})dt_2 \prod_{p=3}^n \delta_{t_p=0}$, and note that

$$\int_{[-1,1]^n} e^{-2\pi i\langle t,\xi\rangle} d\mu_1(t) = (-2\pi i \sin(2\pi\xi_2))\frac{sin(2\pi\xi_1)}{\pi\xi_1},$$

and

$$\int_{[-1,1]^n} e^{-2\pi i\langle t,\xi\rangle} d\mu_2(t) = (2\pi i \sin(2\pi\xi_1))\frac{sin(2\pi\xi_2)}{\pi\xi_2}.$$

Therefore, we conclude that

$$\int_{[-1,1]^n} e^{-2\pi i\langle t,\xi\rangle}(\xi, d\mu(t)) = \xi_1 \int_{[-1,1]^n} e^{-2\pi i\langle t,\xi\rangle} d\mu_1(t) + \xi_2 \int_{[-1,1]^n} e^{-2\pi i\langle t,\xi\rangle} d\mu_2(t) = 0.$$

Hence, the kernel K is not universal when $n \geq 2$. ■

5.4 Projection Kernels

In the final subsection we introduce a class of multi-task kernels associated with projection operators of scalar kernels.

We start with some notation and definitions. Let $\mathcal{X} \subseteq \mathbb{R}^d$, $\Omega \subseteq \mathbb{R}^m$ be a compact set and $\mathcal{Y} = L^2(\Omega)$. We also need a continuous scalar kernel $G : (\mathcal{X} \times \Omega) \times (\mathcal{X} \times \Omega) :\to \mathbb{R}$ with a feature representation given, for any $x, x' \in \mathcal{X}$ and $t, s \in \Omega$, by

$$G((x,t),(x',s)) = \langle \phi(x,t), \phi(x',s)\rangle_{\mathcal{W}}. \tag{39}$$

Then, the projection kernel $K : \mathcal{X} \times \mathcal{X} \to \mathcal{L}(\mathcal{Y}, \mathcal{Y})$ is defined, for any $f \in L^2(\Omega)$, by

$$(K(x,x')f)(t) := \int_\Omega G((x,t),(x',s))f(s)ds, \;\; \forall\, x, x' \in \mathcal{X}, \;\; t \in \mathbb{R}. \tag{40}$$

We first show that K is a multi-task kernel. To see this, for any $m \in \mathbb{N}$, $\{x_i : x_i \in \mathcal{X}, i \in \mathbb{N}_m\}$, and $\{y_i : y_i \in L^2(\Omega), i \in \mathbb{N}_m\}$ there holds

$$\begin{aligned}\sum_{i,j\in\mathbb{N}_m}(K(x_i,x_j)y_j,y_i) &= \sum_{i,j\in\mathbb{N}_m}\int_\Omega\int_\Omega G((x_i,t),(x_j,s))y_j(s)y_i(t)dtds \\ &= \sum_{i\in\mathbb{N}_m}\left\|\int_\Omega \phi(x_i,s)y_i(s)ds\right\|^2 \geq 0,\end{aligned}$$

which implies that K is a kernel.

To investigate its universality from the feature perspective, we define the mapping $\Phi : \mathcal{X} \to \mathcal{L}(\mathcal{Y},\mathcal{W})$, for any $x \in \mathcal{X}$ and $y \in \mathcal{Y}$, by

$$\Phi(x)y := \int_\Omega \phi(x,s)y(s)ds,$$

and also its adjoint operator Φ^* is given, for any $w \in \mathcal{W}$, by $\Phi^*(x)w = \langle \phi(x,\cdot), w\rangle_{\mathcal{W}}$. Hence, for any $x,x' \in \mathcal{X}$, we conclude that $K(x,x') = \Phi^*(x)\Phi(x')$ which implies that K is a multi-task kernel and Φ is its associated feature map.

Our next goal is to prove the universality of K.

Theorem 20 *Let G and K be defined as in Equations* (39) *and* (40)*. If G is a universal scalar kernel then K is a universal multi-task kernel.*

Proof By Theorem 11, it suffices to show that, for any compact $\mathcal{Z} \subseteq \mathcal{X}$, whenever there exists a vector measure μ such that

$$\int_{\mathcal{Z}} \Phi(x)(d\mu(x)) = 0,$$

then $\mu = 0$. Note that μ is an $L^2(\Omega)$-valued measure. Hence, μ can alternatively be interpreted as a measure $\mu(\cdot,\cdot)$ on $\mathcal{Z}\times\Omega$ defined, for any $E \in \mathscr{B}(\mathcal{Z})$ and $E' \in \mathscr{B}(\Omega)$, by $\mu(E,E') := \int_{E'} \mu(E)(s)ds$. From this observation, we know that

$$\int_{\mathcal{Z}} \Phi(x)(d\mu(x)) = \int_{\mathcal{Z}}\int_\Omega \phi(x,s)d\mu(x,s).$$

Since $\mathcal{Z}$ and Ω are both compact, then $\mathcal{Z}\times\Omega$ is also compact by Tychonoff theorem (Folland, 1999, p.136). By assumption, G is universal on $\mathcal{X}\times\Omega$ and ϕ is its feature map, and thus we conclude that the scalar measure $d\mu(x,s)$ is the zero measure. This means that, for any $E \in \mathscr{B}(\mathcal{Z})$ and $E' \in \mathscr{B}(\Omega)$,

$$\int_{E'} \mu(E)(s)ds = 0.$$

Since E, E' are arbitrary, we conclude that the vector measure $\mu = 0$ which completes the assertion. ■

6. Conclusion

We have presented a characterization of multi-task kernels from a Functional Analysis perspective. Our main result, Theorem 4 established the equivalence between two spaces associated with the kernel. The first space, $\mathcal{C}_K(\mathcal{Z},\mathcal{Y})$, is the closure of the linear span of kernel sections; the second space, $\mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y})$, is the closure of the linear span of the features associated with the kernel. In both cases, the closure was relative to the Banach space of continuous vector-valued functions. This result is important in that it allows one to verify the universality of a kernel directly by considering its features.

We have presented two alternate proofs of Theorem 4. The first proof builds upon the work of Micchelli et al. (2006) and the observation that a multi-task kernel can be reduced to a standard scalar-valued kernel on the cross product space $\mathcal{Z}\times\mathcal{Y}$. The second proof relies upon the theory of vector-measures. This proof is constructive and provides necessary and sufficient conditions on the universality of a multi-task kernel. They are summarized in Theorem 11, which is our main tool for verifying the universality of a multi-task kernel.

In both proofs, an important ingredient is a principle from Functional Analysis, which uses the notion of the *annihilator* set. This principle, which is a consequence of the Hahn-Banach Theorem, states that two closed linear subspaces of a Banach space—in our case $\mathcal{C}_K(\mathcal{Z},\mathcal{Y})$ and $\mathcal{C}_\Phi(\mathcal{Z},\mathcal{Y})$—are equal if and only if whenever a bounded linear functional vanishes on one of them, it also vanishes on the other one.

A substantial part of the paper has been devoted to present several examples of multi-task kernels, some of which are valuable for applications. Although much remains to be done on developing applications of the theory of universal kernels, we hope that our theoretical findings, as they are illustrated through the examples, will motivate further work on multi-task learning in applied machine learning.

Appendix A.

This appendix gives the proof of Lemmas 9 and 10 in Section 4.

Proof of Lemma 9 By the definition of the integral appearing in the right-hand side of equation it follows (17) (see, e.g., Diestel and Uhl, Jr., 1977), for any $f \in \mathcal{C}(\mathcal{Z},\mathcal{Y})$, that

$$|L_\mu f| \leq \|\mu\| \sup_{x\in\mathcal{Z}} \|f(x)\|_{\mathcal{Y}}.$$

Therefore, we obtain that $\|L_\mu\| \leq \|\mu\|$, and thus $L_\mu \in \mathcal{C}^*(\mathcal{Z},\mathcal{Y})$.

To show that $\|L\| = \|\mu\|$, it remains to establish that $\|\mu\| \leq \|L_\mu\|$. To this end, for any $\varepsilon > 0$ and, by the definition of $\|\mu\|$, we conclude that there exist pairwise disjoint sets $\{A_j : j \in \mathbb{N}_n\}$ such that $\cup_{j\in\mathbb{N}_n} A_j \subseteq \mathcal{Z}$ and $\|\mu\| := |\mu|(\mathcal{Z}) \leq \varepsilon + \sum_{j\in\mathbb{N}_n} \|\mu(A_j)\|_{\mathcal{Y}}$. We introduce the function $g = \sum_{j\in\mathbb{N}_n} \frac{\mu(A_j)}{\|\mu(A_j)\|_{\mathcal{Y}}}\chi_{A_j}$ which satisfies, for any $x \in \mathcal{Z}$, the bound $\|g(x)\|_{\mathcal{Y}} \leq 1$. Since $|\mu|$ is a regular measure on $\mathcal{Z}$, applying Lusin's theorem (Folland, 1999, p.217) to the function χ_{A_j}, there exists a real-valued continuous function $f_j \in \mathcal{C}(\mathcal{Z})$ such that $|f_j(x)| \leq 1$ for any $x \in \mathcal{Z}$ and $f_j = \chi_{A_j}$, except on a set E_j with $|\mu|(E_j) \leq \frac{\varepsilon}{(n+1)2^{j+1}}$. We now define a function $h : \mathcal{Y} \to \mathcal{Y}$ by setting $h(y) = y$, if $\|y\|_{\mathcal{Y}} \leq 1$ and $h(y) = \frac{y}{\|y\|_{\mathcal{Y}}}$, if $\|y\|_{\mathcal{Y}} \geq 1$, and introduce another function in $\mathcal{C}(\mathcal{Z},\mathcal{Y})$ given by $\bar{f} := \sum_{j\in\mathbb{N}_n} \frac{\mu(A_j)}{\|\mu(A_j)\|_{\mathcal{Y}}} f_j$. Therefore, the function $f = h \circ \bar{f}$ is in $C(\mathcal{Z},\mathcal{Y})$ as well, because $\bar{f} \in \mathcal{C}(\mathcal{Z},\mathcal{Y})$ and, for any $y,y' \in \mathcal{Y}$, $\|h(y) - h(y')\|_{\mathcal{Y}} \leq 2\|y - y'\|_{\mathcal{Y}}$. Moreover, we observe, for any $x \in \left(\cup_{j\in\mathbb{N}_n} E_j\right)^c$, that $f(x) = g(x)$ and, for any $x \in \mathcal{Z}$, that $\|f(x)\|_{\mathcal{Y}} \leq 1$.

We are now ready to estimate the total variation of μ. First, observe that

$$\int_{\mathcal{Z}} \|f(x) - g(x)\|_{\mathcal{Y}}\, d|\mu|(x) \leq \sum_{j\in\mathbb{N}_n} (n+1)|\mu|(E_j) \leq \varepsilon,$$

and consequently we obtain the inequality

$$\begin{aligned}
\|\mu\| &\leq \textstyle\sum_{j\in\mathbb{N}_n} \|\mu(A_j)\|_{\mathcal{Y}} + \varepsilon = \int_{\mathcal{Z}} (g(x), d\mu(x)) + \varepsilon \\
&\leq \left| \int_{\mathcal{Z}} (f(x) - g(x), d\mu(x)) \right| + \left| \int_{\mathcal{Z}} (f(x), d\mu(x)) \right| + \varepsilon \\
&\leq \int_{\mathcal{Z}} \|f(x) - g(x)\|_{\mathcal{Y}} d|\mu|(x) + \|L_\mu\| + \varepsilon \leq 2\varepsilon + \|L_\mu\|.
\end{aligned}$$

This finishes the proof of the lemma. ■

We proceed to the proof of Lemma 10.

Proof of Lemma 10 For each $\mu \in \mathcal{M}(\mathcal{X},\mathcal{Y})$, there exists an $L_\mu \in \mathcal{C}^*(\mathcal{Z},\mathcal{Y})$ given by Equation (17). The isometry of the map $\mu \mapsto L_\mu$ follows from Lemma 9.

Therefore, it suffices to prove, for every $\bar{L} \in \mathcal{C}^*(\mathcal{Z},\mathcal{Y})$, that there is a $\mu \in \mathcal{M}(\mathcal{Z},\mathcal{Y})$ such that $L_\mu = \bar{L}$. To this end, note that $\bar{L} \circ \iota^{-1} \in \mathcal{C}_\iota^*(\mathcal{Z}\times\mathcal{B}_1)$ since ι is an isometric map from $\mathcal{C}(\mathcal{Z},\mathcal{Y})$ onto $\mathcal{C}_\iota(\mathcal{Z}\times\mathcal{B}_1)$ defined by Equation (10). Since $\mathcal{C}_\iota(\mathcal{Z}\times\mathcal{B}_1)$ is a closed subspace of $\mathcal{C}(\mathcal{Z}\times\mathcal{B}_1)$, applying the *Hahn-Banach extension theorem* (see, e.g., Folland, 1999, p.222) yields that, for any $L \in \mathcal{C}_\iota^*(\mathcal{Z}\times\mathcal{B}_1)$, there exists an extension functional $\tilde{L} \in \mathcal{C}^*(\mathcal{Z}\times\mathcal{B}_1)$ such that $\tilde{L}(F) = L \circ \iota^{-1}(F)$ for any $F \in \mathcal{C}_\iota(\mathcal{Z}\times\mathcal{B}_1)$. Moreover, recalling that $\mathcal{Z}\times\mathcal{B}_1$ is compact if $\mathcal{B}_1$ is equipped with the weak topology, by the Riesz representation theorem, for any $\tilde{L}$, there exists a scalar measure ν on $\mathcal{Z}\times\mathcal{B}_1$ such that

$$\tilde{L}(F) = \int_{\mathcal{Z}\times\mathcal{B}_1} F(x,y) d\nu(x,y), \quad \forall F \in \mathcal{C}(\mathcal{Z}\times\mathcal{B}_1).$$

Equivalently, for any $f \in \mathcal{C}(\mathcal{Z},\mathcal{Y})$ there holds

$$\bar{L}f = \bar{L}\circ\iota^{-1}(F) = \int_{\mathcal{Z}\times\mathcal{B}_1} F(x,y)d\nu(x,y) = \int_{\mathcal{Z}} (f(x),d\mu(x)) = L_\mu f,$$

where μ is defined i terms of ν as in Equation (15).

This finishes the identification between functionals in $\mathcal{C}(\mathcal{Z},\mathcal{Y})$ and vector measures with bounded variation. ■

Abstract

The statistical problem of estimating the effective dimension-reduction (EDR) subspace in the multi-index regression model with deterministic design and additive noise is considered. A new procedure for recovering the directions of the EDR subspace is proposed. Many methods for estimating the EDR subspace perform principal component analysis on a family of vectors, say $\hat{\beta}_1,\dots,\hat{\beta}_L$, nearly lying in the EDR subspace. This is in particular the case for the structure-adaptive approach proposed by Hristache et al. (2001a). In the present work, we propose to estimate the projector onto the EDR subspace by the solution to the optimization problem

$$\text{minimize} \quad \max_{\ell=1,\dots,L} \hat{\beta}_\ell^\top (I-A)\hat{\beta}_\ell \quad \text{subject to} \ \ A \in \mathcal{A}_{m^*},$$

where $\mathcal{A}_{m^*}$ is the set of all symmetric matrices with eigenvalues in $[0,1]$ and trace less than or equal to m^*, with m^* being the true structural dimension. Under mild assumptions, $\sqrt{n}$-consistency of the proposed procedure is proved (up to a logarithmic factor) in the case when the structural dimension is not larger than 4. Moreover, the stochastic error of the estimator of the projector onto the EDR subspace is shown to depend on L logarithmically. This enables us to use a large number of vectors $\hat{\beta}_\ell$ for estimating the EDR subspace. The empirical behavior of the algorithm is studied through numerical simulations.

Keywords: dimension-reduction, multi-index regression model, structure-adaptive approach, central subspace

1. Introduction

One of the most challenging problems in modern statistics is to find efficient methods for treating high-dimensional data sets. In various practical situations the problem of predicting or explaining a scalar response variable Y by d scalar predictors $X^{(1)},\dots,X^{(d)}$ arises. For solving this problem one should first specify an appropriate mathematical model and then find an algorithm for estimating that model based on the observed data. In the absence of a priori information on the relationship

between Y and $X = (X^{(1)}, \dots, X^{(d)})$, complex models are to be preferred. Unfortunately, the accuracy of estimation is in general a decreasing function of the model complexity. For example, in the regression model with additive noise and two-times continuously differentiable regression function $f : \mathbb{R}^d \to \mathbb{R}$, the most accurate estimators of f based on a sample of size n have a quadratic risk decreasing as $n^{-4/(4+d)}$ when n becomes large. This rate deteriorates very rapidly with increasing d leading to unsatisfactory accuracy of estimation for moderate sample sizes. This phenomenon is called "curse of dimensionality", the latter term being coined by Bellman (1961).

To overcome the "curse of dimensionality", additional restrictions on the candidates f for describing the relationship between Y and X are necessary. One popular approach is to consider the multi-index model with m^* indices: for some linearly independent vectors ϑ_1, ..., ϑ_{m^*} and for some function $g : \mathbb{R}^{m^*} \to \mathbb{R}$, the relation $f(x) = g(\vartheta_1^\top x, \dots, \vartheta_{m^*}^\top x)$ holds for every $x \in \mathbb{R}^d$. Here and in the sequel the vectors are understood as one column matrices and $M^\top$ denotes the transpose of the matrix M. Of course, such a restriction is useful only if $m^* < d$ and the main argument in favor of using the multi-index model is that for most data sets the underlying structural dimension m^* is substantially smaller than d. Therefore, if the vectors ϑ_1, ..., ϑ_{m^*} are known, the estimation of f reduces to the estimation of g, which can be performed much better because of lower dimensionality of the function g compared to that of f.

Another advantage of the multi-index model is that it postulates that only few linear combinations of the predictors may suffice for "explaining" the response Y. Considering these combinations as new predictors leads to a much simpler model (due to its low dimensionality), which can be successfully analyzed by graphical methods, see Cook and Weisberg (1999) and Cook (1998) for more details.

Throughout this work we assume that we are given n observations $(Y_1, X_1), \dots, (Y_n, X_n)$ from the model

$$Y_i = f(X_i) + \varepsilon_i = g(\vartheta_1^\top X_i, \dots, \vartheta_{m^*}^\top X_i) + \varepsilon_i, \tag{1}$$

where $\varepsilon_1, \dots, \varepsilon_n$ are unobserved errors assumed to be mutually independent zero mean random variables, independent of the design $\{X_i, i \le n\}$.

Since it is unrealistic to assume that $\vartheta_1, \dots, \vartheta_{m^*}$ are known, estimation of these vectors from the data is of high practical interest. When the function g is unspecified, only the linear subspace $\mathcal{S}_\vartheta$ spanned by these vectors may be identified from the sample. This subspace is usually called *index space* or *dimension-reduction (DR) subspace*. Clearly, there are many DR subspaces for a fixed model f. Even if f is observed without error, only the smallest DR subspace, henceforth denoted by $\mathcal{S}$, can be consistently identified. This smallest DR subspace, which is the intersection of all DR subspaces, is called *effective dimension-reduction* (EDR) subspace (Li, 1991) or *central mean subspace* (Cook and Li, 2002). We adopt in this paper the former term, in order to be consistent with Hristache et al. (2001a) and Xia et al. (2002), which are the closest references to our work.

The present work is devoted to studying a new algorithm for estimating the EDR subspace. We call it structural adaptation via maximum minimization (SAMM). It can be regarded as a branch of the structure-adaptive (SA) approach introduced in Hristache et al. (2001b) and Hristache et al. (2001a).

Note that a closely related problem is the estimation of the central subspace (CS), see Cook and Weisberg (1999) for its definition. For model (1) with i.i.d. predictors, the CS coincides with the EDR subspace. Hence, all the methods developed for estimating the CS can potentially be applied in our set-up. We refer to Cook and Li (2002) for background on the difference between the CS and

the central mean subspace and to Cook and Ni (2005) for a discussion of the relationship between different algorithms estimating these subspaces.

There are a number of methods providing an estimator of the EDR subspace in our set-up. These include ordinary least square (Li and Duan, 1989), sliced inverse regression (Li, 1991), sliced inverse variance estimation (Cook and Weisberg, 1991), principal Hessian directions (Li, 1992), graphical regression (Cook, 1998), parametric inverse regression (Bura and Cook, 2001a), SA approach (Hristache et al., 2001a), iterative Hessian transformation (Cook and Li, 2002), minimum average variance estimation (MAVE) (Xia et al., 2002), nonparametric linear smoothing for inverse regression (Bura, 2003), minimum discrepancy approach (Cook and Ni, 2005) marginal high moment regression (Yin and Cook, 2006) density based MAVE and outer product of gradient (Xia, 2007), as well as the refinements using contour-projection (Wang et al., 2008), intraslice covariance estimation (Cook and Ni, 2006) and Lasso shrinkage (Ni et al., 2005; Li, 2007).

All these methods, except SA approach and MAVE, rely on the principle of inverse regression (IR). Therefore they inherit its well known limitations. First, they require a hypothesis on the probabilistic structure of the predictors usually called linearity condition. Second, there is no theoretical justification guaranteeing that these methods estimate the whole EDR subspace and not just a part thereof, see Cook and Li (2004, Section 3.1) and the comments on the third example in Hristache et al. (2001a, Section 4). In the same time, they have the advantage of being simple for implementation and for inference.

The two other methods mentioned above—SA approach and MAVE—have much wider applicability including even time series analysis. The inference for these methods is more involved than that of IR based methods, but SA approach and MAVE need no strong requirements on the design of covariates or on the response variable. Moreover, in many cases they provide more accurate estimates of the EDR subspace (Hristache et al., 2001a; Xia et al., 2002; Xia, 2007).

These arguments, combined with empirical experience, indicate the complementarity of different methods designed to estimate the EDR subspace. It turns out that there is no procedure among those cited above that outperforms all the others in plausible settings. Therefore, a reasonable strategy for estimating the EDR subspace is to execute different procedures and to take a decision after comparing the obtained results. In the case of strong contradictions, collecting additional data is recommended.

The algorithm SAMM we introduce here exploits the fact that the gradient ∇f of the regression function f evaluated at any point $x \in \mathbb{R}^d$ belongs to the EDR subspace. The estimation of the gradient being an ill-posed inverse problem, it is better to estimate some linear combinations of $\nabla f(X_1), \ldots, \nabla f(X_n)$, which still belong to the EDR subspace.

Let L be a positive integer. The main idea behind the algorithm proposed in Hristache et al. (2001a) consists in iteratively estimating L linear combinations $\beta_1, \ldots, \beta_L$ of vectors $\nabla f(X_1), \ldots, \nabla f(X_n)$ and then recovering the EDR subspace from the vectors β_ℓ by running a principal component analysis (PCA). The resulting estimator is proved to be $\sqrt{n}$-consistent provided that L is chosen independently of the sample size n. Unfortunately, if L is small with respect to n, the subspace spanned by the vectors $\beta_1, \ldots, \beta_L$ may cover only a part of the EDR subspace. Therefore, empirical experience advocates for large values of L, even if the desirable feature of $\sqrt{n}$-consistency fails in this case.

The estimator proposed in the present work is designed to provide a remedy for this dissension between the theory and empirical experience. This goal is achieved by introducing a new method of extracting the EDR subspace from the estimators of the vectors $\beta_1, \ldots, \beta_L$. If we think of PCA

as the solution to a minimization problem involving a sum over L terms, see (5) in the next section, then, to some extent, our proposal consists in replacing the sum by the maximum. This motivates the term structural adaptation via maximum minimization. The main advantage of SAMM is that it allows us to deal with the case when L increases polynomially in n and yields an estimator of the EDR subspace which is consistent under a very weak identifiability assumption. In addition, SAMM provides a $\sqrt{n}$-consistent estimator (up to a logarithmic factor) of the EDR subspace when $m^* \leq 4$.

If $m^* = 1$, the corresponding model is referred to as *single-index* regression. There are many methods for estimating the EDR subspace in this case, see Yin and Cook (2005); Delecroix et al. (2006) and the references therein. Note also that the methods for estimating the EDR subspace have often their counterparts in the partially linear regression analysis, see for example Samarov et al. (2005) and Chan et al. (2004).

An interesting problem in the context of dimensionality reduction is the estimation of the true structural dimension m^*. Many approaches exist for constructing estimators of m^*, see (Li, 1991, Section 5), (Xia et al., 2002, Section 2.2), and Bura and Cook (2001b), Bura and Cook (2001a), Bura (2003) and Cook and Li (2004) and the references therein. Here we assume that the structural dimension is known, leaving the development of an extension to the case of unknown m^* for future investigation.

The rest of the paper is organized as follows. We review the structure-adaptive approach and introduce the SAMM procedure in Section 2. Theoretical features including $\sqrt{n}$-consistency of the procedure are stated in Section 3. Section 4 contains an empirical study of the proposed procedure through Monte Carlo simulations. The technical proofs are deferred to Section 5.

2. Structural Adaptation and SAMM

Introduced in Hristache et al. (2001b), the structure-adaptive approach is based on two observations. First, knowing the structural information helps better estimate the model function. Second, improved model estimation contributes to recovering more accurate structural information about the model. These advocate for the following iterative procedure. Start with the null structural information, then iterate the above-mentioned two steps (estimation of the model and extraction of the structure) several times improving the quality of model estimation and increasing the accuracy of structural information during the iteration.

2.1 Purely Nonparametric Local Linear Estimation

When no structural information is available, one can only proceed in a fully nonparametric way. A proper estimation method is based on local linear smoothing (cf. Fan and Gijbels, 1996, for more details): estimators of the function f and its gradient ∇f at a point X_i are given by

$$\begin{aligned}\begin{pmatrix} \hat{f}(X_i) \\ \widehat{\nabla f}(X_i) \end{pmatrix} &= \operatorname*{arg\,min}_{(a,c)^\top} \sum_{j=1}^{n} \big(Y_j - a - c^\top X_{ij}\big)^2 K\big(|X_{ij}|^2/b^2\big) \\ &= \left\{ \sum_{j=1}^{n} \begin{pmatrix} 1 \\ X_{ij} \end{pmatrix} \begin{pmatrix} 1 \\ X_{ij} \end{pmatrix}^\top K\left(\frac{|X_{ij}|^2}{b^2}\right) \right\}^{-1} \sum_{j=1}^{n} Y_j \begin{pmatrix} 1 \\ X_{ij} \end{pmatrix} K\left(\frac{|X_{ij}|^2}{b^2}\right),\end{aligned}$$

where $X_{ij} = X_j - X_i$, b is a *bandwidth* and $K(\cdot)$ is a univariate kernel supported on $[0,1]$. (For a vector v, $|v|$ stands for its Euclidean norm.) The bandwidth b should be selected so that the ball

with radius b centered at the point of estimation X_i contains at least $d+1$ design points. For large value of d this leads to a large bandwidth and to a strong estimation bias. The goal of the structural adaptation is to diminish this bias using an iterative procedure exploiting the available estimated structural information.

In order to transform these general observations into a concrete procedure, let us describe in the rest of this section how the knowledge of the structure can help to improve the quality of the estimation and how the structural information can be obtained when the function or its estimator is given.

2.2 Model Estimation When an Estimator of $\mathcal{S}$ is Available

Let us start with the case of known $\mathcal{S}$. The function f has the same smoothness as g in the directions of the EDR subspace $\mathcal{S}$ spanned by the vectors $\vartheta_1,\dots,\vartheta_{m^*}$, whereas it is constant (and therefore, infinitely smooth) in all the orthogonal directions. This suggests to apply an anisotropic bandwidth for estimating the model function and its gradient. The corresponding local-linear estimator can be defined by

$$\begin{pmatrix} \hat{f}(X_i) \\ \widehat{\nabla f}(X_i) \end{pmatrix} = \left\{ \sum_{j=1}^{n} \begin{pmatrix} 1 \\ X_{ij} \end{pmatrix} \begin{pmatrix} 1 \\ X_{ij} \end{pmatrix}^{\top} w_{ij}^* \right\}^{-1} \sum_{j=1}^{n} Y_j \begin{pmatrix} 1 \\ X_{ij} \end{pmatrix} w_{ij}^* \,, \tag{2}$$

with the weights $w_{ij}^* = K(|\Pi^* X_{ij}|^2/h^2)$, where h is some positive real number and Π^* is the orthogonal projector onto the EDR subspace $\mathcal{S}$. This choice of weights amounts to using infinite bandwidth in the directions lying in the orthogonal complement of the EDR subspace.

If only an estimator $\hat{A}$ of the orthogonal projector Π^* is available, a possible strategy is to replace Π^* by $\hat{A}$ in the definitions of the weights w_{ij}^*. This strategy is however too stringent, since it definitely discards the directions belonging to $\hat{\mathcal{S}}^{\perp}$. Being not sure that our information about the structure is exact, it is preferable to define the neighborhoods in a softer way. This is done by setting $w_{ij} = K(X_{ij}^{\top}(I+\rho^{-2}\hat{A})X_{ij}/h^2)$ and by redefining

$$\begin{pmatrix} \hat{f}(X_i) \\ \widehat{\nabla f}(X_i) \end{pmatrix} = \left\{ \sum_{j=1}^{n} \begin{pmatrix} 1 \\ X_{ij} \end{pmatrix} \begin{pmatrix} 1 \\ X_{ij} \end{pmatrix}^{\top} w_{ij} \right\}^{-1} \sum_{j=1}^{n} Y_j \begin{pmatrix} 1 \\ X_{ij} \end{pmatrix} w_{ij} \,. \tag{3}$$

Here, ρ is a real number from the interval $[0,1]$ measuring the importance attributed to the estimator $\hat{A}$. If we are very confident in our estimator $\hat{A}$, we should choose ρ close to zero.

2.3 Recovering the EDR Subspace from an Estimator of ∇f

Suppose first that the values of the function ∇f at the points X_i are known. Then $\mathcal{S}$ is the linear subspace of $\mathbb{R}^d$ spanned by the vectors $\nabla f(X_i)$, $i=1,\dots,n$. For classifying the directions of $\mathbb{R}^d$ according to the variability of f in each direction and, as a by-product, identifying $\mathcal{S}$, the principal component analysis (PCA) can be used.

Recall that the PCA method is based on the orthogonal decomposition of the matrix $\mathscr{M} = n^{-1}\sum_{i=1}^{n} \nabla f(X_i)\nabla f(X_i)^{\top}$: $\mathscr{M} = O\Lambda O^T$ with an orthogonal matrix O and a diagonal matrix Λ with diagonal entries $\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_d$. Clearly, for the multi-index model with m^*-indices, only the first m^* eigenvalues of $\mathscr{M}$ are positive. The first m^* eigenvectors of $\mathscr{M}$ (or, equivalently, the first m^* columns of the matrix O) define an orthonormal basis in the EDR subspace.

Let L be a positive integer. In Hristache et al. (2001a), a "truncated" matrix $\mathscr{M}_L$ is considered, which coincides with $\mathscr{M}$ if L equals n. Let $\{\psi_\ell, \ell = 1,\dots,L\}$ be a set of vectors of $\mathbb{R}^n$ satisfying the conditions $n^{-1}\sum_{i=1}^n \psi_{\ell,i}\psi_{\ell',i} = \delta_{\ell,\ell'}$ for every $\ell,\ell' \in \{1,\dots,L\}$, with $\delta_{\ell,\ell'}$ being the Kronecker symbol. Define

$$\beta_\ell = n^{-1}\sum_{i=1}^n \nabla f(X_i)\psi_{\ell,i} \tag{4}$$

and $\mathscr{M}_L = \sum_{\ell=1}^L \beta_\ell\beta_\ell^\top$. By the Bessel inequality, it holds $\mathscr{M}_L \preceq \mathscr{M}$. Here and in the sequel, for two symmetric matrices A and B, $A \preceq B$ means that $B-A$ is positive-semidefinite. Moreover, since $\mathscr{M}\mathscr{M}_L = \mathscr{M}_L\mathscr{M}$, any eigenvector of $\mathscr{M}$ is an eigenvector of $\mathscr{M}_L$. Finally, by the Parseval equality, $\mathscr{M}_L = \mathscr{M}$ if $L = n$.

The reason of considering the matrix $\mathscr{M}_L$ instead of $\mathscr{M}$ is that $\mathscr{M}_L$ can be estimated much better than $\mathscr{M}$. In fact, estimators of $\mathscr{M}$ have poor performance for samples of moderate size because of the sparsity of high dimensional data, ill-posedness of the gradient estimation and the non-linear dependence of $\mathscr{M}$ on ∇f. On the other hand, estimation of $\mathscr{M}_L$ reduces to the estimation of L linear functionals of ∇f and may be done with a better accuracy. The obvious limitation of this approach is that it recovers the EDR subspace entirely only if the rank of $\mathscr{M}_L$ coincides with the rank of $\mathscr{M}$, which is equal to m^*. To enhance our chances of seeing the condition $\operatorname{rank}(\mathscr{M}_L) = m^*$ fulfilled, we have to choose L sufficiently large. In practice, L is chosen of the same order as n.

In the case when only an estimator of ∇f is available, the above described method of recovering the EDR directions from an estimator of $\mathscr{M}_L$ has a risk of order $\sqrt{L/n}$ (Hristache et al., 2001a, Theorem 5.1). This fact advocates against using very large values of L. We desire nevertheless to use many linear combinations in order to increase our chances of capturing the whole EDR subspace. To this end, we modify the method of extracting the structural information from the estimators $\hat\beta_\ell$ of vectors β_ℓ.

Let $m \ge m^*$ be an integer. Observe that the estimator $\widetilde\Pi_m$ of the projector Π^* based on the PCA solves the following quadratic optimization problem:

$$\text{minimize } \sum_\ell \hat\beta_\ell^\top(I-\Pi)\hat\beta_\ell \qquad \text{subject to} \qquad \Pi^2 = \Pi, \quad \operatorname{tr}\Pi \le m, \tag{5}$$

where the minimization is carried over the set of all symmetric $(d\times d)$-matrices. The value m^* can be estimated by looking how many eigenvalues of $\widetilde\Pi_m$ are significant. Let $\mathcal{A}_m$ be the set of $(d\times d)$-matrices defined as follows:

$$\mathcal{A}_m = \{A : A = A^\top,\, 0 \preceq A \preceq I,\, \operatorname{tr}A \le m\}.$$

Define $\hat A_m$ as a minimizer of the maximum of the $\hat\beta_\ell^\top(I-A)\hat\beta_\ell$'s instead of their sum:

$$\hat A_m \in \operatorname*{arg\,min}_{A\in\mathcal{A}_m} \max_\ell \hat\beta_\ell^\top(I-A)\hat\beta_\ell. \tag{6}$$

This is a convex optimization problem that can be effectively solved even for a large d although a closed form solution is not known. It is noteworthy that a solution to (6) is not necessarily a projection matrix. In fact, the matrices from $\mathcal{A}_m$ are symmetric positive-semidefinite with eigenvalues between 0 and 1 and not just 0 or 1. This enlargement of the search space guarantees its convexity, which is needed for the algorithm to be tractable. Moreover, as we will show below, the incorporation of (6) in the structural adaptation yields an algorithm having good theoretical and empirical performance.

3. Theoretical Features of SAMM

Throughout this section the true dimension m^* of the EDR subspace is assumed to be known. Thus, we are given n observations $(Y_1,X_1),\dots,(Y_n,X_n)$ from the model

$$Y_i = f(X_i)+\varepsilon_i = g(\vartheta_1^\top X_i,\dots,\vartheta_{m^*}^\top X_i)+\varepsilon_i,$$

where $\varepsilon_1,\dots,\varepsilon_n$ are independent centered random variables. The vectors ϑ_j are assumed to form an orthonormal basis of the EDR subspace entailing thus the representation $\Pi^* = \sum_{j=1}^{m^*}\vartheta_j\vartheta_j^\top$. In what follows, we mainly consider deterministic design. Nevertheless, the results hold in the case of random design as well, provided that the errors are independent of $X_1,\dots,X_n$. Henceforth, without loss of generality we assume that $|X_i|\le 1$ for any $i=1,\dots,n$.

3.1 Description of the Algorithm

The structure-adaptive algorithm with maximum minimization consists of following steps.

a) Specify positive real numbers a_ρ, a_h, ρ_1 and h_1. Choose an integer L and select a set $\{\psi_\ell,\ \ell\le L\}$ of vectors from $\mathbb{R}^n$ verifying $|\psi_\ell|^2 = n$.

b) Set $k=1$ and $\hat A_0 = 0$.

c) Define the estimators $\widehat{\nabla f}_k(X_i)$ for $i=1,\dots,n$ by formula (3) with $w_{ij} = K\big(X_{ij}^\top(I+\rho_k^{-2}\hat A_{k-1})X_{ij}/h_k^2\big)$. Set

$$\hat\beta_{\ell,k} = \frac{1}{n}\sum_{i=1}^n \widehat{\nabla f}_k(X_i)\psi_{\ell,i},\qquad \ell=1,\dots,L,$$

where $\psi_{\ell,i}$ is the ith coordinate of ψ_ℓ.

d) Define the new value $\hat A_k$ by $\hat A_k \in \arg\min_{A\in\mathcal{A}_{m^*}}\max_\ell \hat\beta_{\ell,k}^\top(I-A)\hat\beta_{\ell,k}$.

e) Set $\rho_{k+1} = a_\rho\cdot\rho_k$, $h_{k+1} = a_h\cdot h_k$ and increase k by one.

f) Stop if $\rho_k<\rho_{\min}$ or $h_k>h_{\max}$, otherwise continue with the step c).

Let $k(n)$ be the total number of iterations. We denote by $\widehat\Pi_n$ the orthogonal projection onto the space spanned by the eigenvectors of $\hat A_{k(n)}$ corresponding to the m^* largest eigenvalues. The estimator of the EDR subspace is then the image of $\widehat\Pi_n$.

Both $\hat A_{k(n)}$ and $\widehat\Pi_n$ are estimators of the projector onto $\mathcal{S}$. Our theoretical results are stated for the estimator $\widehat\Pi_n$, but similar results are valid for $\hat A_{k(n)}$, too. The numerical simulations we made showed that these two estimators have comparable performances.

The described algorithm requires the specification of the parameters ρ_1, h_1, a_ρ and a_h, as well as the choice of the set of vectors $\{\psi_\ell\}$. In what follows we use the values

$$\begin{array}{ccc}\rho_1 = 1, & \rho_{\min} = n^{-1/(3\vee m^*)}, & a_\rho = e^{-1/2(3\vee m^*)},\\ h_1 = C_0 n^{-1/(4\vee d)}, & h_{\max} = 2\sqrt{d}, & a_h = e^{1/2(4\vee d)}.\end{array}$$

This choice of input parameters is up to some minor modifications the same as in Hristache et al. (2001b), Hristache et al. (2001a) and Samarov et al. (2005), and is based on the trade-off between

the bias and the variance of estimation. The constant C_0 will be chosen in a design-dependent manner taking into account the fact that the local neighborhoods used in (2) should contain enough design points to entail the consistency of the estimator. The choice of L and that of vectors ψ_ℓ will be discussed in Section 4.

3.2 Assumptions

Prior to stating rigorous theoretical results we need to introduce a set of assumptions. From now on, we use the notation I for the identity matrix of dimension d, $\|A\|^2$ for the largest eigenvalue of $A^\top A$ and $\|A\|_2$ for the Frobenius norm of A (square root of the sum of squares of elements of A).

We start with the smoothness assumption ensuring the adequacy of the local linear approximation of the regression function.

(A1) There exists a positive real C_g such that $|\nabla g(x)| \le C_g$ and $|g(x) - g(x') - (x-x')^\top \nabla g(x)| \le C_g |x-x'|^2$ for every $x, x' \in \mathbb{R}^{m^*}$.

Unlike the smoothness assumption, the assumptions on the identifiability of the model and the regularity of design are more involved and specific to our algorithm. The formal statements read as follows.

(A2) Let the vectors $\beta_\ell \in \mathbb{R}^d$ be defined by (4) and let $\mathcal{B}^* = \big\{\bar\beta = \sum_{\ell=1}^L c_\ell \beta_\ell : \sum_{\ell=1}^L |c_\ell| \le 1\big\}$. There exist vectors $\bar\beta_1, \dots, \bar\beta_{m^*} \in \mathcal{B}^*$ and constants $\mu_1, \dots, \mu_{m^*}$ such that

$$\Pi^* \preceq \sum_{k=1}^{m^*} \mu_k \bar\beta_k \bar\beta_k^\top. \tag{7}$$

We denote $\mu^* = \mu_1 + \ldots + \mu_{m^*}$.

Remark 1 *Assumption (A2) implies that the subspace $\mathcal{S} = \mathrm{Im}(\Pi^*)$ is the smallest DR subspace, therefore it is the EDR subspace. Indeed, for any DR subspace $\mathcal{S}'$, the gradient $\nabla f(X_i)$ belongs to $\mathcal{S}'$ for every i. Therefore $\beta_\ell \in \mathcal{S}'$ for every $\ell \le L$ and $\mathcal{B}^* \subset \mathcal{S}'$. Thus, for every β° from the orthogonal complement $\mathcal{S}'^\perp$, it holds $|\Pi^* \beta^\circ|^2 \le \sum_k \mu_k |\bar\beta_k^\top \beta^\circ|^2 = 0$. Therefore $\mathcal{S}'^\perp \subset \mathcal{S}^\perp$ implying thus the inclusion $\mathcal{S} \subset \mathcal{S}'$.*

Lemma 2 *If the family $\{\psi_\ell\}$ spans $\mathbb{R}^n$, then assumption (A2) is always satisfied with some μ_k (that may depend on n).*

Proof Set $\Psi = (\psi_1, \dots, \psi_L) \in \mathbb{R}^{n \times L}$, $\nabla f = (\nabla f(X_1), \dots, \nabla f(X_n)) \in \mathbb{R}^{d \times n}$ and write the $d \times L$ matrix $B = (\beta_1, \dots, \beta_L)$ in the form $\nabla f \cdot \Psi$. Recall that if M_1, M_2 are two matrices such that $M_1 \cdot M_2$ is well defined and the rank of M_2 coincides with the number of lines in M_2, then $\mathrm{rank}(M_1 \cdot M_2) = \mathrm{rank}(M_1)$. This implies that $\mathrm{rank}(B) = m^*$ provided that $\mathrm{rank}(\Psi) = n$, which amounts to $\mathrm{span}(\{\psi_\ell\}) = \mathbb{R}^n$.

Let now $\tilde\beta_1, \dots, \tilde\beta_{m^*}$ be a linearly independent subfamily of $\{\beta_\ell, \ell \le L\}$. Then the m^*th largest eigenvalue $\lambda_{m^*}(\tilde{\mathscr{M}})$ of the matrix $\tilde{\mathscr{M}} = \sum_{k=1}^{m^*} \tilde\beta_k \tilde\beta_k^\top$ is strictly positive. Moreover, if $v_1, \dots, v_{m^*}$ are the eigenvectors of $\tilde{\mathscr{M}}$ corresponding to the eigenvalues $\lambda_1(\tilde{\mathscr{M}}) \ge \ldots \ge \lambda_{m^*}(\tilde{\mathscr{M}}) > 0$, then

$$\Pi^* = \sum_{k=1}^{m^*} v_k v_k^\top \preceq \frac{1}{\lambda_{m^*}(\tilde{\mathscr{M}})} \sum_{k=1}^{m^*} \lambda_k(\tilde{\mathscr{M}}) v_k v_k^\top = \lambda_{m^*}(\tilde{\mathscr{M}})^{-1} \tilde{\mathscr{M}} = \lambda_{m^*}(\tilde{\mathscr{M}})^{-1} \sum_{k=1}^{m^*} \tilde\beta_k \tilde\beta_k^\top.$$

Hence, inequality (7) is fulfilled with $\mu_k = \lambda_{m^*}(\tilde{\mathscr{M}})^{-1}$ for every $k = 1, \dots, m^*$. ■

These arguments show that the identifiability assumption (A2) is fairly weak. In fact, since we always choose $\{\psi_\ell\}$ so that $\mathrm{span}(\{\psi_\ell\}) = \mathbb{R}^n$, (A2) amounts to requiring that the value μ^* remains bounded when n increases. This assumption is much weaker than the coverage assumption under which the consistency of the inverse regression based methods is proved.

Let us proceed with the assumption on the design regularity. Define $P_1^* = I$ and $P_k^* = (I + \rho_k^{-2}\Pi^*)^{-1/2}$ for every $k \geq 2$. Next, set $Z_{ij}^{(k)} = (h_k P_k^*)^{-1} X_{ij}$ and for any $d \times d$ matrix U put $w_{ij}^{(k)}(U) = K\big((Z_{ij}^{(k)})^\top U Z_{ij}^{(k)}\big)$, $\overline{w}_{ij}^{(k)}(U) = K'\big((Z_{ij}^{(k)})^\top U Z_{ij}^{(k)}\big)$, $N_i^{(k)}(U) = \sum_j w_{ij}^{(k)}(U)$ and

$$V_i^{(k)}(U) = \sum_{j=1}^n \begin{pmatrix} 1 \\ Z_{ij}^{(k)} \end{pmatrix} \begin{pmatrix} 1 \\ Z_{ij}^{(k)} \end{pmatrix}^\top w_{ij}^{(k)}(U).$$

(A3) For some positive constants $C_V, C_K, C_{K'}, C_w$ and for some $\alpha \in]0, 1/2]$, the inequalities

$$\begin{aligned}
&\|V_i^{(k)}(U)^{-1}\| N_i^{(k)}(U) \leq C_V, \qquad i = 1, \dots, n, \\
&\sum_{i=1}^n w_{ij}^{(k)}(U)/N_i^{(k)}(U) \leq C_K, \qquad j = 1, \dots, n, \\
&\sum_{i=1}^n |\overline{w}_{ij}^{(k)}(U)|/N_i^{(k)}(U) \leq C_{K'}, \qquad j = 1, \dots, n, \\
&\sum_{j=1}^n |\overline{w}_{ij}^{(k)}(U)|/N_i^{(k)}(U) \leq C_w \qquad i = 1, \dots, n,
\end{aligned}$$

hold for every $k \leq k(n)$ and for every $d \times d$ matrix U verifying $\|U - I\|_2 \leq \alpha$.

Remark 3 *Note that in (A3) we implicitly assumed that the matrices $V_i^{(k)}$ are invertible, which may be true only if any neighborhood $E^{(k)}(X_i) = \{x : |(I + \rho_k^{-2}\Pi^*)^{-1/2}(X_i - x)| \leq h_k\}$ contains at least d design points different from X_i. The parameters h_1, ρ_1, a_ρ and a_h are chosen so that the volume of ellipsoids $E^{(k)}(X_i)$ is a non-decreasing function of k and $Vol(E^{(1)}(X_i)) = C_0/n$. Therefore, from theoretical point of view, if the design is random with positive density on $[0,1]^d$, it is easy to check that for a properly chosen constant C_0, assumption (A3) is satisfied with a probability close to one. In applications, we define h_1 as the smallest real such that $\min_{i=1,\dots,n} \# E^{(1)}(X_i) = d + 1$ and add to the matrix*

$$\sum_{j=1}^n \begin{pmatrix} 1 \\ X_{ij} \end{pmatrix} \begin{pmatrix} 1 \\ X_{ij} \end{pmatrix}^\top w_{ij},$$

involved in the definition (3), a small full-rank matrix to be sure that the resulting matrix is invertible, see Section 4. This observation also implies that the SAMM procedure can not be applied in the case where the sample size n is smaller than or equal to the dimension d of predictors.

(A4) The errors $\{\varepsilon_i, i \leq n\}$ are centered Gaussian with variance σ^2.

3.3 Risk Bounds for the Projection Matrix Estimation

In this section, we present the main result of the paper assessing the quality of the estimator $\widehat{\Pi}_n$ of the projection matrix Π^* in the asymptotics of large samples. To this end, we assume that the kernel K used in (3) is chosen to be continuous, positive and vanishing outside the interval $[0,1]$. The vectors ψ_ℓ are assumed to verify

$$\max_{\ell=1,\dots,L}\max_{i=1,\dots,n}|\psi_{\ell,i}|<\bar{\psi}, \tag{8}$$

for some constant $\bar{\psi}$ independent of n. In the sequel, we denote by $C,C_1,\dots$ some constants depending only on $m^*,\mu^*,C_g,C_V,C_K,C_{K'},C_w$ and $\bar{\psi}$.

Theorem 4 *Let assumptions **(A1)-(A4)** be fulfilled. There exists $C>0$ such that for any $z\in]0,2\sqrt{\log(nL)}]$ and for sufficiently large values of n, it holds*

$$\mathbf{P}\left(\sqrt{\mathrm{tr}(I-\widehat{\Pi}_n)\Pi^*}>Cn^{-\frac{2}{3\vee m^*}}t_n^2+\frac{2\sqrt{\mu^*}zc_0\sigma}{\sqrt{n(1-\zeta_n)}}\right)\le Lze^{-\frac{z^2-1}{2}}+\frac{3k(n)-5}{n},$$

where $c_0=\bar{\psi}\sqrt{dC_KC_V}$, $t_n=O(\sqrt{\log(Ln)})$ and $\zeta_n=O(t_n n^{-\frac{1}{6\vee m^*}})$.

Corollary 5 *Under the assumptions of Theorem 4, for sufficiently large n, it holds*

$$\mathbf{P}\left(\|\widehat{\Pi}_n-\Pi^*\|_2>Cn^{-\frac{2}{3\vee m^*}}t_n^2+\frac{2\sqrt{2\mu^*}zc_0\sigma}{\sqrt{n(1-\zeta_n)}}\right)\le Lze^{-\frac{z^2-1}{2}}+\frac{3k(n)-5}{n}$$

$$\mathbf{E}(\|\widehat{\Pi}_n-\Pi^*\|_2)\le C\left(n^{-\frac{2}{3\vee m^*}}t_n^2+\frac{\sqrt{\log nL}}{\sqrt{n}}\right)+\frac{\sqrt{2m^*}(3k(n)-5)}{n}.$$

Proof Easy algebra yields

$$\begin{aligned}\|\widehat{\Pi}_n-\Pi^*\|_2^2=\mathrm{tr}(\widehat{\Pi}_n-\Pi^*)^2&=\mathrm{tr}\,\widehat{\Pi}_n^2-2\,\mathrm{tr}\,\widehat{\Pi}_n\Pi^*+\mathrm{tr}\,\Pi^*\\&\le\mathrm{tr}\,\widehat{\Pi}_n+m^*-2\,\mathrm{tr}\,\widehat{\Pi}_n\Pi^*\le 2m^*-2\,\mathrm{tr}\,\widehat{\Pi}_n\Pi^*.\end{aligned}$$

The equality $\mathrm{tr}\,\Pi^*=m^*$ and the linearity of the trace operator complete the proof of the first inequality. The second inequality can be derived from the first one by standard arguments in view of the inequality $\|\widehat{\Pi}_n-\Pi^*\|_2^2\le 2m^*$. ■

According to these results, for $m^*\le 4$, the estimator of the orthogonal projector onto $\mathcal{S}$ provided by the SAMM procedure is $\sqrt{n}$-consistent up to a logarithmic factor. This rate of convergence is known to be optimal for a broad class of semiparametric problems, see Bickel et al. (1998) for a detailed account on the subject.

Remark 6 *The inspection of the proof of Theorem 4 shows that the factor t_n^2 multiplying the "bias" term $n^{-2/(3\vee m^*)}$ disappears when $m^*>3$.*

Remark 7 *The same rate of convergence remains valid in the case when the errors are not necessarily identically distributed Gaussian random variables, but have a bounded exponential moment (uniformly in n). This can be proved along the lines of Proposition 14, see Section 5.*

3.4 Risk Bound for the Estimator of a Basis of the EDR Subspace

The main result of this paper stated in the preceding subsection provides a risk bound for the estimator $\widehat{\Pi}_n$ of Π^*, the orthogonal projector onto $\mathcal{S}$. As a by-product of this result, we show in this section that a similar risk bound holds also for the estimator of an orthonormal basis of $\mathcal{S}$. This means that for an arbitrarily chosen orthonormal basis of the estimated EDR subspace $\hat{\mathcal{S}} = \mathrm{Im}(\widehat{\Pi}_n)$, there is an orthonormal basis of the true EDR subspace $\mathcal{S}$ such that the matrices built from these bases are close in Frobenius norm with a probability tending to one.

Proposition 8 *Let the assumptions of Theorem 4 be fulfilled. For any orthonormal basis $\hat{\vartheta}_1, \ldots, \hat{\vartheta}_{m^*}$ of the estimated EDR subspace $\hat{\mathcal{S}} = \mathrm{Im}(\widehat{\Pi}_n)$ there exists an orthonormal basis $\vartheta_1, \ldots, \vartheta_{m^*}$ of the true EDR subspace $\mathcal{S} = \mathrm{Im}(\Pi^*)$ such that, for sufficiently large n, it holds*

$$\mathbf{P}\left(\|\widehat{\Theta}_n - \Theta\|_2 > C n^{-\frac{2}{3\vee m^*}} t_n^2 + \frac{2(\sqrt{m^*}+1)\sqrt{2\mu^*} z c_0 \sigma}{\sqrt{n(1-\zeta_n)}} \right) \leq L z e^{-\frac{z^2-1}{2}} + \frac{3k(n)-5}{n} ,$$

where $\widehat{\Theta}_n$ (resp. Θ) is the $d \times m^*$ matrix whose jth column is $\hat{\vartheta}_j$ (resp. ϑ_j).

Proof Using the singular value decomposition, we write $\Pi^* \widehat{\Theta}_n = U \Lambda V^\top$, where U and V are orthogonal matrices and Λ is a diagonal matrix. Let us denote by λ_j, u_j, v_j respectively the jth diagonal entry of Λ, the jth column of U and the jth column of V. Since $\Pi^* \widehat{\Theta}_n v_j = \lambda_j u_j$, we have $\lambda_j = |\lambda_j u_j| = |\Pi^* \widehat{\Theta}_n v_j| \leq 1$. On the other hand,

$$\lambda_j = |\Pi^* \widehat{\Theta}_n v_j| \geq |\widehat{\Theta}_n v_j| - |(\widehat{\Pi}_n - \Pi^*)\widehat{\Theta}_n v_j| \geq 1 - \|\widehat{\Pi}_n - \Pi^*\|,$$

where we used the fact that $|\widehat{\Theta}_n v_j|^2 = v_j^\top \widehat{\Theta}_n^\top \widehat{\Theta}_n v_j = v_j^\top v_j = 1$. Let us define the matrix Θ as follows: $\Theta = U I_{d \times m^*} V^\top$, where $I_{d \times m^*}$ is the $d \times m^*$ diagonal matrix with all diagonal entries equal to one. One easily checks that Θ is orthogonal, that is $\Theta^\top \Theta = I_{m^*}$. Moreover, we have $\Theta = \Pi^* \hat{\Theta}_n V \Lambda^- V^\top$, where Λ^- is the $m^* \times m^*$ diagonal matrix having λ_j^{-1} as jth diagonal entry. Note that if the norm of $\hat{\Pi}_n - \Pi^*$ is less than 1, the eigenvalues λ_j are strictly positive. In this case, Λ^- is well defined and we obviously have $\Pi^* \Theta = \Theta$. Thus the columns of Θ form an orthonormal basis of $\mathrm{Im}(\Pi^*)$. Furthermore, we have

$$\begin{aligned}
\|\widehat{\Theta}_n - \Theta\|_2 &\leq \|\Theta - \Pi^* \widehat{\Theta}_n\|_2 + \|(\Pi^* - \widehat{\Pi}_n)\Theta\|_2 \\
&\leq \|U(I_{d \times m^*} - \Lambda) V^\top\|_2 + \|\Pi^* - \widehat{\Pi}_n\|_2 \\
&\leq (\sum_{j=1}^{m^*} (\lambda_j - 1)^2)^{1/2} + \|\Pi^* - \widehat{\Pi}_n\|_2 \\
&\leq (\sqrt{m^*} + 1)\|\Pi^* - \widehat{\Pi}_n\|_2,
\end{aligned}$$

provided that $\|\Pi^* - \widehat{\Pi}_n\| < 1$. This implies that for every $\mathsf{d} \in (0,1)$ the event $\{\|\Pi^* - \widehat{\Pi}_n\|_2 \leq \mathsf{d}\}$ is included in $\{\|\widehat{\Theta}_n - \Theta\|_2 \leq (\sqrt{m^*}+1)\mathsf{d}\}$. By virtue of this inclusion, the assertion of the proposition follows from Corollary 5. ■

4. Simulation Results

The aim of this section is to demonstrate on several examples how the performance of the algorithm SAMM depends on the sample size n, the dimension d and the noise level σ. We also show that our procedure can be successfully applied in autoregressive models. Many unreported results show that in most situations the performance of SAMM is comparable to the performance of SA approach based on PCA and to that of MAVE. A thorough comparison of the numerical virtues of these methods being out of scope of this paper, we simply show on some examples that SAMM may substantially outperform MAVE in the case of large "bias". Our results also show that SAMM and MAVE provide more accurate estimates of the EDR subspace than inverse regression based methods : inverse regression based on Minimum Discrepancy Approach (MDA) introduced in Cook and Ni (2005) and Sliced Average Variance Estimation (SAVE) of Cook and Weisberg (1991). In all simulations for inverse regression based methods, the number of slices is chosen to minimise the risk.

The computer code of the procedure SAMM is distributed freely, it can be downloaded from `http://code.google.com/p/samm07/`. It requires the MATLAB packages SDPT3 and YALMIP. We are grateful to Professor Yingcun Xia for making the computer code of MAVE available to us.

To obtain higher stability of the algorithm, we preliminarily standardize the response Y and the predictors $X^{(j)}$. More precisely, we deal with $\tilde{Y}_i = Y_i/\sigma_Y$ and $\tilde{X} = \mathrm{diag}(\Sigma_X)^{-1/2}X$, where σ_Y^2 is the empirical variance of Y, Σ_X is the empirical covariance matrix of X and $\mathrm{diag}(\Sigma_X)$ is the $d \times d$ matrix obtained from Σ_X by replacing the off-diagonal elements by zero. To preserve consistency, we set $\tilde{\beta}_{\ell,k(n)} = \mathrm{diag}(\Sigma_X)^{-1/2}\hat{\beta}_{\ell,k(n)}$, where $\hat{\beta}_{\ell,k(n)}$ is the last-step estimate of β_ℓ, and define $\widehat{\Pi}_{k(n)}$ as the solution to (6) with $\hat{\beta}_\ell$ replaced by $\tilde{\beta}_{\ell,k(n)}$. Furthermore, we add the small full-rank matrix I_{d+1}/n to $\sum_{j=1}^n \binom{1}{X_{ij}}\binom{1}{X_{ij}}^\top w_{ij}$ in (3).

In all examples presented below the number of replications is $N = 250$; for each replication, a new sample of the design and the error vector $(\varepsilon_1, \ldots, \varepsilon_n)$ has been generated at random. The mean loss $\overline{\mathrm{er}_N} = \frac{1}{N}\sum_j \mathrm{er}_j$ and the standard deviation $\sqrt{\frac{1}{N}\sum_j (\mathrm{er}_j - \overline{\mathrm{er}_N})^2}$ are reported, where $\mathrm{er}_j = \|\widehat{\Pi}^{(j)} - \Pi^*\|$ with $\widehat{\Pi}^{(j)}$ being the estimator of Π^* for jth replication.

4.1 Choice of $\{\psi_\ell, \ell \le L\}$

The set $\{\psi_\ell\}$ plays an essential role in the algorithm. The optimal choice of this set is an important issue that needs further investigation. We content ourselves with giving one particular choice which agrees with theory and leads to nice empirical results.

Let $\mathfrak{S}_j$, $j \le d$, be the permutation of the set $\{1, \ldots, n\}$ satisfying $X^{(j)}_{\mathfrak{S}_j(1)} \le \ldots \le X^{(j)}_{\mathfrak{S}_j(n)}$. Let $\mathfrak{S}_j^{-1}$ be the inverse of $\mathfrak{S}_j$, that is, $\mathfrak{S}_j(\mathfrak{S}_j^{-1}(k)) = k$ for every $k = 1, \ldots, n$. Define $\{\psi_\ell\}$ as the set of vectors

$$\left\{ \begin{pmatrix} \cos\big(\frac{2\pi(k-1)\mathfrak{S}_j^{-1}(1)}{n}\big), \ldots, \cos\big(\frac{2\pi(k-1)\mathfrak{S}_j^{-1}(n)}{n}\big) \end{pmatrix}^\top \\ \begin{pmatrix} \sin\big(\frac{2\pi k\mathfrak{S}_j^{-1}(1)}{n}\big), \ldots, \sin\big(\frac{2\pi k\mathfrak{S}_j^{-1}(n)}{n}\big) \end{pmatrix}^\top , k \le [n/2],\ j \le d \right\}$$

normalized to satisfy $\sum_{i=1}^n \psi_{\ell,i}^2 = n$ for every ℓ. It is easily seen that these vectors satisfy conditions (8) and $\mathrm{span}(\{\psi_\ell\}) = \mathbb{R}^n$, so the conclusion of Lemma 2 holds. Above, $[n/2]$ is the integer part of $n/2$ and k and j are positive integers.

The idea behind the above described choice of vectors ψ_ℓ is the following: if the design is uniformly distributed in $[0,1]^d$ and $H(x)$ is a function $\mathbb{R}^d \to \mathbb{R}$ depending only on one coordinate of x, the projections of the vector $g = (H(X_1),\dots,H(X_n))^\top$ on some of directions ψ_ℓ are nearly equal to the Fourier coefficients of H. Indeed, for n odd and for every fixed j, the vectors $\{e_{k,j} = \big(\phi_k(\mathfrak{S}_j^{-1}(1)/n), \phi_k(\mathfrak{S}_j^{-1}(2)/n),\dots,\phi_k(\mathfrak{S}_j^{-1}(n)/n)\big)^\top; 1 \le k \le n\}$ with $\{\phi_k\}$ being the trigonometric basis (that is $\phi_{2p}(x) = \sqrt{2}\sin(2\pi px)$ and $\phi_{2p+1}(x) = \sqrt{2}\cos(2\pi px)$ for every $p \in \mathbb{N}$) form an orthonormal basis of $\mathbb{R}^n$. Therefore, for any function H from $\mathbb{R}^d$ to $\mathbb{R}$, which depends exclusively on the j^{th} coordinate $x^{(j)}$ of x, one has $g^\top e_{kj} = \sum_{i=1}^n H_0(X_i^{(j)})\phi_k(\mathfrak{S}_j^{-1}(i)/n) = \sum_{i=1}^n H_0(X^{(j)}_{\mathfrak{S}_j(i)})\phi_k(i/n)$ for some function $H_0 : \mathbb{R} \to \mathbb{R}$. Since for a sample $X_1^{(j)},\dots,X_n^{(j)}$ drawn from uniform distribution in $[0,1]$ the order statistics are nearly equal to i/n, we get $\frac{1}{n} g^\top e_{kj} \approx \frac{1}{n}\sum_{i=1}^n H_0(i/n)\phi_k(i/n) \approx \langle H_0, \phi_k\rangle_{L^2[0,1]}$. Note that although this explanation is valid only for uniform design and a function H depending only on one coordinate, empirical results show that this choice leads to satisfactory results in more general situations.

4.2 Example 1 (Single-index)

We set $d = 5$ and $f(x) = g(\vartheta^\top x)$ with

$$g(t) = 4|t|^{1/2}\sin^2(\pi t), \quad \text{and} \quad \vartheta = (1/\sqrt{5}, 2/\sqrt{5}, 0, 0, 0)^\top \in \mathbb{R}^5.$$

We ran SAMM, MAVE, MDA and SAVE procedures on the data generated by the model

$$Y_i = f(X_i) + 0.5\cdot\varepsilon_i,$$

where the design X is such that the coordinates $(X_i^{(j)}, j \le 5, i \le n)$ are i.i.d. uniform in $[-1,1]$, and the errors ε_i are i.i.d. standard Gaussian independent of the design.

Table 1 contains the average loss for different values of the sample size n for the first step estimator by SAMM, the final estimator provided by SAMM and the estimators based on MAVE, MDA and SAVE. The first observation is that inverse regression based methods are not consistent in this case. We plot in Figure 1 the average loss normalized by the square root of the sample size n versus n. It is clearly seen that the iterative procedure improves considerably the quality of estimation and that the final estimator provided by SAMM is $\sqrt{n}$-consistent. In this example, MAVE method often fails to recover the EDR subspace. However, the number of failures decreases very rapidly with increasing n. This is the reason why the curve corresponding to MAVE in Figure 1 decreases with a strong slope.

4.3 Example 2 (Double-index)

For $d \ge 2$ we set $f(x) = g(\vartheta^\top x)$ with

$$g(x) = (x_1 - x_2^3)(x_1^3 + x_2);$$

and $\vartheta_1 = (1,0,\dots,0) \in \mathbb{R}^d$, $\vartheta_2 = (0,1,\dots,0) \in \mathbb{R}^d$. We ran SAMM, MAVE, MDA and SAVE procedures on the data generated by the model

$$Y_i = f(X_i) + 0.1\cdot\varepsilon_i, \qquad i = 1,\dots,300,$$

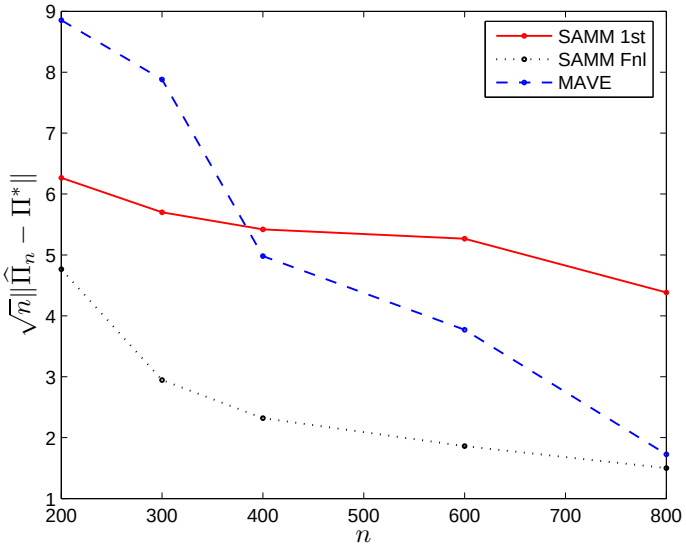

Figure 1: Average loss multiplied by $\sqrt{n}$ versus n for the first step (solid line) and the final (dotted line) estimators provided by SAMM and for the estimator by MAVE (dashed line) in Example 1.

Table 1: Average loss $\|\widehat{\Pi} - \Pi^*\|$ of the estimators obtained by SAMM, MAVE, MDA and SAVE procedures in Example 1. The standard deviation is given in parentheses.

where the design X is such that the coordinates $(X_i^{(j)}, j \le d, i \le n)$ are i.i.d. uniform in $[-40,40]$, and the errors ε_i are i.i.d. standard Gaussian independent of the design. The results of simulations for different values of d are reported in Table 2.

As expected, we found that (cf. Figure 2) the quality of SAMM, as well as the quality of SAVE, deteriorated linearly in d as d increased. This agrees with our theoretical results. It should be noted that in this case MAVE and MDA fail to find the EDR subspace.

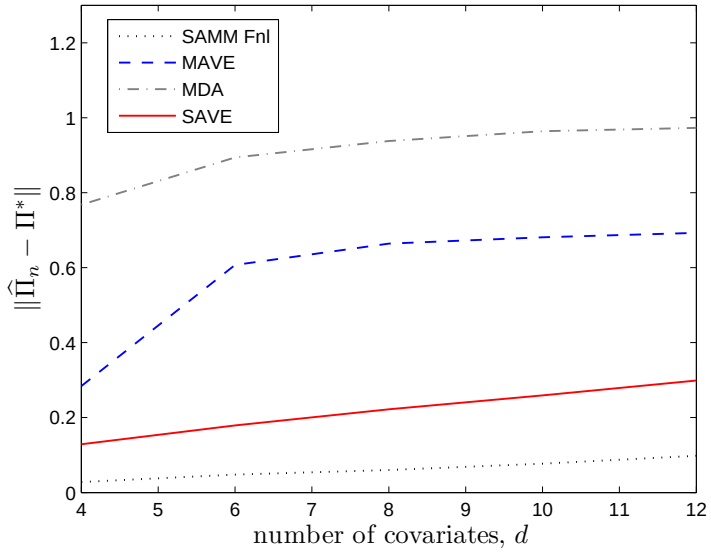

Figure 2: Average loss versus d for the estimators provided by SAMM (dotted line), by MAVE (dashed line), by MDA (dash-dot line) and by SAVE (solid line) in Example 2.

4.4 Example 3

For $d = 5$ we set $f(x) = g(\vartheta^\top x)$ with

$$g(x) = (1+x_1)(1+x_2)(1+x_3)$$

and $\vartheta_1 = (1,0,0,0,0)$, $\vartheta_2 = (0,1,0,0,0)$, $\vartheta_3 = (0,0,1,0,0)$. We ran SAMM, MAVE, MDA and SAVE procedures on the data generated by the model

$$Y_i = f(X_i) + \sigma \cdot \varepsilon_i, \qquad i = 1, \ldots, 250,$$

where the design X is such that the coordinates $(X_i^{(j)}, j \le d, i \le n)$ are i.i.d. uniform in $[0,20]$, and the errors ε_i are i.i.d. standard Gaussian independent of the design.

Figure 3 shows that the qualities of both SAMM and MAVE deteriorate linearly in σ, when σ increases. These results also demonstrate that, thanks to an efficient bias reduction, the SAMM procedure outperforms MAVE when stochastic error is small, whereas MAVE works better than SAMM in the case of dominating stochastic error (that is when σ is large).

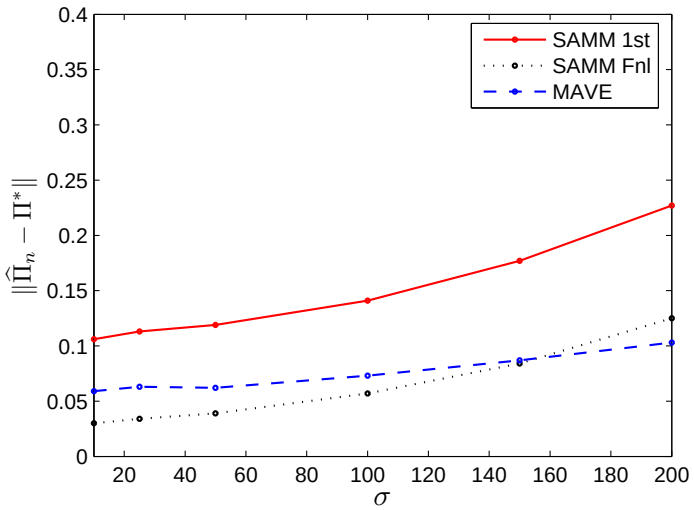

Figure 3: Average loss versus σ for the first step (solid line) and the final (dotted line) estimators provided by SAMM and for the estimator based on MAVE (dashed line) in Example 3.

4.5 Example 4 (Time Series)

Let now $T_1,\dots,T_{n+6}$ be generated by the autoregressive model

$$T_{i+6} = f(T_{i+5},T_{i+4},T_{i+3},T_{i+2},T_{i+1},T_i) + 0.2\cdot\varepsilon_i, \qquad i=1,\dots,n,$$

with initial variables $T_1,\dots,T_6$ being independent standard normal independent of the innovations ε_i, which are i.i.d. standard normal as well. Let now $f(x) = g(\vartheta^\top x)$ with

$$g(x) = -1 + 0.6x_1 - \cos(0.5\pi x_2) + e^{-x_3^2},$$

and

$$\begin{aligned}\vartheta_1 &= (1,0,0,2,0,0)/\sqrt{5},\\ \vartheta_2 &= (0,0,1,0,0,2)/\sqrt{5},\\ \vartheta_3 &= (-2,2,-2,1,-1,1)/\sqrt{15}.\end{aligned}$$

We ran SAMM and MAVE procedures on the data (X_i,Y_i), $i=1,\dots,250$, where $Y_i = T_{i+6}$ and $X_i = (T_i,\dots,T_{i+5})^\top$. The results of simulations reported in Table 4 show that the qualities of SAMM and MAVE are comparable, with SAMM being slightly better. SAVE is better than MDA, but both of them are far less accurate than SAMM and MAVE.

5. Proofs

Since the proof of the main result is carried out in several steps, we give a short road map for guiding the reader throughout the proof. The main idea is to evaluate the accuracy of the first step estimators of β_ℓ and, given the accuracy of the estimator at the step k, evaluate the accuracy of the estimators at the step $k+1$. This is done in Subsections 5.2 and 5.1. These results are based on a maximal inequality proved in Subsection 5.4 and on some properties of the solution to (6) proved in Subsection 5.5. The proof of Theorem 4 is presented in Subsection 5.3, while some technical lemmas are postponed to Subsection 5.6.

5.1 One Step Improvement

Let $\{\delta_k\}$ be a sequence of positive numbers to be chosen later and let $\mathscr{P}_k = \big\{A \in \mathcal{A}_{m^*} : \operatorname{tr}(I-A)\Pi^* \le \delta_k^2\big\}$. Recall that we use the following notation:

$$P_k^* = (I+\rho_k^{-2}\Pi^*)^{-1/2}, \quad Z_{ij}^{(k)} = (h_k P_k^*)^{-1} X_{ij}, \quad w_{ij}^{(k)}(U) = K\big((Z_{ij}^{(k)})^\top U Z_{ij}^{(k)}\big)$$
$$N_i^{(k)}(U) = \sum_j w_{ij}^{(k)}(U), \qquad V_i^{(k)}(U) = \sum_{j=1}^n \begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix}\begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix}^\top w_{ij}^{(k)}(U),$$

where U is a $d\times d$ symmetric positive-semidefinite matrix. Let us define $S_k = (I+\rho_k^{-2}\hat{A}_{k-1})^{1/2}$ and $U_k = P_k^* S_k^2 P_k^*$.

One easily checks that the estimator $\widehat{\nabla f}_k(X_i)$ is given by

$$\begin{pmatrix}\hat{f}_k(X_i)\\ \widehat{\nabla f}_k(X_i)\end{pmatrix} = \Big\{\sum_{j=1}^n \begin{pmatrix}1\\ X_{ij}\end{pmatrix}\begin{pmatrix}1\\ X_{ij}\end{pmatrix}^\top w_{ij}^{(k)}(U_k)\Big\}^{-1} \sum_{j=1}^n Y_j \begin{pmatrix}1\\ X_{ij}\end{pmatrix} w_{ij}^{(k)}(U_k),$$

Simple algebra yields

$$\begin{pmatrix}h_k^{-1}\hat{f}_k(X_i)\\ P_k^*\widehat{\nabla f}_k(X_i)\end{pmatrix} = h_k^{-1} V_i^{(k)}(U_k)^{-1} \sum_{j=1}^n Y_j \begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix} w_{ij}^{(k)}(U_k).$$

In order to study the behavior of $\widehat{\nabla f}_k$, we will proceed in a first step as if U_k were deterministic. For this reason, the notation

$$\begin{pmatrix}h_k^{-1}\overline{f}_k(X_i)\\ P_k^*\overline{\nabla f}_k(X_i)\end{pmatrix} = h_k^{-1} V_i^{(k)}(U_k)^{-1} \sum_{j=1}^n f(X_j) \begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix} w_{ij}^{(k)}(U_k),$$

will be useful. In fact, $\overline{\nabla f}_k(X_i)$ defined as above would be the expectation of $\widehat{\nabla f}_k(X_i)$ if U_k were deterministic.

Proposition 9 *Let assumptions (A1)-(A4) be fulfilled. If for some integer $k \in [2, k(n)]$ the real number $\alpha_k = 2\delta_{k-1}^2\rho_k^{-2} + 2\delta_{k-1}\rho_k^{-1}$ is less than the constant α appearing in assumption (A3), then there exist Gaussian vectors $\xi_{1,k}^*, \dots, \xi_{L,k}^* \in \mathbb{R}^d$ such that $\max_{1\le\ell\le L}\mathbf{E}[|\xi_{\ell,k}^*|^2] \le c_0^2\sigma^2$ and*

$$\mathbf{P}\Big(\max_{1\le\ell\le L}\Big|P_k^*(\hat{\beta}_{\ell,k}-\beta_\ell) - \frac{\xi_{\ell,k}^*}{\sqrt{n}h_k}\Big| \ge \Upsilon_k,\ \hat{A}_{k-1}\in\mathscr{P}_{k-1}\Big) \le \frac{2}{n}\ ,$$

where we used the notation $\Upsilon_k = \sqrt{C_V}C_g(\rho_k+\delta_{k-1})^2 h_k + c_1\sigma\alpha_k t_n/(\sqrt{n}h_k)$ with $t_n = 4+(3\log(Ln)+\frac{3}{2}d^2\log n)^{1/2}$, $c_0 = \bar{\psi}(dC_KC_V)^{1/2}$ and $c_1 = 15\bar{\psi}(C_w^2C_V^4C_K^2 + C_V^2C_{K'}^2)^{1/2}$.

Proof Let us start with evaluating the "bias" term $|P_k^*(\bar{\beta}_{\ell,k}-\beta_\ell)|$, where the vectors $\bar{\beta}_{\ell,k}$ are defined as $\frac{1}{n}\sum_{i=1}^n \overline{\nabla f}_k(X_i)\psi_{\ell,i}$. According to the Cauchy-Schwarz inequality, it holds

$$\begin{aligned}\big|P_k^*\big(\bar{\beta}_{\ell,k}-\beta_\ell\big)\big|^2 &= n^{-2}\Big|\sum_{i=1}^n P_k^*\big(\overline{\nabla f}_k(X_i) - \nabla f(X_i)\big)\psi_{\ell,i}\Big|^2\\ &\le n^{-2}\sum_{i=1}^n\big|P_k^*\big(\overline{\nabla f}_k(X_i)-\nabla f(X_i)\big)\big|^2\sum_{i=1}^n\psi_{l,i}^2\\ &\le \max_{i=1,\dots,n}\big|P_k^*\big(\overline{\nabla f}_k(X_i)-\nabla f(X_i)\big)\big|^2.\end{aligned}$$

Simple computations show that

$$\begin{aligned}\left|P_k^*\left(\overline{\nabla f}_k(X_i)-\nabla f(X_i)\right)\right| &\le \left|\begin{pmatrix} h_k^{-1}\overline{f}_k(X_i)\\ P_k^*\overline{\nabla f}_k(X_i)\end{pmatrix}-\begin{pmatrix} h_k^{-1}f(X_i)\\ P_k^*\nabla f(X_i)\end{pmatrix}\right| \\ &= \left|h_k^{-1}V_i^{(k)}(U_k)^{-1}\sum_{j=1}^n f(X_j)\begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix}w_{ij}^{(k)}(U_k)-\begin{pmatrix} h_k^{-1}f(X_i)\\ P_k^*\nabla f(X_i)\end{pmatrix}\right| \\ &= h_k^{-1}\left|V_i^{(k)}(U_k)^{-1}\sum_{j=1}^n r_{ij}\begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix}w_{ij}^{(k)}(U_k)\right| := b(X_i),\end{aligned}$$

where $r_{ij}=f(X_j)-f(X_i)-X_{ij}^\top\nabla f(X_i)$. Define $v_j=V_i^{(k)}(U_k)^{-1/2}\begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix}\sqrt{w_{ij}^{(k)}(U_k)}$, $\lambda_j=h_k^{-1}r_{ij}\sqrt{w_{ij}^{(k)}(U_k)}$ and $\lambda=(\lambda_1,\dots,\lambda_n)^\top$. Then $\sum_j v_j v_j^\top=I_{d+1}$ and

$$b(X_i)=\left|V_i^{(k)}(U_k)^{-1/2}\sum_{j=1}^n\lambda_j v_j\right|\le\left\|V_i^{(k)}(U_k)^{-1/2}\right\|\cdot|\lambda|.$$

Note now that in view of Lemma 21, $\|U_k-I\|_2\le\alpha_k$ on the event $\{\hat{A}_{k-1}\in\mathscr{P}_{k-1}\}$. Therefore,

$$\begin{aligned}b(X_i)^2 &\le h_k^{-2}\left\|V_i^{(k)}(U_k)^{-1/2}\right\|^2\cdot\sum_{j=1}^n r_{ij}^2 w_{ij}^{(k)}(U_k)\\ &\le h_k^{-2}\max_{j:w_{ij}^{(k)}(U_k)\ne0} r_{ij}^2\left\|V_i^{(k)}(U_k)^{-1}\right\|\cdot\sum_{j=1}^n w_{ij}^{(k)}(U_k)\le C_V h_k^{-2}\max_{j:w_{ij}^{(k)}(U_k)\ne0} r_{ij}^2.\end{aligned}$$

Let us denote by Θ the $(d\times m^*)$ matrix having ϑ_l as lth column. Then $\Pi^*=\Theta\Theta^\top$ and therefore, in view of (A1),

$$\begin{aligned}|r_{ij}| &= |f(X_j)-f(X_i)-X_{ij}^\top\nabla f(X_i)|\\ &= |g(\Theta^\top X_j)-g(\Theta^\top X_i)-(\Theta^\top X_{ij})^\top\nabla g(\Theta^\top X_i)|\\ &\le C_g|\Theta^\top X_{ij}|^2=C_g|\Pi^*X_{ij}|^2.\end{aligned}$$

Since the weights $w_{ij}^{(k)}$ are defined via the kernel function K vanishing on the interval $[1,\infty[$, we have $\max_{j:w_{ij}^{(k)}(U_k)\ne0} r_{ij}^2=\max\{r_{ij}^2:|S_kX_{ij}|\le h_k\}$. By Corollary 19, the inequality $|S_kX_{ij}|\le h_k$ implies $|\Pi^*X_{ij}|\le(\rho_k+\delta_{k-1})h_k$. On the other hand, $|\Pi^*X_{ij}|\le|X_{ij}|\le|S_kX_{ij}|\le h_k$. These estimates yield $|b(X_i)|\le\sqrt{C_V}C_g\{(\rho_k+\delta_{k-1})\wedge1\}^2h_k$, and consequently,

$$\max_{\ell=1,\dots,L}\left|P_k^*\left(\overline{\beta}_{\ell,k}-\beta_\ell\right)\right|\le\max_i b(X_i)\le\sqrt{C_V}C_g\{(\rho_k+\delta_{k-1})\wedge1\}^2h_k. \tag{9}$$

Let us evaluate now the "stochastic" error $P_k^*\left(\hat{\beta}_{\ell,k}-\overline{\beta}_{\ell,k}\right)$. Define E_1 as the $d\times(d+1)$ matrix $(0\ I)$, where 0 stands for the vector all coordinates of which are zero and I is the $d\times d$ identity matrix. Using this notation, we have $P_k^*\left(\hat{\beta}_{\ell,k}-\overline{\beta}_{\ell,k}\right)=\sum_{j=1}^n c_{j,\ell}(U_k)\,\varepsilon_j$, where

$$c_{j,\ell}(U_k)=\frac{1}{nh_k}\sum_{i=1}^n E_1V_i^{(k)}(U_k)^{-1}\begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix}w_{ij}^{(k)}(U_k)\psi_{\ell,i}.$$

Let us define $\xi^*_{\ell,k} = \sqrt{n}h_k \sum_{j=1}^n c_{j,\ell}(I)\,\varepsilon_j$. Clearly, the vectors $\xi^*_{\ell,k}$ are centered Gaussian and, in view of Lemma 22, they satisfy $\mathbf{E}[|\xi^*_{\ell,k}|^2] \le nh_k^2\sigma^2 \sum_j |c_{j,\ell}(I)|^2 \le c_0^2\sigma^2$.

By virtue of Lemma 21, on the event $\{\hat{A}_{k-1} \in \mathscr{P}_{k-1}\}$, for any $\ell = 1,\dots,L$ we have

$$\left| P_k^*(\hat{\beta}_{\ell,k} - \bar{\beta}_{\ell,k}) - \frac{\xi^*_{\ell,k}}{\sqrt{n}h_k} \right| \le \sup_{\|U-I\|_2 \le \alpha_k} \left| \sum_{j=1}^n \big(c_{j,\ell}(U) - c_{j,\ell}(I)\big)\,\varepsilon_j \right|.$$

Set $a_{j,\ell}(U) = c_{j,\ell}(U) - c_{j,\ell}(I)$. Lemma 23 and inequality (12) imply that Proposition 14 can be applied with $\kappa_0 = \frac{c_1\alpha_k}{\sqrt{n}h_k}$ and $\kappa_1 = \frac{c_1}{\sqrt{n}h_k}$. Setting $\varepsilon = 2\alpha_k/\sqrt{n}$ we get that the probability of the event

$$\left\{ \sup_{U,\ell} \left| \sum_{j=1}^n \big(c_{j,\ell}(U) - c_{j,\ell}(I)\big)\,\varepsilon_j \right| \ge \frac{c_1\sigma\alpha_k(4 + \sqrt{3\log(Ln) + 3d^2\log(\sqrt{n})})}{\sqrt{n}h_k} \right\}$$

is less than $2/n$. This completes the proof of the proposition. ■

Corollary 10 *If $nL \ge 6$ and the assumptions of Proposition 9 are fulfilled, then*

$$\mathbf{P}\left(\max_\ell \left|P_k^*(\hat{\beta}_{\ell,k} - \beta_\ell)\right| \ge \Upsilon_k + \frac{\sigma c_0 z}{\sqrt{n}h_k}, \hat{A}_{k-1} \in \mathscr{P}_{k-1} \right) \le Lze^{-\frac{z^2-1}{2}}.$$

In particular, if $nL \ge 6$, the probability of the event

$$\left\{ \max_\ell \left|P_k^*(\hat{\beta}_{\ell,k} - \beta_\ell)\right| \ge \Upsilon_k + \frac{2\sigma c_0\sqrt{\log(Ln)}}{\sqrt{n}h_k} \right\} \cap \{\hat{A}_{k-1} \in \mathscr{P}_{k-1}\}$$

does not exceed $3/n$, where Υ_k and c_0 are defined in Proposition 9.

Proof In view of Lemma 7 in Hristache et al. (2001b), we have

$$\mathbf{P}\big(\max_{\ell=1,\dots,L} \left|\xi^*_{\ell,k}\right| \ge zc_0\sigma\big) \le \sum_{\ell=1}^L \mathbf{P}\big(\left|\xi^*_{\ell,k}\right| \ge zc_0\sigma\big) \le Lze^{-(z^2-1)/2}.$$

The choice $z = \sqrt{4\log(nL)}$ leads to the desired inequality provided that $nL \ge 6$. ■

5.2 The Accuracy of the First-step Estimator

Since at the first step no information about the EDR subspace is available, we use the same bandwidth in all directions, that is the local neighborhoods are balls (and not ellipsoids) of radius h. Therefore the first step estimator $\hat{\beta}_{\ell,1}$ of the vector β_ℓ is the same as the one used in Hristache et al. (2001a).

Proposition 11 *Under assumptions (A1), (A3), (A4) and (8), for every $\ell \le L$, there exists a d-dimensional zero mean Gaussian vector $\xi^*_{\ell,1}$ so that*

$$\left| \hat{\beta}_{\ell,1} - \beta_\ell - \frac{\xi^*_{\ell,1}}{\sqrt{n}h_1} \right| \le h_1 C_g \sqrt{C_V},$$

and $\mathbf{E}|\xi^*_{\ell,1}|^2 \le d\sigma^2 C_V C_K \overline{\psi}^2$.

Proof Since P_1^* coincides by definition with the identity matrix, the arguments used in the proof of Proposition 9 apply with $S_1 = I$ and therefore $\delta_0 = \alpha_1 = 0$. More precisely, in view of (9) and $\rho_1 = 1$, we have $|\beta_{\ell,1} - \beta_\ell| \le h_1\sqrt{C_V}C_g$ for all ℓ, while in view of the relation $U_1 = I$, we have $\hat\beta_{\ell,1} - \bar\beta_{\ell,1} = \frac{1}{\sqrt{n}h_1}\xi^*_{\ell,1}$. This yields the desired result. ■

Corollary 12 *If $nL \ge 6$ and the assertions of Proposition 11 hold, then*

$$\mathbf{P}\left(\max_\ell |\hat\beta_{\ell,1} - \beta_\ell| \ge h_1 C_g\sqrt{C_V} + \frac{2\sqrt{dC_VC_K\log(nL)}\,\sigma\bar\psi}{h_1\sqrt{n}} \right) \le \frac{1}{n}.$$

Remark 13 *In order that the kernel estimator of $\nabla f(x)$ be consistent, the ball centered at x with radius h_1 should contain at least d points from $\{X_i, i = 1,\dots,n\}$. If the design is regular, this means that h_1 is at least of order $n^{-1/d}$. The optimization of the risk of $\hat\beta_{1,\ell}$ with respect to h_1 verifying $h_1 \ge n^{-1/d}$ leads to $h_1 = Const.n^{-1/(4\vee d)}$. This motivates the choice of h_1 presented in Section 3.*

5.3 Proof of Theorem 4

Recall that at the first step we use the following values of parameters: $\hat A_0 = 0$, $\rho_1 = 1$ and $h_1 = n^{-1/(d\vee 4)}$. Let us denote

$$\gamma_1 = h_1C_g\sqrt{C_V} + \frac{2\sigma\bar\psi\sqrt{2dC_VC_K\log(nL)}}{h_1\sqrt{n}}, \quad \delta_1 = 2\gamma_1\sqrt{\mu^*},$$

and introduce the event $\Omega_1 = \{\max_\ell |\hat\beta_{1,\ell} - \beta_\ell| \le \gamma_1\}$. According to Corollary 12 the probability of the event Ω_1 is at least $1 - n^{-1}$. In conjunction with Proposition 17, this implies that $\mathbf{P}(\mathrm{tr}(I - \hat A_1)\Pi^* \le \delta_1^2) \ge 1 - n^{-1}$.

Recall that for any integer $k \in [2, k(n)]$—where $k(n)$ is the total number of iterations—we use the notation $\rho_k = a_\rho\rho_{k-1}$, $h_k = a_h h_{k-1}$ and $\alpha_k = 2\delta_{k-1}^2\rho_k^{-2} + 2\delta_{k-1}\rho_k^{-1}$. Let us introduce the additional notation

$$\begin{aligned}
\gamma_k &= \frac{1}{\sqrt{n}h_k}\begin{cases}\sqrt{n}h_k\Upsilon_k + 2\sigma c_0\sqrt{\log(nL)}, & k < k(n),\\ \sqrt{n}h_k\Upsilon_k + \sigma c_0 z, & k = k(n),\end{cases}\\
\zeta_k &= 2\mu^*(\gamma_k^2\rho_k^{-2} + \sqrt{2}\,\gamma_k\rho_k^{-1}C_g),\\
\delta_k &= 2\gamma_k\sqrt{\mu^*}/\sqrt{1-\zeta_k},\\
\Omega_k &= \{\max_\ell |P_k^*(\hat\beta_{\ell,k} - \beta_\ell)| \le \gamma_k\}.
\end{aligned}$$

Combining Lemmas 24 and 25, we obtain $\mathbf{P}(\mathrm{tr}(I - \hat A_{k-1})\Pi^* > \delta_{k-1}^2) \le \mathbf{P}(\Omega_{k-1}^c)$ and therefore, using Corollary 10, we get

$$\begin{aligned}
\mathbf{P}\big(\Omega_k^c\big) &\le \mathbf{P}\Big(\max_\ell |P_k^*(\hat\beta_{\ell,k} - \beta_\ell)| > \gamma_k,\, \hat A_{k-1} \in \mathscr{P}_{k-1}\Big) + \mathbf{P}\big(\Omega_{k-1}^c\big)\\
&\le \frac{3}{n} + \mathbf{P}\big(\Omega_{k-1}^c\big), \qquad \forall\, k \le k(n) - 1.
\end{aligned}$$

Since $\mathbf{P}(\Omega_1^c) \le 1/n$, it holds $\mathbf{P}(\Omega_{k(n)-1}^c) \le (3k(n)-5)/n$ and, by virtue of Corollary 10, $\mathbf{P}(\Omega_{k(n)}^c) \le Lze^{-(z^2-1)/2} + \frac{3k(n)-5}{n}$. In conjunction with Lemma 25, this yields

$$\mathbf{P}\big(\operatorname{tr}(I-\hat{A}_{k(n)})\Pi^* > \delta_{k(n)}^2\big) \le Lze^{-(z^2-1)/2} + \frac{3k(n)-5}{n}\,. \tag{10}$$

According to Lemma 24, we have $\delta_{k(n)-2} \le \rho_{k(n)-1}$, $\alpha_{k(n)-1} \le 4$ and $\zeta_{k(n)-1} \le 1/2$. Consequently, for n sufficiently large, we have

$$\delta_{k(n)-1} = \frac{2\sqrt{\mu^*}\gamma_{k(n)-1}}{\sqrt{1-\zeta_{k(n)-1}}} \le C\left(\frac{\log(Ln)}{n}\right)^{1/2} \vee n^{-2/3\vee m^*}$$

and $\alpha_{k(n)} \le 4\delta_{k(n)-1}\rho_{k(n)}^{-1} \le C[(\sqrt{\log(Ln)}(\rho_{k(n)}\sqrt{n})^{-1}) \vee n^{-1/3\vee m^*}]$. Since $h_{k(n)} = 1$ and $(n\rho_{k(n)})^{-1} \le \rho_{k(n)}^2 = n^{-2/(3\vee m^*)}$, we infer that

$$\begin{aligned}\gamma_{k(n)} &= C_g\sqrt{C_V}\,(\rho_{k(n)} + \delta_{k(n)-1})^2 + \frac{\sigma(zc_0 + c_1\alpha_{k(n)}t_n)}{\sqrt{n}} \\ &\le Ct_n^2 n^{-2/(3\vee m^*)} + \frac{c_0\sigma z}{\sqrt{n}}.\end{aligned}$$

Therefore $\zeta_n := \zeta_{k(n)} = O(\gamma_{k(n)}\rho_{k(n)}^{-1})$ tends to zero as n tends to infinity not slower than $\sqrt{\log(nL)}\,n^{-1/(6\vee m^*)}$ and the assertion of the theorem follows from (10), the definition of $\delta_{k(n)}$ and Lemma 20.

5.4 Maximal Inequality

The following result contains a well known maximal inequality for the maximum of a Gaussian process. We include its proof for the completeness of exposition. Let $\mathbb{S}_{d-1}$ denote the unit ball of $\mathbb{R}^d$.

Proposition 14 *Let r be a positive number and let Γ be a finite set. Let functions $a_{j,\gamma} : \mathbb{R}^p \to \mathbb{R}^d$ obey the conditions*

$$\begin{aligned}&\sup_{\gamma\in\Gamma}\sup_{|u-u^*|\le r}\sum_{j=1}^n |a_{j,\gamma}(u)|^2 \le \kappa_0^2, \\ &\sup_{\gamma\in\Gamma}\sup_{|u-u^*|\le r}\sup_{e\in\mathbb{S}_{d-1}}\sum_{j=1}^n \left|\frac{d}{du}\,(e^\top a_{j,\gamma}(u))\right|^2 \le \kappa_1^2\end{aligned}$$

for some $u^* \in \mathbb{R}^p$. If the ε_j's are independent $\mathcal{N}(0,\sigma^2)$-distributed random variables, then

$$\mathbf{P}\left(\sup_{\gamma\in\Gamma}\sup_{|u-u^*|\le r}\left|\sum_{j=1}^n a_{j,\gamma}(u)\,\varepsilon_j\right| > t\sigma\kappa_0 + 2\sqrt{n}\sigma\kappa_1\varepsilon\right) \le \frac{2}{n},$$

where $t = \sqrt{3\log(|\Gamma|(2r/\varepsilon)^p n)}$ and $|\Gamma|$ is the cardinality of Γ.

Proof Let B_r be the ball $\{u : |u-u^*| \le r\} \subset \mathbb{R}^p$ and $\Sigma_{r,\varepsilon}$ be an ε-net on B_r such that for any $u \in B_r$ there is an element $u_l \in \Sigma_{r,\varepsilon}$ such that $|u-u_l| \le \varepsilon$. It is easy to see that such a net with cardinality $N_{r,\varepsilon} < (2r/\varepsilon)^p$ can be constructed. For every $u \in B_r$ we denote$\eta_\gamma(u) = \sum_{j=1}^n a_{j,\gamma}(u)\varepsilon_j$. Since $\mathbf{E}(|\eta_\gamma(u)|^2) \le \sigma^2\kappa_0^2$ for any γ and for any u, we have

$$\mathbf{P}\big(|\eta_\gamma(u_l)| > t\sigma\kappa_0\big) \le \mathbf{P}\Big(|\eta_\gamma(u_l)| > t\sqrt{\mathbf{E}(|\eta_\gamma(u_l)|^2)}\Big) \le te^{-(t^2-1)/2}.$$

Thus we get

$$\mathbf{P}\Big(\sup_{\gamma\in\Gamma}\sup_{u_l\in\Sigma_{r,\varepsilon}}\big|\eta_\gamma(u_l)\big| > t\sigma\kappa_0\Big) \le \sum_{\gamma\in\Gamma}\sum_{l=1}^{N_{r,\varepsilon}}\mathbf{P}\Big(\big|\eta_\gamma(u_l)\big| > t\sigma\kappa_0\Big) \le |\Gamma|N_{r,\varepsilon}te^{-(t^2-1)/2}.$$

Hence, if $t = \sqrt{3\log(|\Gamma|N_{r,\varepsilon}n)}$, then $\mathbf{P}\Big(\sup_{\gamma\in\Gamma}\sup_{u_l\in\Sigma_{r,\varepsilon}}\big|\eta_\gamma(u_l)\big| > t\sigma\kappa_0\Big) \le 1/n$. On the other hand, for any $u, u' \in B_r$,

$$\begin{aligned}
\big|\eta_\gamma(u)-\eta_\gamma(u')\big|^2 &= \sup_{e\in\mathbb{S}_{d-1}}\big|e^\top\big(\eta_\gamma(u)-\eta_\gamma(u')\big)\big|^2 \\
&\le |u-u'|^2\cdot\sup_{u\in B_r}\sup_{e\in\mathbb{S}_{d-1}}\left|\frac{d(e^\top\eta_\gamma)}{du}(u)\right|^2 \\
&= |u-u'|^2\cdot\sup_{u\in B_r}\sup_{e\in\mathbb{S}_{d-1}}\left|\sum_{j=1}^n\frac{d(e^\top a_{j,\gamma})}{du}(u)\varepsilon_j\right|^2.
\end{aligned}$$

The Cauchy-Schwarz inequality yields

$$\frac{\big|\eta_\gamma(u)-\eta_\gamma(u')\big|^2}{|u-u'|^2} \le \sup_{u\in B_r}\sup_{e\in\mathbb{S}_{d-1}}\sum_{j=1}^n\left|\frac{d(e^\top a_{j,\gamma})}{du}(u)\right|^2\sum_{j=1}^n\varepsilon_j^2 \le \kappa_1^2\sum_{j=1}^n\varepsilon_j^2.$$

Since $\mathbf{P}\big(\sum_{j=1}^n\varepsilon_j^2 > 4n\sigma^2\big)$ is certainly less than n^{-1}, we have

$$\begin{aligned}
&\mathbf{P}\Big(\sup_{\gamma\in\Gamma}\sup_{u\in B_r}\big|\eta_\gamma(u)\big| > t\sigma\kappa_0 + 2\sqrt{n}\sigma\kappa_1\varepsilon\Big) \\
&\quad\le \mathbf{P}\Big(\sup_{\gamma\in\Gamma}\sup_{u_l\in\Sigma_{r,\varepsilon}}\frac{|\eta_\gamma(u_l)|}{t\sigma\kappa_0} > 1\Big) + \mathbf{P}\Big(\sup_{\gamma\in\Gamma}\sup_{u\in B_r}\frac{|\eta_\gamma(u)-\eta_\gamma(u_l(u))|}{2\sqrt{n}\sigma\kappa_1\varepsilon} > 1\Big) \\
&\quad\le \frac{1}{n} + \mathbf{P}\Big(\sup_{u\in B_r}\kappa_1^2|u-u_l(u)|^2\sum_{j=1}^n\varepsilon_j^2 > 4n\sigma^2\kappa_1^2\varepsilon^2\Big) \le \frac{2}{n},
\end{aligned}$$

and the assertion of proposition follows. ■

5.5 Properties of the Solution to (6)

We collect below some simple facts concerning the solution to the optimization problem (6). By classical arguments, it is always possible to choose a measurable solution $\hat{A}$ to (6). This measurability will be assumed in the sequel.

In Proposition 15, the case of general m (not necessarily equal to m^*) is considered. As we explain below, this generality is useful for further developments of the method extending it to the case of unknown structural dimension m^*.

The vectors β_ℓ are assumed to belong to a m^*-dimensional subspace $\mathcal{S}$ of $\mathbb{R}^d$, but in this subsection we do not necessarily assume that β_ℓs are defined by (4). In fact, we will apply the results of this subsection to the vectors $\Pi^*\hat\beta_\ell$.

For every $A \in \mathcal{A}_{m^*}$, let us define

$$R(A) = \max_{1\le\ell\le L} \hat\beta_\ell^\top (I-A)\hat\beta_\ell, \quad \hat A_m = \operatorname*{arg\,min}_{A\in\mathcal{A}_m} R(A),$$
$$\hat{\mathcal{R}}(m) = \min_{A\in\mathcal{A}_m} \sqrt{R(A)} = \sqrt{R(\hat A_m)} = \min_{A\in\mathcal{A}_m} \max_{1\le\ell\le L} |(I-A)^{1/2}\hat\beta_\ell|.$$

We also define

$$\mathcal{R}^*(m) = \min_{A\in\mathcal{A}_m} \max_{1\le\ell\le L} |(I-A)^{1/2}\beta_\ell|$$

and denote by A_m^* a minimizer of $\max_\ell \beta_\ell^\top (I-A)\beta_\ell$ over $A \in \mathcal{A}_m$. Note also that for every $m \ge m^*$ the projector Π^* belongs to $\mathcal{A}_m$. Therefore, we have $A_m^* = \Pi^*$ and $\mathcal{R}^*(m) = 0$ for every $m \ge m^*$.

Proposition 15 *Let $\mathcal{B}^* = \{\bar\beta = \sum_\ell c_\ell\beta_\ell : \sum_\ell |c_\ell| \le 1\}$ be the convex hull of vectors $\pm\beta_\ell$. If $\max_\ell |\hat\beta_\ell - \beta_\ell| \le \varepsilon$, then*

$$\hat{\mathcal{R}}(m) \le \mathcal{R}^*(m) + \varepsilon,$$
$$\max_{\bar\beta\in\mathcal{B}^*} |(I-\hat A_m)^{1/2}\bar\beta| \le \mathcal{R}^*(m) + 2\varepsilon.$$

When $m < m^*$, we have also the lower bound $\hat{\mathcal{R}}(m) \ge (\mathcal{R}^*(m) - \varepsilon)_+$.

Proof For every $\ell \in 1,\dots,L$, we have

$$\begin{aligned}|(I-A_m^*)^{1/2}\hat\beta_\ell| &\le |(I-A_m^*)^{1/2}\beta_\ell| + |(I-A_m^*)^{1/2}(\hat\beta_\ell - \beta_\ell)| \\ &\le \mathcal{R}^*(m) + |\hat\beta_\ell - \beta_\ell| \le \mathcal{R}^*(m) + \varepsilon.\end{aligned}$$

Since $\hat A_m$ minimizes $\max_\ell |(I-A)^{1/2}\hat\beta_\ell|$ over $A \in \mathcal{A}_m$, we have

$$\max_\ell |(I-\hat A_m)^{1/2}\hat\beta_\ell| \le \max_\ell |(I-A_m^*)^{1/2}\hat\beta_\ell| \le \mathcal{R}^*(m) + \varepsilon.$$

Since $\hat A_m \in \mathcal{A}_m$, we have $0 \preceq (I-\hat A_m)^{1/2} \preceq I$ and consequently, for every ℓ,

$$\begin{aligned}|(I-\hat A_m)^{1/2}\beta_\ell| &\le |(I-\hat A_m)^{1/2}\hat\beta_\ell| + |(I-\hat A_m)^{1/2}(\beta_\ell - \hat\beta_\ell)| \\ &\le |(I-\hat A_m)^{1/2}\hat\beta_\ell| + |\beta_\ell - \hat\beta_\ell| \le \mathcal{R}^*(m) + 2\varepsilon.\end{aligned}$$

The second inequality of the proposition follows now from $|(I-\hat A_m)^{1/2}\bar\beta| \le \max_\ell |(I-\hat A_m)^{1/2}\beta_\ell|$ for every $\bar\beta \in \mathcal{B}^*$.

Let us prove the last assertion of the proposition. According to the definition of $\mathcal{R}^*(m)$, for every matrix $A \in \mathcal{A}_m$ there exists an index $\ell(A)$ such that $|(I-A)^{1/2}\beta_{\ell(A)}| \ge \mathcal{R}^*(m)$. In particular, $|(I-\hat A_m)^{1/2}\beta_{\ell(\hat A_m)}| \ge \mathcal{R}^*(m)$ and hence $|(I-\hat A_m)^{1/2}\hat\beta_{\ell(\hat A_m)}| \ge |(I-\hat A_m)^{1/2}\beta_{\ell(\hat A_m)}| - |\hat\beta_{\ell(\hat A_m)} - \beta_{\ell(\hat A_m)}| \ge \mathcal{R}^*(m) - \varepsilon$. ■

Remark 16 *Proposition 15 can be used for estimating the structural dimension m. Indeed,* $\hat{\mathcal{R}}(m) \le \varepsilon$ *for* $m \ge m^*$ *and* $\hat{\mathcal{R}}(m) \ge (\mathcal{R}^*(m) - \varepsilon)_+$ *for* $m < m^*$. *Therefore, it is natural to search for the smallest value* $\widehat{m}$ *of m such that the function* $\hat{\mathcal{R}}(m)$ *does not significantly decrease for* $m \ge \widehat{m}$. *The rigorous application of this heuristic argument is currently under investigation.*

From now on, we assume that the structural dimension m^* is known and we use the shortened notation $\hat{A}$ instead of $\hat{A}_{m^*}$.

Proposition 17 *If the vectors* β_ℓ *satisfy* ***(A2)*** *and* $\max_\ell |\hat{\beta}_\ell - \beta_\ell| \le \varepsilon$, *then* $\operatorname{tr}(I - \hat{A})\Pi^* \le 4\varepsilon^2\mu^*$ *and* $\operatorname{tr}[(\hat{A} - \Pi^*)^2] \le 8\varepsilon^2\mu^*$.

Proof In view of the relations $\operatorname{tr}\hat{A}^2 \le \operatorname{tr}\hat{A} \le m^*$ and $\operatorname{tr}(\Pi^*)^2 = \operatorname{tr}\Pi^* = m^*$, we have

$$\operatorname{tr}(\hat{A} - \Pi^*)^2 = \operatorname{tr}(\hat{A}^2 - \Pi^*) + 2\operatorname{tr}(I - \hat{A})\Pi^* \le 2|\operatorname{tr}(I - \hat{A})\Pi^*|.$$

Note also that the equality $\operatorname{tr}(I - \hat{A})\Pi^* = \operatorname{tr}(I - \hat{A})^{1/2}\Pi^*(I - \hat{A})^{1/2}$ implies that $\operatorname{tr}(I - \hat{A})\Pi^* \ge 0$. Now condition (7) and Proposition 15 imply

$$\begin{aligned}\operatorname{tr}(I - \hat{A})\Pi^* &= \operatorname{tr}(I - \hat{A})^{1/2}\Pi^*(I - \hat{A})^{1/2} \\ &\le \sum_{k=1}^{m^*} \mu_k \operatorname{tr}(I - \hat{A})^{1/2}\bar{\beta}_k\bar{\beta}_k^\top(I - \hat{A})^{1/2} \\ &\le \sum_{k=1}^{m^*} \mu_k \bar{\beta}_k^\top(I - \hat{A})\bar{\beta}_k \le (2\varepsilon)^2 \sum_{k=1}^{m^*} \mu_k\end{aligned}$$

and the assertion follows. ■

Lemma 18 *Let* $\operatorname{tr}(I - \hat{A})\Pi^* \le \delta^2$ *for some* $\delta > 0$. *Then for any* $x \in \mathbb{R}^d$

$$|\Pi^* x| \le |\hat{A}^{1/2}x| + \delta|x|.$$

Proof In view of the triangle inequality, $|\Pi^* x| \le |\Pi^*\hat{A}^{1/2}x| + |\Pi^*(I - \hat{A}^{1/2})x|$. On the other hand,

$$|\Pi^*(I - \hat{A}^{1/2})x|^2 \le \|\Pi^*(I - \hat{A}^{1/2})\|_2^2 \cdot |x|^2 \le \operatorname{tr}[\Pi^*(I - \hat{A}^{1/2})^2\Pi^*] \cdot |x|^2.$$

For every $A \in \mathcal{A}_m$, it obviously holds $(I - A^{1/2})^2 = I - 2A^{1/2} + A \preceq I - A$, and hence, $\operatorname{tr}\Pi^*(I - A^{1/2})^2\Pi^* \le \operatorname{tr}\Pi^*(I - A)\Pi^*$. Therefore,

$$\operatorname{tr}\Pi^*(I - \hat{A}^{1/2})^2\Pi^* \le \operatorname{tr}\Pi^*(I - \hat{A})\Pi^* = \operatorname{tr}(I - \hat{A})\Pi^* \le \delta^2$$

yielding $|\Pi^* x| \le |\Pi^*\hat{A}^{1/2}x| + \delta|x| \le |\hat{A}^{1/2}x| + \delta|x|$ as required. ■

Corollary 19 *If for some* $\rho \in (0,1)$ *and for some* $x \in \mathbb{R}^d$, *we have* $|(I + \rho^{-2}\hat{A})^{1/2}x| \le h$, *then* $|\Pi^* x| \le (\rho + \sqrt{\operatorname{tr}(I - \hat{A})\Pi^*})h$.

Proof The result follows from Lemma 18 and the inequalities $|x| \le |(I+\rho^{-2}\hat{A})^{1/2}x| \le h$ and $|\hat{A}^{1/2}x| \le \rho|(I+\rho^{-2}\hat{A})^{1/2}x| \le \rho h$. ■

Lemma 20 *Let* $\mathrm{tr}(I-\hat{A})\Pi^* \le \delta^2$ *for some* $\delta \in [0,1)$ *and let* $\widehat{\Pi}_{m^*}$ *be the orthogonal projection matrix in* $\mathbb{R}^d$ *onto the subspace spanned by the eigenvectors of* $\hat{A}$ *corresponding to its largest* m^* *eigenvalues. Then* $\mathrm{tr}(I-\widehat{\Pi}_{m^*})\Pi^* \le \delta^2/(1-\delta^2)$.

Proof Let $\hat{\lambda}_j$ and $\hat{\vartheta}_j$, $j=1,\dots,d$ be respectively the eigenvalues and the eigenvectors of $\hat{A}$. Assume that $\hat{\lambda}_1 \ge \hat{\lambda}_2 \ge \ldots \ge \hat{\lambda}_d$. Then $\hat{A} = \sum_{j=1}^d \hat{\lambda}_j \hat{\vartheta}_j \hat{\vartheta}_j^\top$ and $\widehat{\Pi}_{m^*} = \sum_{j=1}^{m^*} \hat{\vartheta}_j \hat{\vartheta}_j^\top$. Moreover, $\sum_{j=1}^d \hat{\vartheta}_j \hat{\vartheta}_j^\top = I$ since $\{\hat{\vartheta}_1,\dots,\hat{\vartheta}_d\}$ is an orthonormal basis of $\mathbb{R}^d$. This implies that

$$\begin{aligned}
\mathrm{tr}[\hat{A}\Pi^*] &\le \sum_{j\le m^*} \hat{\lambda}_j \,\mathrm{tr}[\hat{\vartheta}_j\hat{\vartheta}_j^\top\Pi^*] + \hat{\lambda}_{m^*} \sum_{j>m^*} \mathrm{tr}[\hat{\vartheta}_j\hat{\vartheta}_j^\top\Pi^*] \\
&= \sum_{j\le m^*} (\hat{\lambda}_j - \hat{\lambda}_{m^*})\,\mathrm{tr}[\hat{\vartheta}_j\hat{\vartheta}_j^\top\Pi^*] + \hat{\lambda}_{m^*}\,\mathrm{tr}\Big[\sum_{j=1}^d \hat{\vartheta}_j\hat{\vartheta}_j^\top\Pi^*\Big] \\
&= \sum_{j\le m^*} (\hat{\lambda}_j - \hat{\lambda}_{m^*})\,\mathrm{tr}[\hat{\vartheta}_j\hat{\vartheta}_j^\top\Pi^*] + m^*\hat{\lambda}_{m^*}.
\end{aligned}$$

Since $\mathrm{tr}[\hat{\vartheta}_j\hat{\vartheta}_j^\top\Pi^*] = |\Pi^*\hat{\vartheta}_j|^2 \le 1$, we get $\mathrm{tr}[\hat{A}\Pi^*] \le \sum_{j\le m^*}\hat{\lambda}_j$. Taking into account the relations $\sum_{j\le d}\hat{\lambda}_j \le m^*$, $\mathrm{tr}\,\Pi^* = m^*$ and $(1-\hat{\lambda}_{m^*+1})(I-\widehat{\Pi}_{m^*}) \preceq I-\hat{A}$, we get $\hat{\lambda}_{m^*+1} \le m^* - \sum_{j\le m^*}\hat{\lambda}_j \le \mathrm{tr}[(I-\hat{A})\Pi^*] \le \delta^2$ and therefore $I-\widehat{\Pi}_{m^*} \preceq (1-\delta^2)^{-1}(I-\hat{A})$. Consequently, $\mathrm{tr}[(I-\widehat{\Pi}_{m^*})\Pi^*] \le (1-\delta^2)^{-1}\mathrm{tr}[(I-\hat{A})\Pi^*] \le \delta^2/(1-\delta^2)$. ■

5.6 Technical Lemmas

This subsection contains five technical results. The first three lemmas have been used in the proof of Proposition 9, whereas the two last lemmas have been used in the proof of Theorem 4.

Lemma 21 *For every* $\rho \in (0,1]$ *and for every* $A \in \mathcal{A}_{m^*}$ *we have*

$$\|P_\rho^*(I+\rho^{-2}A)P_\rho^* - I\|_2 \le 2\delta_A^2\rho^{-2} + 2\delta_A\rho^{-1},$$

where $P_\rho^* = (I+\rho^{-2}\Pi^*)^{-1/2}$ *and* $\delta_A^2 = \mathrm{tr}[(I-A)\Pi^*]$.

Proof The inequality $P_\rho^* \preceq (I-\Pi^*) + \rho\Pi^*$ implies that

$$\begin{aligned}
\rho^2\big\|P_\rho^*(I+\rho^{-2}A)P_\rho^* - I\big\|_2 &= \big\|P_\rho^*(A-\Pi^*)P_\rho^*\big\|_2 \\
&\le \rho^2\big\|\Pi^*(A-\Pi^*)\Pi^*\big\|_2 + \big\|(I-\Pi^*)(A-\Pi^*)(I-\Pi^*)\big\|_2 \\
&\quad + 2\rho\big\|\Pi^*(A-\Pi^*)(I-\Pi^*)\big\|_2.
\end{aligned}$$

Since $\|B\|_2^2 = \mathrm{tr}\,BB^\top \le (\mathrm{tr}(BB^\top)^{1/2})^2$ for any matrix B, it holds

$$\begin{aligned}
\big\|\Pi^*(A-\Pi^*)\Pi^*\big\|_2 &= \big\|\Pi^*(I-A)\Pi^*\big\|_2 \\
&\le \mathrm{tr}\,\Pi^*(I-A)\Pi^* = \mathrm{tr}(I-A)\Pi^* = \delta_A^2.
\end{aligned}$$

By similar arguments one checks that

$$\begin{aligned}\left\|(I-\Pi^*)(A-\Pi^*)(I-\Pi^*)\right\|_2 &= \left\|(I-\Pi^*)A(I-\Pi^*)\right\|_2 \le \mathrm{tr}(I-\Pi^*)A \\ &= \mathrm{tr}A - \mathrm{tr}\Pi^* + \mathrm{tr}\Pi^*(I-A) \le \delta_A^2,\end{aligned}$$

and

$$\begin{aligned}\left\|\Pi^*(A-\Pi^*)(I-\Pi^*)\right\|_2 &\le \left\|\Pi^*(A-\Pi^*)\right\|_2 = \left\|\Pi^*(I-A)\right\|_2 \\ &\le \left\|\Pi^*(I-A)^{1/2}\right\|_2 = (\mathrm{tr}\Pi^*(I-A)\Pi^*)^{1/2} \\ &= (\mathrm{tr}(I-A)\Pi^*)^{1/2} = \delta_A.\end{aligned}$$

This leads to the inequality $\|P_\rho^*(I+\rho^{-2}A)P_\rho^* - I\|_2 \le \delta_A^2(1+\rho^{-2}) + 2\delta_A\rho^{-1}$, which, in view of the condition $\rho \le 1$, yields the assertion of the lemma. ■

Lemma 22 *If ψ_ℓs and U satisfy (8) and **(A3)**, then $\sum_{j=1}^n |c_{j,\ell}(U)|^2 \le dC_KC_V\overline{\psi}^2/(nh_k^2)$.*

Proof Simple computations yield

$$\sum_{j=1}^n \left| E_1V_i^{(k)}(U)^{-1}\begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix}\right|^2 w_{ij}^{(k)}(U) = \mathrm{tr}(E_1V_i^{(k)}(U)^{-1}E_1) \le \frac{dC_V}{N_i^{(k)}(U)}. \tag{11}$$

Hence, we have

$$\begin{aligned}\sum_{j=1}^n |c_{j,\ell}|^2 &= \frac{1}{n^2h_k^2}\sum_{j=1}^n \left|\sum_{i=1}^n E_1V_i^{(k)}(U_k)^{-1}\begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix} w_{ij}^{(k)}(U)\,\psi_{\ell,i}\right|^2 \\ &\le \frac{\overline{\psi}^2}{n^2h_k^2}\sum_{j=1}^n \left(\sum_{i=1}^n \frac{w_{ij}^{(k)}(U)}{N_i^{(k)}(U)}\right)\left(\sum_{i=1}^n \left|E_1V_i^{(k)}(U)^{-1}\begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix}\right|^2 N_i^{(k)}(U)w_{ij}^{(k)}(U)\right) \\ &\le \frac{C_K\overline{\psi}^2}{n^2h_k^2}\sum_{j=1}^n\sum_{i=1}^n \left|E_1V_i^{(k)}(U)^{-1}\begin{pmatrix}1\\ Z_{ij}^{(k)}\end{pmatrix}\right|^2 N_i^{(k)}(U)w_{ij}^{(k)}(U).\end{aligned}$$

Interchanging the order of summation and using inequality (11) we get the desired result. ■

Lemma 23 *If **(A3)** and (8) are fulfilled, then, for any $e \in \mathbb{S}_{d-1}$, we have*

$$\sup_{U:\|U-I\|_2\le 1/2}\max_{j=1,\dots,n}\left\|\frac{d}{dU}(e^\top c_{j,\ell})(U)\right\|_2^2 \le \frac{24C_w^2C_V^4C_K^2\overline{\psi}^2}{n^2h_k^2} + \frac{216C_V^2C_{K'}^2\overline{\psi}^2}{n^2h_k^2},$$

where $\frac{d}{dU}(e^\top c_{j,\ell})(U)$ is the $d\times d$ matrix with entries $\frac{\partial e^\top c_{j,\ell}(U)}{\partial U_{pq}}$.

Proof In order to ease the notation, we will remove the superscripts (k) in this proof. Thus, we will write V_i, w_{ij} and Z_{ij} instead of $V_i^{(k)}$, $w_{ij}^{(k)}$ and $Z_{ij}^{(k)}$. By definition of $c_{j,\ell}$ we have

$$\begin{aligned}\left\|\frac{d}{dU}\,(e^\top c_{j,\ell})(U)\right\|_2^2 &\le 2\left\|\frac{1}{nh_k}\sum_{i=1}^n\left[\frac{d}{dU}\,\tilde e^\top V_i^{-1}(U)\begin{pmatrix}1\\ Z_{ij}\end{pmatrix}\right]w_{ij}(U)\psi_{\ell,i}\right\|_2^2\\ &\quad+2\left\|\frac{1}{nh_k}\sum_{i=1}^n\tilde e^\top V_i^{-1}(U)\begin{pmatrix}1\\ Z_{ij}\end{pmatrix}\frac{dw_{ij}(U)}{dU}\,\psi_{\ell,i}\right\|_2^2\\ &=\Delta_1+\Delta_2,\end{aligned}$$

where $\tilde e = E_1^\top e$ satisfies $|\tilde e|\le|e|=1$. One checks that $d\,w_{ij}(U)/dU = \bar w_{ij}(U)Z_{ij}Z_{ij}^\top$, where we used the notation $\bar w_{ij}(U)=K'(Z_{ij}^\top UZ_{ij})$. On the one hand, $|\bar w_{ij}(U)|\cdot|Z_{ij}|^2=0$ if $Z_{ij}^\top UZ_{ij}>1$. On the other hand, the inequality $\|I-U\|_2\le 1/2$ implies that

$$|Z_{ij}|^2 \le Z_{ij}^\top UZ_{ij}+|Z_{ij}^\top(I-U)Z_{ij}| \le Z_{ij}^\top UZ_{ij}+|Z_{ij}|^2\|I-U\|_2 \le Z_{ij}^\top UZ_{ij}+|Z_{ij}|^2/2.$$

Therefore $|Z_{ij}|^2\le 2$ for all Z_{ij} verifying $Z_{ij}^\top UZ_{ij}\le 1$. Hence, $\|d\,w_{ij}(U)/dU\|_2=|\bar w_{ij}(U)|\cdot|Z_{ij}|^2\le 2|\bar w_{ij}(U)|$ and we get

$$\Delta_2 \le \frac{8\overline{\psi}^2}{n^2h_k^2}\left(\sum_{i=1}^n\left|V_i^{-1}(U)\begin{pmatrix}1\\ Z_{ij}\end{pmatrix}\bar w_{ij}(U)\right|\right)^2 \le \frac{24\overline{\psi}^2C_V^2C_{K'}^2}{n^2h_k^2}\,.$$

In order to estimate the term Δ_1, remark that the differentiation (with respect to U_{pq}) of the identity $V_i^{-1}(U)V_i(U)=I_{d+1}$ yields

$$\frac{\partial V_i^{-1}}{\partial U_{pq}}\,(U) = -V_i^{-1}(U)\,\frac{\partial V_i}{\partial U_{pq}}\,(U)V_i^{-1}(U).$$

Simple computations show that

$$\begin{aligned}\frac{\partial V_i}{\partial U_{pq}}\,(U) &= \sum_{j=1}^n\begin{pmatrix}1\\ Z_{ij}\end{pmatrix}\begin{pmatrix}1\\ Z_{ij}\end{pmatrix}^\top\frac{\partial}{\partial U_{pq}}w_{ij}(U)\\ &= \sum_{j=1}^n\begin{pmatrix}1\\ Z_{ij}\end{pmatrix}\begin{pmatrix}1\\ Z_{ij}\end{pmatrix}^\top\bar w_{ij}(U)(Z_{ij})_p(Z_{ij})_q.\end{aligned}$$

Hence, for any $a_1,a_2\in\mathbb{R}^{d+1}$,

$$\frac{da_1^\top V_i^{-1}(U)a_2}{dU} = \sum_{j=1}^n a_1^\top V_i^{-1}(U)\begin{pmatrix}1\\ Z_{ij}\end{pmatrix}\begin{pmatrix}1\\ Z_{ij}\end{pmatrix}^\top V_i^{-1}(U)a_2\;\bar w_{ij}(U)Z_{ij}Z_{ij}^\top.$$

This relation, combined with the estimate $|Z_{ij}|^2\le 2$ for all i,j such that $\bar w_{ij}\ne 0$, implies the norm estimate

$$\begin{aligned}\left\|\frac{da_1^\top V_i^{-1}(U)a_2}{dU}\right\|_2 &\le 2\sum_{j=1}^n\left|a_1^\top V_i^{-1}(U)\begin{pmatrix}1\\ Z_{ij}\end{pmatrix}\begin{pmatrix}1\\ Z_{ij}\end{pmatrix}^\top V_i^{-1}(U)a_2\;\bar w_{ij}(U)\right|\\ &\le 6|a_1|\,|a_2|\sum_{j=1}^n\left\|V_i^{-1}(U)\right\|^2|\bar w_{ij}(U)|\\ &\le 6C_wC_V^2|a_1|\,|a_2|N_i(U)^{-1}.\end{aligned}$$

This yields $\Delta_1 \le 216 C_w^2 C_V^4 C_K^2 \overline{\psi}^2/(nh_k)^2$ and the assertion of the lemma follows. ■

Note that under the assumptions of Lemma 23, for some $\tilde{U}$ satisfying $\|\tilde{U}-I\|_2 \le \|U-I\|_2$, it holds

$$\begin{aligned}
|c_{j,\ell}(U)-c_{j,\ell}(I)| &= \sup_{e\in\mathbb{S}_{d-1}} |e^\top (c_{j,\ell}(U)-c_{j,\ell}(I))| \\
&= \sup_{e\in\mathbb{S}_{d-1}} |\mathbf{vec}\Big[\frac{d\, e^\top c_{j,\ell}}{dU}(\tilde{U})\Big]^\top \mathbf{vec}(U-I)| \\
&\le \sup_{e\in\mathbb{S}_{d-1}} \Big\|\frac{d\, e^\top c_{j,\ell}}{dU}(\tilde{U})\Big\|_2 \|U-I\|_2 \\
&\le \frac{\sqrt{216}\,\overline{\psi}}{nh_k}\,(C_w^2 C_V^4 C_K^2 + C_V^2 C_{K'}^2)^{1/2}\|U-I\|_2, \qquad (12)
\end{aligned}$$

where $\mathbf{vec}(\cdot)$ is a matrix operator that stacks the matrix's columns one by one. In other terms, for every $d\times d$ matrix M, $\mathbf{vec}(M) = (m_{\bullet,1}^\top,\dots,m_{\bullet,d}^\top)^\top$ where $m_{\bullet,j}$ stands for the j^{th} column of M.

Lemma 24 *There exists an integer $n_0 \ge 0$ such that, for every $n \ge n_0$ and for all $k \in \{2,\dots,k(n)\}$, we have $\delta_{k-1} \le \rho_k$, $\alpha_k \le 4$ and $\zeta_k \le 1/2$.*

Proof In view of the relations $C_0 n^{-1/(d\vee 4)} = \rho_1 h_1$ and $\rho_{k(n)} h_{k(n)} \ge C_2 n^{-1/3}$, the sequence

$$s_n = 4\sqrt{C_V} C_g h_1 + \frac{4\sigma(c_0\sqrt{\log(Ln)}+c_1 t_n)}{\sqrt{n}\,\rho_{k(n)} h_{k(n)}}$$

tends to zero as $n\to\infty$.

We do now induction on k. Since $s_n \to 0$ as $n\to\infty$ and $\gamma_1 \le s_n$, the inequality $\delta_1 = 2\gamma_1\sqrt{\mu^*} \le 1/\sqrt{2} = \rho_1/\sqrt{2}$ is true for sufficiently large values of n. Let us prove the implication

$$\delta_{k-1} \le \rho_{k-1}/\sqrt{2} \quad\Longrightarrow\quad \begin{cases} \zeta_k \le 1/2, \\ \delta_k \le \rho_k/\sqrt{2}. \end{cases}$$

Since $1/\sqrt{2} \le e^{-1/6}$, the inequality $\delta_{k-1} \le \rho_k/\sqrt{2}$ entails that $\delta_{k-1} \le \rho_k$ and therefore $\alpha_k \le 4$. By our choice of a_h and a_ρ, we have $\rho_1 h_1 \ge \rho_k h_k \ge \rho_{k(n)} h_{k(n)}$. Therefore,

$$\begin{aligned}
\frac{\gamma_k}{\rho_k} &\le 4\sqrt{C_V} C_g \rho_k h_k + \frac{4\sigma(c_0\sqrt{\log(Ln)}+c_1 t_n)}{\sqrt{n}\,\rho_k h_k} \\
&\le 4\sqrt{C_V} C_g h_1 + \frac{4\sigma(c_0\sqrt{\log(Ln)}+c_1 t_n)}{\sqrt{n}\rho_{k(n)} h_{k(n)}} = s_n.
\end{aligned}$$

Thus, for n large enough, $\zeta_k \le 1/2$ and $\gamma_k \le \rho_k/4$. This implies that $\delta_k = 2\gamma_k(1-\zeta_k)^{-1/2} \le \rho_k/\sqrt{2}$.

By induction we infer that $\delta_{k-1} \le \rho_{k-1}/\sqrt{2} \le \rho_k$ and $\zeta_k \le 1/2$ for any $k = 2,\dots,k(n)-1$. This completes the proof of the lemma. ■

Lemma 25 *If $k > 2$ and $\zeta_{k-1} < 1$ then $\Omega_{k-1} \subset \{\mathrm{tr}(I - \hat{A}_{k-1})\Pi^* \le \delta_{k-1}^2\}$.*

Proof Let us denote by $\tilde{\beta}_\ell$ the vector $\Pi^* \hat{\beta}_{\ell,k-1}$, which clearly belongs to $\mathcal{S}$. It holds

$$|P_{k-1}^*(\hat{\beta}_{\ell,k-1} - \beta_\ell)| \le \gamma_{k-1} \quad \Longrightarrow \quad \begin{cases} |\hat{\beta}_{\ell,k-1} - \tilde{\beta}_\ell| \le \gamma_{k-1}, \\ |\tilde{\beta}_\ell - \beta_\ell| \le \sqrt{2}\gamma_{k-1}/\rho_{k-1}. \end{cases}$$

Set $B = \sum_{i=1}^{m^*} \mu_i \bar{\beta}_i \bar{\beta}_i^\top$ and $\tilde{B} = \sum_{i=1}^{m^*} \mu_i \bar{\tilde{\beta}}_i \bar{\tilde{\beta}}_i^\top$, where $\bar{\tilde{\beta}}_i = \sum_\ell c_\ell \tilde{\beta}_\ell$ if $\bar{\beta}_i = \sum_\ell c_\ell \beta_\ell$, see assumption (A2). Since $\sum_\ell |c_\ell| \le 1$, we have $|\bar{\beta}_i| \le \max_\ell |\beta_\ell| \le \|\nabla f\|_\infty$ and $|\bar{\beta}_i - \bar{\tilde{\beta}}_i| \le \max_\ell |\beta_\ell - \tilde{\beta}_\ell|$. Therefore

$$\begin{aligned} \|B - \tilde{B}\| &\le \sum_{i=1}^{m^*} \mu_i \|\bar{\beta}_i \bar{\beta}_i^\top - \bar{\tilde{\beta}}_i \bar{\tilde{\beta}}_i^\top\| \le \mu^* \max_i \|\bar{\beta}_i \bar{\beta}_i^\top - \bar{\tilde{\beta}}_i \bar{\tilde{\beta}}_i^\top\| \\ &\le \mu^* \max_i \Big(|\bar{\beta}_i - \bar{\tilde{\beta}}_i|^2 + 2|\bar{\beta}_i| \cdot |\bar{\beta}_i - \bar{\tilde{\beta}}_i| \Big) \\ &\le \mu^* \big(2\gamma_{k-1}^2 \rho_{k-1}^{-2} + 2\sqrt{2}\gamma_{k-1}\rho_{k-1}^{-1} \max_\ell |\beta_\ell| \big) = \zeta_{k-1} \end{aligned}$$

and hence, for every unit vector $v \in \mathcal{S}$, $v^\top \tilde{B} v \ge \big(v^\top B v - \big| v^\top B v - v^\top \tilde{B} v \big| \big) \ge v^\top B v - \|B - \tilde{B}\| \ge 1 - \zeta_{k-1}$. This inequality implies that $\Pi^* \preceq (1 - \zeta_{k-1})^{-1} \tilde{B}$. Thus the vectors $\tilde{\beta}_\ell$ satisfy assumption (A2) with μ^* replaced by $\mu^*/(1 - \zeta_{k-1})$. Applying Proposition 17 to these vectors we obtain the assertion of the lemma. ■

Acknowledgments

Much of this work has been carried out when the first author was visiting the Weierstrass Institute for Applied Analysis and Stochastics. The financial support from the institute and the hospitality of Professor Spokoiny are gratefully acknowledged.

The authors are grateful to the referees for their constructive comments, which have greatly improved the paper.

Abstract

The paper investigates the possibility of applying value function based reinforcement learning (RL) methods in cases when the environment may change over time. First, theorems are presented which show that the optimal value function of a discounted Markov decision process (MDP) Lipschitz continuously depends on the immediate-cost function and the transition-probability function. Dependence on the discount factor is also analyzed and shown to be non-Lipschitz. Afterwards, the concept of (ε, δ)-MDPs is introduced, which is a generalization of MDPs and ε-MDPs. In this model the environment may change over time, more precisely, the transition function and the cost function may vary from time to time, but the changes must be bounded in the limit. Then, learning algorithms in changing environments are analyzed. A general relaxed convergence theorem for stochastic iterative algorithms is presented. We also demonstrate the results through three classical RL methods: asynchronous value iteration, Q-learning and temporal difference learning. Finally, some numerical experiments concerning changing environments are presented.

Keywords: Markov decision processes, reinforcement learning, changing environments, (ε, δ)-MDPs, value function bounds, stochastic iterative algorithms

1. Introduction

Stochastic control problems are often modeled by Markov decision processes (MDPs) that constitute a fundamental tool for computational learning theory. The theory of MDPs has grown extensively since Bellman introduced the discrete stochastic variant of the optimal control problem in 1957. These kinds of stochastic optimization problems have great importance in diverse fields, such as engineering, manufacturing, medicine, finance or social sciences. Several solution methods are known, for example, from the field of [neuro-]dynamic programming (NDP) or reinforcement learning (RL), which compute or approximate the optimal control policy of an MDP. These methods succeeded in solving many different problems, such as transportation and inventory control (Van Roy et al., 1996), channel allocation (Singh and Bertsekas, 1997), robotic control (Kalmár et al., 1998), production scheduling (Csáji and Monostori, 2006), logical games and problems from financial mathematics. Many applications of RL and NDP methods are also considered by the textbooks of Bertsekas and Tsitsiklis (1996), Sutton and Barto (1998) as well as Feinberg and Shwartz (2002).

∗. Also faculty in Mechanical Engineering at the Budapest University of Technology and Economics.

The dynamics of (Markovian) control problems can often be formulated as follows:

$$x_{t+1} = f(x_t, a_t, w_t), \tag{1}$$

where x_t is the state of the system at time $t \in \mathbb{N}$, a_t is a control action and w_t is some disturbance. There is also a cost function $g(x_t, a_t)$ and the aim is to find an optimal control policy that minimizes the [discounted] costs over time (the next section will contain the basic definitions). In many applications the calculation of a control policy should be fast and, additionally, environmental changes should also be taken into account. These two criteria are against each other. In most control applications during the computation of a control policy the system uses a *model* of the environment. The dynamics of (1) can be modeled with an MDP, but what happens when the model is wrong (e.g., if the transition function is incorrect) or the dynamics have changed? The changing of the dynamics can also be modeled as an MDP, however, including environmental changes as a higher level MDP very likely leads to problems which do not have any practically efficient solution methods.

The paper argues that if the model was "close" to the environment, then a "good" policy based on the model cannot be arbitrarily "wrong" from the viewpoint of the environment and, moreover, "slight" changes in the environment result only in "slight" changes in the optimal cost-to-go function. More precisely, the optimal value function of an MDP depends Lipschitz continuously on the cost function and the transition probabilities. Applying this result, the concept of (ε, δ)-MDPs is introduced, in which these functions are allowed to vary over time, as long as the cumulative changes remain bounded in the limit.

Afterwards, a general framework for analyzing stochastic iterative algorithms is presented. A novelty of our approach is that we allow the value function update operator to be time-dependent. Then, we apply that framework to deduce an approximate convergence theorem for time-dependent stochastic iterative algorithms. Later, with the help of this general theorem, we show relaxed convergence properties (more precisely, κ-approximation) for value function based reinforcement learning methods working in (ε, δ)-MDPs.

The main contributions of the paper can be summarized as follows:

1. We show that the optimal value function of a discounted MDP Lipschitz continuously depends on the immediate-cost function (Theorem 12). This result was already known for the case of transition-probability functions (Müller, 1996; Kalmár et al., 1998), however, we present an improved bound for this case, as well (Theorem 11). We also present value function bounds (Theorem 13) for the case of changes in the discount factor and demonstrate that this dependence is not Lipschitz continuous.

2. In order to study changing environments, we introduce (ε, δ)-MDPs (Definition 17) that are generalizations of MDPs and ε-MDPs (Kalmár et al., 1998; Szita et al., 2002). In this model the transition function and the cost function may change over time, provided that the accumulated changes remain bounded in the limit. We show (Lemma 18) that potential changes in the discount factor can be incorporated into the immediate-cost function, thus, we do not have to consider discount factor changes.

3. We investigate stochastic iterative algorithms where the value function operator may change over time. A relaxed convergence theorem for this kind of algorithm is presented (Theorem 20). As a corollary, we get an approximation theorem for value function based reinforcement learning methods in (ε, δ)-MDPs (Corollary 21).

4. Furthermore, we illustrate our results through three classical RL algorithms. Relaxed convergence properties in (ε,δ)-MDPs for asynchronous value iteration, Q-learning and temporal difference learning are deduced. Later, we show that our approach could also be applied to investigate approximate dynamic programming methods.

5. We also present numerical experiments which highlight some features of working in varying environments. First, two simple stochastic iterative algorithms, a "well-behaving" and a "pathological" one, are shown. Regarding learning, we illustrate the effects of environmental changes through two problems: scheduling and grid world.

2. Definitions and Preliminaries

Sequential decision making under the presence of uncertainties is often modeled by MDPs (Bertsekas and Tsitsiklis, 1996; Sutton and Barto, 1998; Feinberg and Shwartz, 2002). This section contains the basic definitions, the applied notations and some preliminaries.

Definition 1 *By a (finite, discrete-time, stationary, fully observable) Markov decision process (MDP) we mean a stochastic system characterized by a 6-tuple $\langle \mathbb{X}, \mathbb{A}, \mathcal{A}, p, g, \alpha \rangle$, where the components are as follows: $\mathbb{X}$ is a finite set of discrete states and $\mathbb{A}$ is a finite set of control actions. Mapping $\mathcal{A} : \mathbb{X} \to \mathcal{P}(\mathbb{A})$ is the availability function that renders a set of actions available to each state where $\mathcal{P}$ denotes the power set. The transition function is given by $p : \mathbb{X} \times \mathbb{A} \to \Delta(\mathbb{X})$, where $\Delta(\mathbb{X})$ is the set of all probability distributions over $\mathbb{X}$. Let $p(y|x,a)$ denote the probability of arrival at state y after executing action $a \in \mathcal{A}(x)$ in state x. The immediate-cost function is defined by $g : \mathbb{X} \times \mathbb{A} \to \mathbb{R}$, where $g(x,a)$ is the cost of taking action a in state x. Finally, $\alpha \in [0,1)$ denotes the discount rate.*

An interpretation of an MDP can be given, which viewpoint is often taken in RL, if we consider an agent that acts in an uncertain environment. The agent receives information about the state of the environment x, at each state x the agent is allowed to choose an action $a \in \mathcal{A}(x)$. After the action is selected, the environment moves to the next state according to the probability distribution $p(x,a)$ and the decision-maker collects its one-step cost, $g(x,a)$. The aim of the agent is to find an optimal behavior (policy), such that applying this strategy minimizes the expected cumulative costs.

Definition 2 *A (stationary, Markovian) control policy determines the action to take in each state. A deterministic policy, $\pi : \mathbb{X} \to \mathbb{A}$, is simply a function from states to control actions. A randomized policy, $\pi : \mathbb{X} \to \Delta(\mathbb{A})$, is a function from states to probability distributions over actions. We denote the probability of executing action a in state x by $\pi(x)(a)$ or, for short, by $\pi(x,a)$. Unless indicated otherwise, we consider randomized policies.*

For any $\widetilde{x}_0 \in \Delta(\mathbb{X})$ initial probability distribution of the states, the transition probabilities p together with a control policy π completely determine the progress of the system in a stochastic sense, namely, they define a *homogeneous Markov chain* on $\mathbb{X}$,

$$\widetilde{x}_{t+1} = P(\pi)\widetilde{x}_t,$$

where $\widetilde{x}_t$ is the state probability distribution vector of the system at time t and $P(\pi)$ denotes the probability transition matrix induced by control policy π,

$$[P(\pi)]_{x,y} = \sum_{a \in \mathbb{A}} p(y|x,a)\,\pi(x,a).$$

Definition 3 *The value or cost-to-go function of a policy π is a function from states to costs, $J^\pi : \mathbb{X} \to \mathbb{R}$. Function $J^\pi(x)$ gives the expected value of the cumulative (discounted) costs when the system is in state x and it follows policy π thereafter,*

$$J^\pi(x) = \mathbb{E}\left[\sum_{t=0}^{N} \alpha^t g(X_t, A_t^\pi) \,\middle|\, X_0 = x\right], \tag{2}$$

where X_t and A_t^π are random variables, A_t^π is selected according to control policy π and the distribution of X_{t+1} is $p(X_t, A_t^\pi)$. The horizon of the problem is denoted by $N \in \mathbb{N} \cup \{\infty\}$. Unless indicated otherwise, we will always assume that the horizon is infinite, $N = \infty$.

Definition 4 *We say that $\pi_1 \leq \pi_2$ if and only if $\forall x \in \mathbb{X} : J^{\pi_1}(x) \leq J^{\pi_2}(x)$. A control policy is (uniformly) optimal if it is less than or equal to all other control policies.*

There always exists at least one optimal policy (Sutton and Barto, 1998). Although there may be many optimal policies, they all share the same unique optimal cost-to-go function, denoted by J^*. This function must satisfy the Bellman optimality equation (Bertsekas and Tsitsiklis, 1996), $TJ^* = J^*$, where T is the *Bellman operator*, defined for all $x \in \mathbb{X}$, as

$$(TJ)(x) = \min_{a \in \mathcal{A}(x)} \Big[g(x,a) + \alpha \sum_{y \in \mathbb{X}} p(y \,|\, x, a) J(y) \Big].$$

Definition 5 *We say that function $f : \mathcal{X} \to \mathcal{Y}$, where $\mathcal{X}$, $\mathcal{Y}$ are normed spaces, is Lipschitz continuous if there exists a $\beta \geq 0$ such that $\forall x_1, x_2 \in \mathcal{X} : \|f(x_1) - f(x_2)\|_\mathcal{Y} \leq \beta \|x_1 - x_2\|_\mathcal{X}$, where $\|\cdot\|_\mathcal{X}$ and $\|\cdot\|_\mathcal{Y}$ denote the norm of $\mathcal{X}$ and $\mathcal{Y}$, respectively. The smallest such β is called the Lipschitz constant of f. Henceforth, assume that $\mathcal{X} = \mathcal{Y}$. If the Lipschitz constant $\beta < 1$, then the function is called a contraction. A mapping is called a pseudo-contraction if there exists an $x^* \in \mathcal{X}$ and a $\beta \geq 0$ such that $\forall x \in \mathcal{X}$, we have $\|f(x) - x^*\|_\mathcal{X} \leq \beta \|x - x^*\|_\mathcal{X}$.*

Naturally, every contraction mapping is also a pseudo-contraction, however, the opposite is not true. The pseudo-contraction condition implies that x^* is the fixed point of function f, namely, $f(x^*) = x^*$, moreover, x^* is unique, thus, f cannot have other fixed points.

It is known that the Bellman operator is a supremum norm contraction with Lipschitz constant α. In case we consider *stochastic shortest path* (SSP) problems, which arise if the MDP has an absorbing terminal (goal) state, then the Bellman operator becomes a pseudo-contraction in the weighted supremum norm (Bertsekas and Tsitsiklis, 1996).

From a given value function J, it is straightforward to get a policy, for example, by applying a *greedy* and deterministic policy (w.r.t. J), that always selects actions with minimal costs,

$$\pi(x) \in \operatorname*{arg\,min}_{a \in \mathcal{A}(x)} \Big[g(x,a) + \alpha \sum_{y \in \mathbb{X}} p(y \,|\, x, a) J(y) \Big].$$

Similarly to the definition of J^π, one can define *action-value* functions of control polices,

$$Q^\pi(x,a) = \mathbb{E}\left[\sum_{t=0}^{N} \alpha^t g(X_t, A_t^\pi) \,\middle|\, X_0 = x, A_0^\pi = a\right],$$

where the notations are the same as in (2). MDPs have an extensively studied theory and there exist a lot of exact and approximate solution methods, for example, value iteration, policy iteration, the Gauss-Seidel method, Q-learning, Q(λ), SARSA and TD(λ)—temporal difference learning (Bertsekas and Tsitsiklis, 1996; Sutton and Barto, 1998; Feinberg and Shwartz, 2002). Most of these reinforcement learning algorithms work by iteratively approximating the optimal value function and typically consider stationary environments.

If J is "close" to J^*, then the greedy policy with one-stage lookahead based on J will also be "close" to an optimal policy, as it was proven by Bertsekas and Tsitsiklis (1996):

Theorem 6 *Let M be a discounted MDP and J is an arbitrary value function. The value function of the greedy policy based on J is denoted by J^π. Then, we have*

$$\|J^\pi - J^*\|_\infty \leq \frac{2\alpha}{1-\alpha} \|J - J^*\|_\infty,$$

where $\|\cdot\|_\infty$ denotes the supremum norm, namely $\|f\|_\infty = \sup\{|f(x)| : x \in domain(f)\}$. Moreover, there exists an $\varepsilon > 0$ such that if $\|J - J^*\|_\infty < \varepsilon$ then $J^* = J^\pi$.

Consequently, if we could obtain a good approximation of the optimal value function, then we immediately had a good control policy, as well, for example, the greedy policy with respect to our approximate value function. Therefore, the main question for most RL approaches is that how a good approximation of the optimal value function could be achieved.

3. Asymptotic Bounds for Generalized Value Iteration

In this section we will briefly overview a unified framework to analyze value function based reinforcement learning algorithms. We will use this approach later when we prove convergence properties in changing environments. The theory presented in this section was developed by Szepesvári and Littman (1999) and was extended by Szita et al. (2002).

3.1 Generalized Value Functions and Approximate Convergence

Throughout the paper we denote the set of value functions by $\mathcal{V}$ which contains, in general, all bounded real-valued functions over an arbitrary set $\mathcal{X}$, for example, $\mathcal{X} = \mathbb{X}$, in the case of state-value functions, or $\mathcal{X} = \mathbb{X} \times \mathbb{A}$, in the case of action-value functions. Note that the set of value functions, $\mathcal{V} = \mathcal{B}(\mathcal{X})$, where $\mathcal{B}(\mathcal{X})$ denotes the set of all bounded real-valued functions over set $\mathcal{X}$, is a normed space, for example, with the supremum norm. Naturally, bounded functions constitute no real restriction in case of analyzing finite MDPs.

Definition 7 *We say that a sequence of random variables, denoted by X_t, κ-approximates random variable X with $\kappa \geq 0$, in a given norm, if we have*

$$\mathbb{P}\left(\limsup_{t\to\infty} \|X_t - X\| \leq \kappa\right) = 1. \tag{3}$$

Hence, the "meaning" of this definition is that sequence X_t converges almost surely to an environment of X and the radius of this environment is less than or equal to a given constant κ. Naturally, this definition is weaker (more general) than the probability one convergence, which arises as a special case, when $\kappa = 0$. In the paper we will always consider convergence in the supremum norm.

3.2 Relaxed Convergence of Generalized Value Iteration

A general form of value iteration type algorithms can be given as follows,

$$V_{t+1} = H_t(V_t, V_t),$$

where H_t is a random operator on $\mathcal{V} \times \mathcal{V} \to \mathcal{V}$ (Szepesvári and Littman, 1999). Consider, for example, the SARSA (state-action-reward-state-action) algorithm which is a model-free policy evaluation method. It aims at finding Q^π for a given policy π and it is defined as

$$Q_{t+1}(x,a) = (1-\gamma_t(x,a))\,Q_t(x,a) + \gamma_t(x,a)(g(x,a) + \alpha\, Q_t(Y,B)),$$

where $\gamma_t(x,a)$ denotes the stepsize associated with state x and action a at time t; Y and B are random variables, Y is generated from the pair (x,a) by simulation, that is, according to the distribution $p(x,a)$, and the distribution of B is $\pi(Y)$. In this case, H_t is defined as

$$H_t(Q_a, Q_b)(x,a) = (1-\gamma_t(x,a))\,Q_a(x,a) + \gamma_t(x,a)(g(x,a) + \alpha\, Q_b(Y,B)), \tag{4}$$

for all x and a. Therefore, the SARSA algorithm takes the form $Q_{t+1} = H_t(Q_t, Q_t)$.

Definition 8 *We say that the operator sequence H_t κ-approximates operator $H : \mathcal{V} \to \mathcal{V}$ at $V \in \mathcal{V}$ if for any initial $V_0 \in \mathcal{V}$ the sequence $V_{t+1} = H_t(V_t, V)$ κ-approximates HV.*

The next theorem (Szita et al., 2002) will be an important tool for proving convergence results for value function based RL algorithms in varying environments.

Theorem 9 *Let H be an arbitrary mapping with fixed point V^*, and let H_t κ-approximate H at V^* over set $\mathcal{X}$. Additionally, assume that there exist random functions $0 \le F_t(x) \le 1$ and $0 \le G_t(x) \le 1$ satisfying the four conditions below with probability one*

1. *For all $V_1, V_2 \in \mathcal{V}$ and for all $x \in \mathcal{X}$,*

$$|H_t(V_1, V^*)(x) - H_t(V_2, V^*)(x)| \le G_t(x)\,|V_1(x) - V_2(x)|\,.$$

2. *For all $V_1, V_2 \in \mathcal{V}$ and for all $x \in \mathcal{X}$,*

$$|H_t(V_1, V^*)(x) - H_t(V_1, V_2)(x)| \le F_t(x)\,\|V^* - V_2\|_\infty\,.$$

3. *For all $k > 0$, $\prod_{t=k}^{n} G_t(x)$ converges to zero uniformly in x as n increases.*

4. *There exist $0 \le \xi < 1$ such that for all $x \in \mathcal{X}$ and sufficiently large t,*

$$F_t(x) \le \xi\,(1 - G_t(x)).$$

Then, $V_{t+1} = H_t(V_t, V_t)$ κ'-approximates V^* over $\mathcal{X}$ for any $V_0 \in \mathcal{V}$, where $\kappa' = 2\kappa/(1-\xi)$.

Usually, functions F_t and G_t can be interpreted as the ratio of mixing the two arguments of operator H_t. In the case of the SARSA algorithm, described above by (4), $\mathcal{X} = \mathbb{X} \times \mathbb{A}$, $G_t(x,a) = (1-\gamma_t(x,a))$ and $F_t(x,a) = \alpha\gamma_t(x,a)$ would be a suitable choice.

One of the most important aspects of this theorem is that it shows how to reduce the problem of approximating V^* with $V_t = H_t(V_t, V_t)$ type operators to the problem of approximating it with a $V_t' = H_t(V_t', V^*)$ sequence, which is, in many cases, much easier to be dealt with. This makes, for example, the convergence of Watkins' Q-learning a consequence of the classical Robbins-Monro theory (Szepesvári and Littman, 1999; Szita et al., 2002).

4. Value Function Bounds for Environmental Changes

In many control problems it is typically not possible to "practise" in the real environment, only a dynamic *model* is available to the system and this model can be used for predicting how the environment will respond to the control signals (model predictive control). MDP based solutions usually work by *simulating* the environment with the model, through simulation they produce *simulated experience* and by *learning* from these experience they improve their value functions. Computing an approximately optimal value function is essential because, as we have seen (Theorem 6), close approximations to optimal value functions lead directly to good policies. Though, there are alternative approaches which directly approximate optimal control policies (see Sutton et al., 2000). However, what happens if the model was inaccurate or the environment had changed slightly? In what follows we investigate the effects of environmental changes on the optimal value function. For continuous Markov processes questions like these were already analyzed (Gordienko and Salem, 2000; Favero and Runggaldier, 2002; de Oca et al., 2003), hence, we will focus on *finite* MDPs.

The theorems of this section have some similarities with two previous results. First, Munos and Moore (2000) studied the dependence of the Bellman operator on the transition-probabilities and the immediate-costs. Later, Kearns and Singh (2002) applied a *simulation lemma* to deduce polynomial time bounds to achieve near-optimal return in MDPs. This lemma states that if two MDPs differ only in their transition and cost functions and we want to approximate the value function of a fixed policy concerning one of the MDPs in the other MDP, then how close should we choose the transitions and the costs to the original MDP relative to the mixing time or the horizon time.

4.1 Changes in the Transition-Probability Function

First, we will see that the optimal value function of a *discounted* MDP Lipschitz continuously depends on the transition-probability function. This question was analyzed by Müller (1996), as well, but the presented version of Theorem 10 was proven by Kalmár et al. (1998).

Theorem 10 *Assume that two discounted MDPs differ only in their transition functions, denoted by p_1 and p_2. Let the corresponding optimal value functions be J_1^* and J_2^*, then*

$$\|J_1^* - J_2^*\|_\infty \leq \frac{n\alpha\|g\|_\infty}{(1-\alpha)^2}\|p_1 - p_2\|_\infty,$$

recall that n is the size of the state space and $\alpha \in [0,1)$ is the discount rate.

A disadvantage of this theorem is that the estimation heavily depends on the size of the state space, *n*. However, this bound can be improved if we consider an induced matrix norm for transition-probabilities instead of the supremum norm. The following theorem presents our improved estimation for transition changes. Its proof can be found in the appendix.

Theorem 11 *With the assumptions and notations of Theorem 10, we have*

$$\|J_1^* - J_2^*\|_\infty \leq \frac{\alpha\|g\|_\infty}{(1-\alpha)^2}\|p_1 - p_2\|_1,$$

where $\|\cdot\|_1$ is a norm on $f : \mathbb{X}\times\mathbb{A}\times\mathbb{X} \to \mathbb{R}$ type functions, for example, $f(x,a,y) = p(y|x,a)$,

$$\|f\|_1 = \max_{x,a}\sum_{y\in\mathbb{X}} |f(x,a,y)|. \tag{5}$$

If we consider f as a matrix which has a column for each state-action pair $(x,a) \in \mathbb{X} \times \mathbb{A}$ and a row for each state $y \in \mathbb{X}$, then the above definition gives us the usual "maximum absolute column sum norm" definition for matrices, which is conventionally denoted by $\|\cdot\|_1$.

It is easy to see that for all f, we have $\|f\|_1 \leq n\|f\|_\infty$, where n is size of the state space. Therefore, the estimation of Theorem 11 is at least as good as the estimation of Theorem 10. In order to see that it is a real improvement consider, for example, the case when we choose a particular state-action pair, $(\hat{x},\hat{a})$, and take a p_1 and p_2 that only differ in $(\hat{x},\hat{a})$. For example, $p_1(\hat{x},\hat{a}) = \langle 1,0,0,\ldots,0\rangle$ and $p_2(\hat{x},\hat{a}) = \langle 0,1,0,\ldots,0\rangle$, and they are equal for all other $(x,a) \neq (\hat{x},\hat{a})$. Then, by definition, $\|p_1 - p_2\|_1 = 2$, but $n\|p_1 - p_2\|_\infty = n$. Consequently, in this case, we have improved the bound of Theorem 10 by a factor of $2/n$.

4.2 Changes in the Immediate-Cost Function

The same kind of Lipschitz continuity can be proven in case of changes in the cost function.

Theorem 12 *Assume that two discounted MDPs differ only in the immediate-costs functions, g_1 and g_2. Let the corresponding optimal value functions be J_1^* and J_2^*, then*

$$\|J_1^* - J_2^*\|_\infty \leq \frac{1}{1-\alpha}\|g_1 - g_2\|_\infty .$$

4.3 Changes in the Discount Factor

The following theorem shows that the change of the value function can also be estimated in case there were changes in the discount rate (all proofs can be found in the appendix).

Theorem 13 *Assume that two discounted MDPs differ only in the discount factors, denoted by $\alpha_1, \alpha_2 \in [0,1)$. Let the corresponding optimal value functions be J_1^* and J_2^*, then*

$$\|J_1^* - J_2^*\|_\infty \leq \frac{|\alpha_1 - \alpha_2|}{(1-\alpha_1)(1-\alpha_2)}\|g\|_\infty .$$

The next example demonstrates, however, that this dependence is not Lipschitz continuous. Consider, for example, an MDP that has only one state x and one action a. Taking action a loops back deterministically to state x with cost $g(x,a) = 1$. Suppose that the MDP has discount factor $\alpha_1 = 0$, thus, $J_1^*(x) = 1$. Now, if we change the discount rate to $\alpha_2 \in (0,1)$, then $|\alpha_1 - \alpha_2| < 1$ but $\|J_1^* - J_2^*\|_\infty$ could be arbitrarily large, since $J_2^*(x) \to \infty$ as $\alpha_2 \to 1$.

At the same time, we can notice that if we fix a constant $\alpha_0 < 1$ and only allow discount factors from the interval $[0,\alpha_0]$, then this dependence became Lipschitz continuous, as well.

4.4 Case of Action-Value Functions

Many reinforcement learning algorithms, such as Q-learning, work with action-value functions which are important, for example, for model-free approaches. Now, we investigate how the previously presented theorems apply to this type of value functions. The optimal action-value function, denoted by Q^*, is defined for all state-action pair (x,a) by

$$Q^*(x,a) = g(x,a) + \alpha \sum_{y \in \mathbb{X}} p(y|x,a)J^*(y),$$

where J^* is the optimal state-value function. Note that in the case of the optimal action-value function, first, we take a given action (which can have very high cost) and, only after that the action was taken, follow an optimal policy. Thus, we can estimate $\|Q^*\|_\infty$ by

$$\|Q^*\|_\infty \leq \|g\|_\infty + \alpha \|J^*\|_\infty .$$

Nevertheless, the next lemma shows that the same estimations can be derived for environmental changes in the case of action-value functions as in the case of state-value functions.

Lemma 14 *Assume that we have two discounted MDPs which differ only in the transition-probability functions or only in the immediate-cost functions or only in the discount factors. Let the corresponding optimal action-value functions be Q_1^* and Q_2^*, respectively. Then, the bounds for $\|J_1^* - J_2^*\|_\infty$ of Theorems 11, 12 and 13 are also bounds for $\|Q_1^* - Q_2^*\|_\infty$.*

4.5 Further Remarks on Inaccurate Models

In this section we saw that the optimal value function of a discounted MDP depends smoothly on the transition function, the cost function and the discount rate. This dependence is of Lipschitz type in the first two cases and non-Lipschitz for discount rates.

If we treat one of the MDPs in the previous theorems as a system which describes the "real" behavior of the environment and the other MDP as our model, then these results show that even if the model is slightly inaccurate or there were changes in the environment, the optimal value function based on the model cannot be arbitrarily wrong from the viewpoint of the environment. These theorems are of special interest because in "real world" problems the transition-probabilities and the immediate-costs are mostly estimated only, for example, by statistical methods from historical data. Later, we will see that changes in the discount rate can be traced back to changes in the cost function (Lemma 18), therefore, it is sufficient to consider transition and cost changes. The following corollary summarizes the results.

Corollary 15 *Assume that two discounted MDPs (E and M) differ only in their transition functions and their cost functions. Let the corresponding transition and cost functions be denoted by p_E, p_M and g_E, g_M, respectively. The corresponding optimal value functions are denoted by J_E^* and J_M^*. The value function in E of the deterministic and greedy policy (π) with one stage-lookahead that is based upon J_M^* is denoted by J_E^π. Then,*

$$\|J_E^\pi - J_E^*\|_\infty \leq \frac{2\alpha}{1-\alpha}\left[\frac{\|g_E - g_M\|_\infty}{1-\alpha} + \frac{c\,\alpha\,\|p_E - p_M\|_1}{(1-\alpha)^2}\right],$$

where $c = \min\{\|g_E\|_\infty, \|g_M\|_\infty\}$ and $\alpha \in [0,1)$ is the discount factor.

The proof simply follows from Theorems 6, 11 and 12 and from the triangle inequality. Another interesting question is the effects of environmental changes on the value function of a *fixed* control policy. However, it is straightforward to prove (Csáji, 2008) that the same estimations can be derived for $\|J_1^\pi - J_2^\pi\|_\infty$, where π is an arbitrary (stationary, Markovian, randomized) control policy, as the estimations of Theorems 10, 11, 12 and 13.

Note that the presented theorems are only valid in case of *discounted* MDPs. Though, a large part of the MDP related research studies the expected total discounted cost optimality criterion, in

some cases discounting is inappropriate and, therefore, there are alternative optimality approaches, as well. A popular alternative approach is to optimize the *expected average cost* (Feinberg and Shwartz, 2002). In this case the value function is defined as

$$J^\pi(x) = \limsup_{N\to\infty} \frac{1}{N}\,\mathbb{E}\left[\sum_{t=0}^{N-1} \alpha^t g(X_t, A_t^\pi) \;\middle|\; X_0 = x\right],$$

where the notations are the same as previously, for example, as applied in Equation (2).

Regarding the validity of the results of Section 4 concerning MDPs with the expected average cost minimization objective, we can recall that, in the case of finite MDPs, discounted cost offers a good approximation to the other optimality criterion. More precisely, it can be shown that there exists a large enough $\alpha_0 < 1$ such that $\forall\,\alpha \in (\alpha_0, 1)$ optimal control policies for the discounted cost problem are also optimal for the average cost problem (Feinberg and Shwartz, 2002). These policies are called *Blackwell optimal*.

5. Learning in Varying Environments

In this section we investigate how value function based learning methods can act in environments which may change over time. However, without restrictions, this approach would be too general to establish convergence results. Therefore, we restrict ourselves to the case when the changes remain bounded over time. In order to precisely define this concept, the idea of (ε, δ)-MDPs is introduced, which is a generalization of classical MDPs and ε-MDPs. First, we recall the definition of ε-MDPs (Kalmár et al., 1998; Szita et al., 2002).

Definition 16 *A sequence of MDPs $(\mathcal{M}_t)_{t=1}^\infty$ is called an ε-MDP with $\varepsilon > 0$ if the MDPs differ only in their transition-probability functions, denoted by p_t for $\mathcal{M}_t$, and there exists an MDP with transition function p, called the base MDP, such that $\sup_t \|p - p_t\| \leq \varepsilon$.*

5.1 Varying Environments: (ε, δ)-MDPs

Now, we extend the idea described above. The following definition of (ε, δ)-MDPs generalizes the concept of ε-MDPs in two ways. First, we also allow the cost function to change over time and, additionally, we require the changes to remain bounded by parameters ε and δ only asymptotically, in the limit. A finite number of large deviations is tolerated.

Definition 17 *A tuple $\langle \mathbb{X}, \mathbb{A}, \mathcal{A}, \{p_t\}_{t=1}^\infty, \{g_t\}_{t=1}^\infty, \alpha\rangle$ is an (ε, δ)-MDP with $\varepsilon, \delta \geq 0$, if there exists an MDP $\langle \mathbb{X}, \mathbb{A}, \mathcal{A}, p, g, \alpha\rangle$, called the base MDP, such that*

1. $\limsup_{t\to\infty} \|p - p_t\| \leq \varepsilon$
2. $\limsup_{t\to\infty} \|g - g_t\| \leq \delta$

The optimal value function of the base MDP and of the current MDP at time t (which MDP has transition function p_t and cost function g_t) are denoted by J^* and J_t^*, respectively.

In order to keep the analysis as simple as possible, we do not allow the discount rate parameter α to change over time; not only because, for example, with Theorem 13 at hand, it would be straightforward to extend the results to the case of changing discount factors, but even more because, as

Lemma 18 demonstrates, the effects of changes in the discount rate can be incorporated into the immediate-cost function, which is allowed to change in (ε,δ)-MDPs.

Lemma 18 *Assume that two discounted MDPs, $\mathcal{M}_1$ and $\mathcal{M}_2$, differ only in the discount factors, denoted by α_1 and α_2. Then, there exists an MDP, denoted by $\mathcal{M}_3$, such that it differs only in the immediate-cost function from $\mathcal{M}_1$, thus its discount factor is α_1, and it has the same optimal value function as $\mathcal{M}_2$. The immediate-cost function of $\mathcal{M}_3$ is*

$$\widehat{g}(x,a) = g(x,a) + (\alpha_2 - \alpha_1) \sum_{y\in\mathbb{X}} p(y|x,a) J_2^*(y),$$

where p is the probability-transition function of $\mathcal{M}_1$, $\mathcal{M}_2$ and $\mathcal{M}_3$; g is the immediate-cost function of $\mathcal{M}_1$ and $\mathcal{M}_2$; and $J_2^*(y)$ denotes the optimal cost-to-go function of $\mathcal{M}_2$.

On the other hand, we can notice that changes in the cost function cannot be traced back to changes in the transition function. Consider, for example, an MDP with a constant zero cost function. Then, no matter what the transition-probabilities are, the optimal value function remains zero. However, we may achieve non-zero optimal value function values if we change the immediate-cost function. Therefore, (ε,δ)-MDPs cannot be traced back to ε-MDPs.

Now, we briefly investigate the applicability of (ε,δ)-MDPs and a possible motivation behind them. When we model a "real world" problem as an MDP, then we typically take only the *major characteristics* of the system into account, but there could be many *hidden parameters*, as well, which may affect the transition-probabilities and the immediate-costs, however, which are not explicitly included in the model. For example, if we model a production control system as an MDP (Csáji and Monostori, 2006), then the workers' fatigue, mood or the quality of the materials may affect the durations of the tasks, but these characteristics are usually not included in the model. Additionally, the values of these hidden parameters may change over time. In these cases, we could either try to incorporate as many aspects of the system as possible into the model, which would most likely lead to *computationally intractable* results, or we could model the system as an (ε,δ)-MDP, which would result in a simplified model and, presumably, in a more tractable system.

5.2 Relaxed Convergence of Stochastic Iterative Algorithms

In this section we present a general relaxed convergence theorem for a large class of stochastic iterative algorithms. Later, we will apply this theorem to investigate the convergence properties of value function based reinforcement learning methods in (ε,δ)-MDPs.

Many learning and optimization methods can be written in a general form as a *stochastic iterative algorithm* (Bertsekas and Tsitsiklis, 1996). More precisely, as

$$V_{t+1}(x) = (1-\gamma_t(x))V_t(x) + \gamma_t(x)((K_tV_t)(x) + W_t(x)), \tag{6}$$

where $V_t \in \mathcal{V}$, operator $K_t : \mathcal{V} \to \mathcal{V}$ acts on value functions, each $\gamma_t(x)$ is a random variable which determines the stepsize and $W_t(x)$ is also a random variable, a noise parameter.

Regarding reinforcement learning algorithms, for example, (asynchronous) value iteration, Gauss-Seidel methods, Q-learning and TD(λ) – temporal difference learning can be formulated this way. We will show that under suitable conditions these algorithms work in (ε,δ)-MDPs, more precisely, κ-approximation to the optimal value function of the base MDP will be proven.

Now, in order to provide our relaxed convergence result, we introduce assumptions on the noise parameters, on the stepsize parameters and on the value function operators.

Definition 19 *We denote the history of the algorithm until time t by $\mathcal{F}_t$, defined as*

$$\mathcal{F}_t = \{V_0, \ldots, V_t, W_0, \ldots, W_{t-1}, \gamma_0, \ldots, \gamma_t\}.$$

The sequence $\mathcal{F}_0 \subseteq \mathcal{F}_1 \subseteq \mathcal{F}_2 \subseteq \ldots$ can be seen as a *filtration*, viz., as an increasing sequence of σ-fields. The set $\mathcal{F}_t$ represents the information available at each time t.

Assumption 1 *There exits a constant $C > 0$ such that for all state x and time t, we have*

$$\mathbb{E}[W_t(x) \,|\, \mathcal{F}_t] = 0 \quad \textit{and} \quad \mathbb{E}\left[W_t^2(x) \,|\, \mathcal{F}_t\right] < C < \infty.$$

Regarding the stepsize parameters, γ_t, we make the "usual" stochastic approximation assumptions. Note that there is a separate stepsize parameter for each possible state.

Assumption 2 *For all x and t, $0 \leq \gamma_t(x) \leq 1$, and we have with probability one*

$$\sum_{t=0}^{\infty} \gamma_t(x) = \infty \quad \textit{and} \quad \sum_{t=0}^{\infty} \gamma_t^2(x) < \infty.$$

Intuitively, the first requirement guarantees that the stepsizes are able to overcome the effects of finite noises, while the second criterion ensures that they eventually converge.

Assumption 3 *For all t, operator $K_t : \mathcal{V} \to \mathcal{V}$ is a supremum norm contraction mapping with Lipschitz constant $\beta_t < 1$ and with fixed point V_t^*. Formally, for all $V_1, V_2 \in \mathcal{V}$,*

$$\|K_t V_1 - K_t V_2\|_\infty \leq \beta_t \|V_1 - V_2\|_\infty.$$

Let us introduce a common Lipschitz constant $\beta_0 = \limsup_{t\to\infty} \beta_t$, and assume that $\beta_0 < 1$.

Because our aim is to analyze changing environments, each K_t operator can have different fixed points and different Lipschitz constants. However, to avoid the progress of the algorithm to "slow down" infinitely, we should require that $\limsup_{t\to\infty} \beta_t < 1$. In the next section, when we apply this theory to the case of (ε, δ)-MDPs, each value function operator can depend on the current MDP at time t and, thus, can have different fixed points.

Now, we present a theorem (its proof can be found in the appendix) that shows how the function sequence generated by iteration (6) can converge to an environment of a function.

Theorem 20 *Suppose that Assumptions 1-3 hold and let V_t be the sequence generated by iteration (6). Then, for any $V^*, V_0 \in \mathcal{V}$, the sequence V_t κ-approximates function V^* with*

$$\kappa = \frac{4\rho}{1-\beta_0} \quad \textit{where} \quad \rho = \limsup_{t\to\infty} \|V_t^* - V^*\|_\infty.$$

This theorem is very general, it is valid even in the case of non-finite MDPs. Notice that V^* can be an *arbitrary* function but, naturally, the radius of the environment of V^*, which the sequence V_t almost surely converges to, depends on $\limsup_{t\to\infty} \|V_t^* - V^*\|_\infty$.

If we take a closer look at the proof, we can notice that the theorem is still valid if each K_t is only a *pseudo-contraction* but, additionally, it also attracts points to V^*. Formally, it is enough if we assume that for all $V \in \mathcal{V}$, we have $\|K_t V - K_t V_t^*\|_\infty \leq \beta_t \|V - V_t^*\|_\infty$ and $\|K_t V - K_t V^*\|_\infty \leq \beta_t \|V - V^*\|_\infty$ for a suitable $\beta_t < 1$. This remark could be important in case we want to apply Theorem 20 to changing *stochastic shortest path (SSP)* problems.

5.2.1 A SIMPLE NUMERICAL EXAMPLE

Consider a one dimensional stochastic process characterized by the iteration

$$v_{t+1} = (1-\gamma_t)v_t + \gamma_t(K_t(v_t) + w_t), \tag{7}$$

where γ_t is the learning rate and w_t is a noise term. Let us suppose we have n alternating operators k_i with Lipschitz constants $b_i < 1$ and fixed points v_i^* where $i \in \{0,\ldots,n-1\}$,

$$k_i(v) = v + (1-b_i)(v_i^* - v).$$

The current operator at time t is $K_t = k_i$ (thus, $V_t^* = v_i^*$ and $\beta_t = b_i$) if $i \equiv t \pmod n$, that is, if i is congruent with t modulo n: if they have the same remainder when they are divided by n. In other words, we apply a *round-robin* type schedule for the operators.

Figure 1 shows that the trajectories remained close to the fixed points. The figure illustrates the case of two (-1 and 1) and six ($-3,-2,-1,1,2,3$) alternating fixed points.

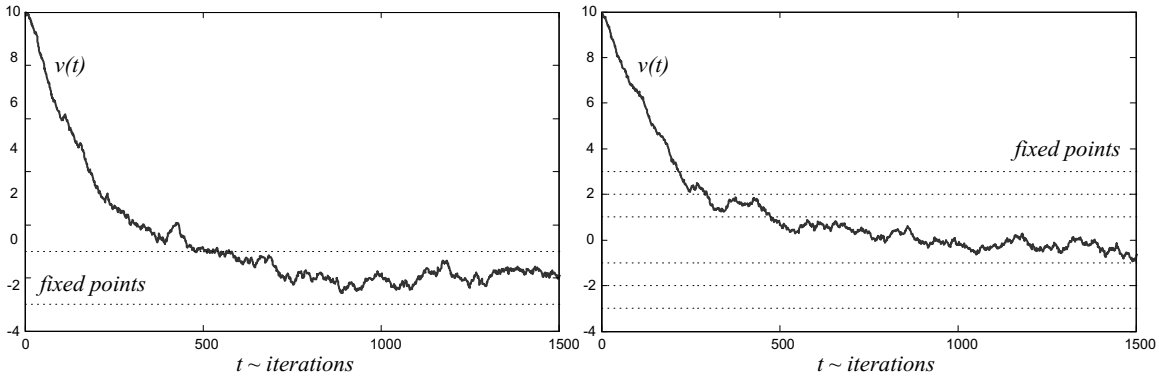

Figure 1: Trajectories generated by (7) with two (left) and six (right) fixed points.

5.2.2 A PATHOLOGICAL EXAMPLE

During this example we will restrict ourselves to deterministic functions. According to the *Banach fixed point theorem*, if we have a contraction mapping f over a complete metric space with fixed point $v^* = f(v^*)$, then, for any initial v_0 the sequence $v_{t+1} = f(v_t)$ converges to v^*. It could be thought that this result can be easily generalized to the case of alternating operators. For example, suppose we have n alternating contraction mappings k_i with Lipschitz constants $b_i < 1$ and fixed points v_i^*, respectively, where $i \in \{0,\ldots,n-1\}$, and we apply them iteratively starting from an arbitrary v_0, viz., $v_{t+1} = K_t(v_t)$, where $K_t = k_i$ if $i \equiv t \pmod n$. One may think that since each k_i attracts the point towards its fixed point, the sequence v_t converges to the *convex hull* of the fixed points. However, as the following example demonstrates, this is not the case, since it is possible that the point moves away from the convex hull and, in fact, it gets farther and farther after each iteration.

Now, let us consider two one-dimensional functions, $k_i : \mathbb{R} \to \mathbb{R}$, where $i \in \{a,b\}$, defined below by Equation (8). It can be easily proven that these functions are contractions with fixed points v_i^*

and Lipschitz constants b_i (in Figure 2, $v_a^* = 1$, $v_b^* = -1$ and $b_i = 0.9$).

$$k_i(v) = \begin{cases} v + (1-b_i)(v_i^* - v) & \text{if } sgn(v_i^*) = sgn(v - v_i^*), \\ v_i^* + (v_i^* - v) + (1-b_i)(v - v_i^*) & \text{otherwise,} \end{cases} \tag{8}$$

where $sgn(\cdot)$ denotes the signum[1] function. Figure 2 demonstrates that even if the iteration starts from the middle of the convex hull (from the center of mass), $v_0 = 0$, it starts getting farther and farther from the fixed points in each step when we apply k_a and k_b after each other. Nevertheless,

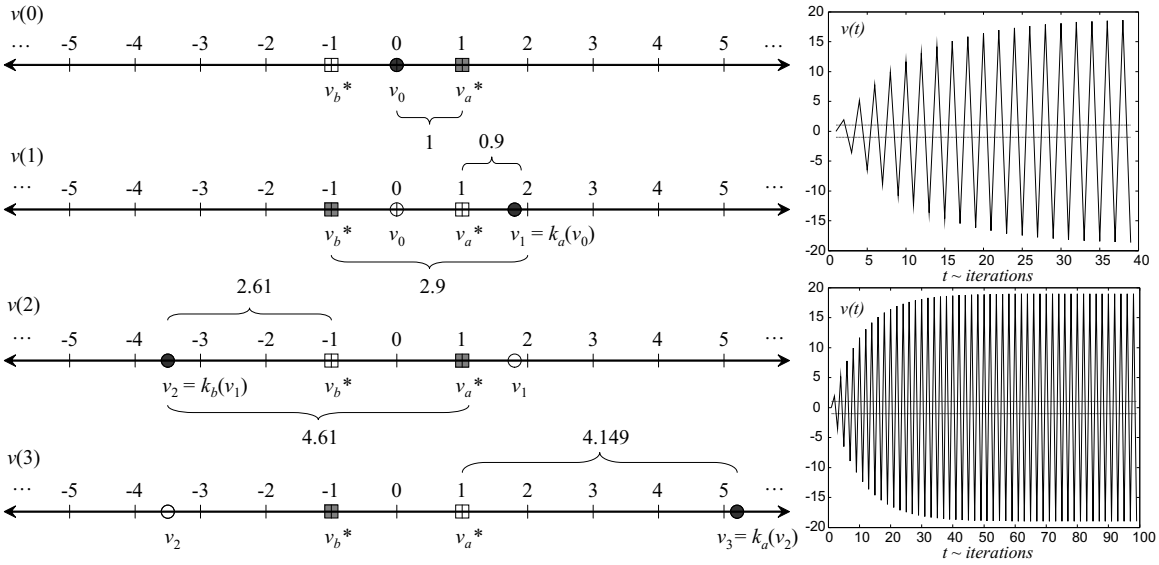

Figure 2: A deterministic pathological example, generated by the iterative application of (8). The left part demonstrates the first steps, while the two images on the right-hand side show the behavior of the trajectory in the long run.

the following argument shows that sequence v_t cannot get arbitrarily far from the fixed points. Let us denote the *diameter* of the convex hull of the fixed points by ρ. Since this convex hull is a polygon (where the vertices are fixed points) $\rho = \max_{i,j} \|v_i^* - v_j^*\|$. Furthermore, let β_0 be defined as $\beta_0 = \max_i b_i$ and d_t as $d_t = \min_i \|v_i^* - v_t\|$. Then, it can be proven that for all t, we have $d_{t+1} \leq \beta_0(2\rho + d_t)$. If we assume that $d_{t+1} \geq d_t$, then it follows that $d_t \leq d_{t+1} \leq \beta_0(2\rho + d_t)$. After rearrangement, we get the following inequality

$$d_t \leq \frac{2\beta_0\rho}{1-\beta_0} = \phi(\beta_0, \rho).$$

Therefore, $d_t > \phi(\beta_0, \rho)$ implies that $d_{t+1} < d_t$. Consequently, if v_t somehow got farther than $\phi(\beta_0, \rho)$, in the next step it would inevitably be attracted towards the fixed points. It is easy to see that this argument is valid in an arbitrary normed space, as well.

1. $sgn(x) = 0$ if $x = 0$, $sgn(x) = -1$ if $x < 0$ and $sgn(x) = 1$ if $x > 0$.

5.3 Reinforcement Learning in (ε,δ)-MDPs

In case of finite (ε,δ)-MDPs we can formulate a relaxed convergence theorem for value function based reinforcement learning algorithms, as a corollary of Theorem 20. Suppose that $\mathcal{V}$ consists of state-value functions, namely, $\mathcal{X}=\mathbb{X}$. Then, we have

$$\limsup_{t\to\infty}\|J^*-J_t^*\|_\infty \le d(\varepsilon,\delta),$$

where J_t^* is the optimal value function of the MDP at time t and J^* is the optimal value function of the base MDP. In order to calculate $d(\varepsilon,\delta)$, Theorems 11 (or 10), 12 and the triangle inequality could be applied. Assume, for example, that we use the supremum norm, $\|\cdot\|_\infty$, for cost functions and $\|\cdot\|_1$, defined by Equation (5), for transition functions. Then,

$$d(\varepsilon,\delta)=\frac{\varepsilon\alpha\|g\|_\infty}{(1-\alpha)^2}+\frac{\delta}{1-\alpha},$$

where g is the cost function of the base MDP. Now, by applying Theorem 20, we have

Corollary 21 *Suppose that we have an (ε,δ)-MDP and Assumptions 1-3 hold. Let V_t be the sequence generated by iteration (6). Furthermore, assume that the fixed point of each operator K_t is J_t^*. Then, for any initial $V_0\in\mathcal{V}$, the sequence V_t κ-approximates J^* with*

$$\kappa=\frac{4d(\varepsilon,\delta)}{1-\beta_0}.$$

Notice that as parameters ε and δ go to zero, we get back to a classical convergence theorem for this kind of stochastic iterative algorithm (still in a little bit generalized form, since β_t might still change over time). Now, with the help of these results, we will investigate the convergence of some classical reinforcement learning algorithms in (ε,δ)-MDPs.

5.3.1 ASYNCHRONOUS VALUE ITERATION IN (ε,δ)-MDPS

The method of value iteration is one of the simplest reinforcement learning algorithms. In ordinary MDPs it is defined by the iteration $J_{t+1}=TJ_t$, where T is the Bellman operator. It is known that the sequence J_t converges in the supremum norm to J^* for any initial J_0 (Bertsekas and Tsitsiklis, 1996). The asynchronous variant of value iteration arises when the states are updated asynchronously, for example, only one state in each iteration. In the case of (ε,δ)-MDPs a small stepsize variant of asynchronous value iteration can be defined as

$$J_{t+1}(x)=(1-\gamma_t(x))J_t(x)+\gamma_t(x)(T_tJ_t)(x),$$

where T_t is the Bellman operator of the current MDP at time t. Since there is no noise term in the iteration, Assumption 1 is trivially satisfied. Assumption 3 follows from the fact that each T_t operator is an α contraction where α is the discount factor. Therefore, if the stepsizes satisfy Assumption 2 then, by applying Corollary 21, we have that the sequence J_t κ-approximates J^* for any initial value function J_0 with $\kappa=(4d(\varepsilon,\delta))/(1-\alpha)$.

5.3.2 Q-LEARNING IN (ε,δ)-MDPS

Watkins' Q-learning is a very popular off-policy model-free reinforcement learning algorithm (Even-Dar and Mansour, 2003). Its generalized version in ε-MDPs was studied by Szita et al. (2002). The Q-learning algorithm works with action-value functions, therefore, $\mathcal{X} = \mathbb{X} \times \mathbb{A}$, and the one-step Q-learning rule in (ε,δ)-MDPs can be defined as follows

$$Q_{t+1}(x,a) = (1-\gamma_t(x,a))Q_t(x,a) + \gamma_t(x,a)(\widetilde{T}_t Q_t)(x,a), \tag{9}$$

$$(\widetilde{T}_t Q_t)(x,a) = g_t(x,a) + \alpha \min_{B\in\mathcal{A}(Y)} Q_t(Y,B),$$

where g_t is the immediate-cost function of the current MDP at time t and Y is a random variable generated from the pair (x,a) by simulation, that is, according to the probability distribution $p_t(x,a)$, where p_t is the transition function of the current MDP at time t.

Operator $\widetilde{T}_t$ is randomized, but as it was shown by Bertsekas and Tsitsiklis (1996) in their convergence theorem for Q-learning, it can be rewritten in a form as follows

$$(\widetilde{T}_t Q)(x,a) = (\widetilde{K}_t Q)(x,a) + \widetilde{W_t}(x,a),$$

where $\widetilde{W_t}(x,a)$ is a noise term with zero mean and finite variance, and $\widetilde{K}_t$ is defined as

$$(\widetilde{K}_t Q)(x,a) = g_t(x,a) + \alpha \sum_{y\in\mathbb{X}} p_t(y \mid x,a) \min_{b\in\mathcal{A}(y)} Q(y,b).$$

Let us denote the optimal action-value function of the current MDP at time t and the base MDP by Q_t^* and Q^*, respectively. By using the fact that $J^*(x) = \min_a Q^*(x,a)$, it is easy to see that for all t, Q_t^* is the fixed point of operator $\widetilde{K}_t$ and, moreover, each $\widetilde{K}_t$ is an α contraction. Therefore, if the stepsizes satisfy Assumption 2, then the Q_t sequence generated by iteration (9) κ-approximates Q^* for any initial Q_0 with $\kappa = (4d(\varepsilon,\delta))/(1-\alpha)$.

In some situations the immediate costs are randomized, however, even in this case the relaxed convergence of Q-learning would follow as long as the random immediate costs had finite expected value and variance, which is required for satisfying Assumption 1.

5.3.3 TEMPORAL DIFFERENCE LEARNING IN (ε,δ)-MDPS

Temporal difference learning, or for short TD-learning, is a policy evaluation algorithm. It aims at finding the corresponding value function J^π for a given control policy π (Bertsekas and Tsitsiklis, 1996; Sutton and Barto, 1998). It can also be used for approximating the optimal value function, for example, if we apply it together with the policy iteration algorithm.

First, we briefly review the off-line first-visit variant of TD(λ) in case of ordinary MDPs. It can be shown that the value function of a policy π can be rewritten in a form as

$$J^\pi(x) = \mathbb{E}\left[\sum_{m=0}^{\infty} (\alpha\lambda)^m D^\pi_{\alpha,m} \,\middle|\, X_0 = x\right] + J^\pi(x),$$

where $\lambda \in [0,1)$ and $D^\pi_{\alpha,m}$ denotes the "temporal difference" coefficient at time m,

$$D^\pi_{\alpha,m} = g(X_m, A^\pi_m) + \alpha J^\pi(X_{m+1}) - J^\pi(X_m),$$

where X_m, X_{m+1} and A_m^π are random variables, X_{m+1} has $p(X_m, A_m^\pi)$ distribution and A_m^π is a random variable for actions, it is selected according to the distribution $\pi(X_m)$.

Based on this observation, we can define a stochastic approximation algorithm as follows. Let us suppose that we have a generative model of the environment, for example, we can perform simulations in it. Each simulation produces a state-action-reward trajectory. We can assume that all simulations eventually end, for example, there is an absorbing termination state or we can stop the simulation after a given number of steps. Note that even in this case we can treat each trajectory as infinitely long, viz., we can define all costs after the termination as zero. The off-line first-visit TD(λ) algorithm updates the value function after each simulation,

$$J_{t+1}(x_k^t) = J_t(x_k^t) + \gamma_t(x_k^t) \sum_{m=k}^{\infty} (\alpha\lambda)^{m-k} d_{\alpha,m,t}, \tag{10}$$

where x_k^t is the state at step k in trajectory t and $d_{\alpha,m,t}$ is the temporal difference coefficient,

$$d_{\alpha,m,t} = g(x_m^t, a_m^t) + \alpha J_t(x_{m+1}^t) - J_t(x_m^t).$$

For the case of ordinary MDPs it is known that TD(λ) converges almost surely to J^π for any initial J_0 provided that each state is visited by infinitely many trajectories and the stepsizes satisfy Assumption 2. The proof is based on the observation that iteration (10) can be seen as a Robbins-Monro type stochastic iterative algorithm for finding the fixed point of $J^\pi = HJ^\pi$, where H is a contraction mapping with Lipschitz constant α (Bertsekas and Tsitsiklis, 1996). The only difference in the case of (ε, δ)-MDPs is that the environment may change over time and, therefore, operator H becomes time-dependent. However, each H_t is still an α contraction, but they potentially have different fixed points. Therefore, we can apply Theorem 20 to achieve a relaxed convergence result for off-line first-visit TD(λ) in changing environments under the same conditions as in the case of ordinary MDPs.

The convergence of the on-line every-visit variant can be proven in the same way as in the case of ordinary MDPs, viz., by showing that the difference between the two variants is of second order in the size of γ_t and hence inconsequential as γ_t diminishes to zero.

5.3.4 APPROXIMATE DYNAMIC PROGRAMMING

Most RL algorithms in their standard forms, for example, with lookup table representations, are highly intractable in practice. This phenomenon, which was named "curse of dimensionality" by Bellman, has motivated approximate approaches that result in more tractable methods, but often yield suboptimal solutions. These techniques are usually referred to as *approximate dynamic programming* (ADP). Many ADP methods are combined with simulation, but their key issue is to approximate the value function with a suitable *approximation architecture*: $V \approx \Phi(r)$, where r is a parameter vector. Direct ADP methods collect samples by using simulation, and fit the architecture to the samples. Indirect methods obtain parameter r by using an approximate version of the Bellman equation (Bertsekas, 2007).

The *power of the approximation architecture* is the smallest error that can be achieved, $\eta = \inf_r \|V^* - \Phi(r)\|$, where V^* is the optimal value function. Suppose that $\eta > 0$, then no algorithm can provide a result whose distance from V^* is less than η. Hence, the maximum that we can hope for is to converge to an environment of V^* (Bertsekas and Tsitsiklis, 1996). In what follows, we briefly investigate the connection of our results with ADP.

In general, many direct and indirect ADP methods can be formulated as follows

$$\Phi(r_{t+1}) = \Pi\big((1-\gamma_t)\Phi(r_t) + \gamma_t(B_t(\Phi(r_t)) + W_t)\big), \tag{11}$$

where $r_t \in \Theta$ is an approximation parameter, Θ is the parameter space, for example, $\Theta \subseteq \mathbb{R}^p$, $\Phi : \Theta \to \mathcal{F}$ is an approximation architecture where $\mathcal{F} \subseteq \mathcal{V}$ is a Hilbert space that can be represented by using Φ with parameters from Θ. Function $\Pi : \mathcal{V} \to \mathcal{F}$ is a projection mapping, it renders a representation from $\mathcal{F}$ to each value function from $\mathcal{V}$. Operator $B_t : \mathcal{F} \to \mathcal{V}$ acts on (approximated) value functions. Finally, γ_t denotes the stepsize and W_t is a noise parameter representing the uncertainties coming from, for example, the simulation.

Operator B_t is time-dependent since, for example, if we model an approximate version of optimistic policy iteration, then in each iteration the control policy changes and, therefore, the update operator changes, as well. We can notice that if Π was a linear operator (see below), Equation (11) would be a stochastic iterative algorithm with $K_t = \Pi B_t$. Consequently, the algorithm described by Equation (6) is a generalization of many ADP methods, as well.

Now, we show that a convergence theorem for ADP methods can also be deduced by using Theorem 20. In order to apply the theorem, we should ensure that each update operator be a contraction. If we assume that every B_t is a contraction, we should require two properties from Π to guarantee that the resulted operators remain contractions. First, Π should be *linear*. Operator Π is linear if it is *additive* and *homogeneous*, more precisely, if $\forall V_1, V_2 : \Pi(V_1 + V_2) = \Pi(V_1) + \Pi(V_2)$ and $\forall V : \forall \alpha : \Pi(\alpha V) = \alpha \Pi(V)$, where α is a scalar. This requirement allows the separation of the components. Moreover, Π should be *nonexpansive* w.r.t. the supremum norm, namely: $\forall V_1, V_2 : \|\Pi(V_1) - \Pi(V_2)\| \leq \|V_1 - V_2\|$. Then, the update operator of the algorithm, $K_t = \Pi B_t$, is guaranteed to be a contraction.

If we assume that V_t^* is the fixed point of K_t, thus, $(\Pi B_t)V_t^* = V_t^*$ and β_t is the Lipschitz constant of K_t with $\limsup_{t\to\infty} \beta_t = \beta_0 < 1$, we can deduce a convergence theorem for ADP methods, as a corollary of Theorem 20. Suppose that Assumptions 1-2 hold and each B_t is a contraction as well as Π is linear and supremum norm nonexpansive, then $\Phi(r_t)$ κ-approximates V^* for any initial r_0 with $\kappa = 4\rho/(1-\beta_0)$, where $\rho = \limsup_{t\to\infty} \|V_t^* - V^*\|$. In case all of the fixed points were the same, viz., $\forall t : V_0^* = V_t^*$, then $\Phi(r_t)$ would converge to V_0^* almost surely, consequently, $\Phi(r_t)$ would κ-approximate V^* with $\kappa = \|V_0^* - V^*\|$.

Naturally, these results are quite loose, since we did not make strong assumptions on the applied algorithm and on the approximation architecture. They only illustrate that the approach we took, which allows time-dependent update operators and analyzes approximate convergence, could also provide results for ordinary MDPs, for example, in the case of ADP.

6. Experimental Results

In this section we present two numerical experiments. The first one demonstrates the effects of environmental changes during Q-learning based *scheduling*. The second one presents a parameter analysis concerning the effectiveness of SARSA in (ε, δ)-type *grid world* domains.

6.1 Environmental Changes During Scheduling

Scheduling is the allocation of *resources* over time to perform a collection of *jobs*. Each job consists of a set of *tasks*, potentially with precedence constraints, to be executed on the resources. The

job-shop scheduling problem (JSP) is one of the basic scheduling problems (Pinedo, 2002). We investigated an extension of JSP, called the *flexible job-shop* scheduling problem (FJSP), in which some of the resources are interchangeable, that is, there may be tasks that can be executed on several resources. This problem can be formulated as a finite horizon MDP and can be solved by Q-learning based methods (Csáji and Monostori, 2006).

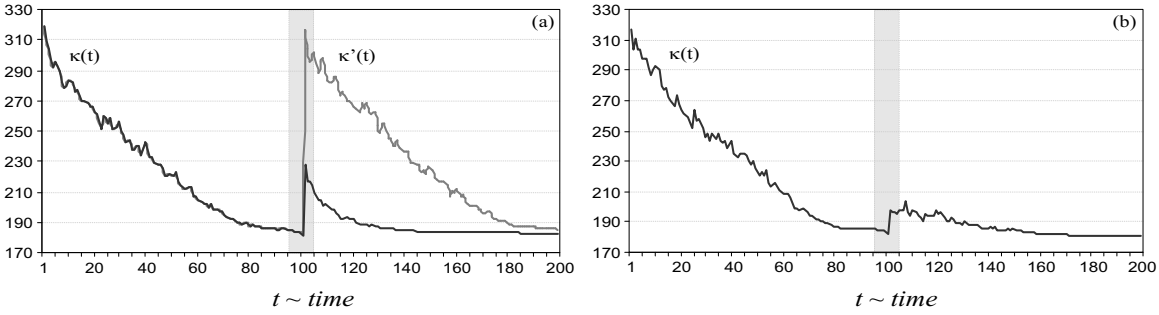

Figure 3: The black curves, $\kappa(t)$, show the performance measure in case there was a resource breakdown (a) or a new resource availability (b) at time $t = 100$; the gray curve in (a), $\kappa'(t)$, demonstrates the case the policy would be recomputed from scratch.

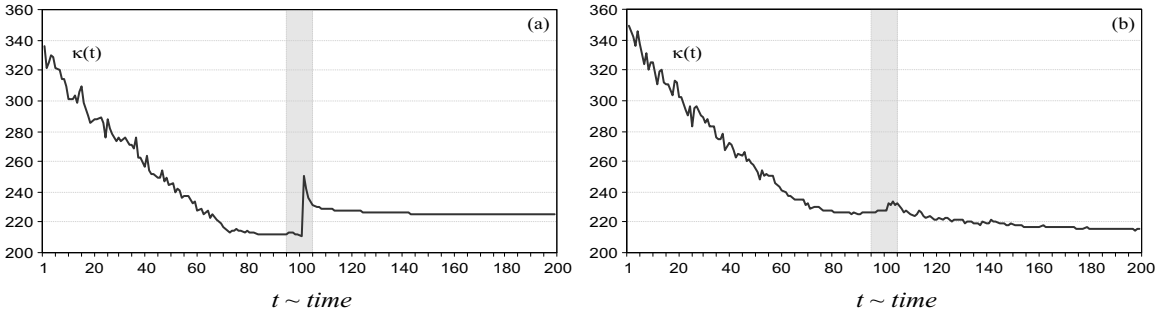

Figure 4: The black curves, $\kappa(t)$, show the performance measure during resource control in case there was a new job arrival (a) or a job cancellation (b) at time $t = 100$.

In order to investigate the effects of environmental changes during scheduling, numerical experiments were initiated and carried out. The aim of scheduling was to minimize the maximum completion time of the tasks, which performance measure is called "makespan". The adaptive features of the Q-learning based approach were tested by confronting the system with unexpected events, such as: resource breakdown, new resource availability (Figure 3), new job arrival or job cancellation (Figure 4). In Figures 3 and 4 the horizontal axis represents time, while the vertical one, the achieved performance measure. The figures were made by averaging hundred random samples. In these tests a fixed number of 20 resources were used with few dozens of jobs, where each job contained a sequence of tasks. In each case there was an unexpected event at time $t = 100$. After the change took place, we considered two possibilities: we either restarted the iterative scheduling process from scratch or we continued the learning using the current (obsolete) value function. We experienced that the latter approach is much more efficient. That was one of the reasons why we started to study how the optimal value function of an MDP depends on the dynamics of the system.

Recall that Theorems 10, 11 and 12 measure the amount of the possible change in the value function in case there were changes in the MDP, but since these theorems apply supremum norm, they only provide bounds for *worst case* situations. However, the results of our numerical experiments, shown in Figures 3 and 4, are indicative of the phenomenon that in an *average case* the change is much less. Therefore, applying the obsolete value function after a change took place is preferable over restarting the optimization from scratch.

The results, black curves, show the case when the obsolete value function approximation was applied after the change took place. The performance which would arise if the system recomputed the whole schedule from scratch is drawn in gray in part (a) of Figure 3.

6.2 Varying Grid World

We also performed numerical experiments on a variant of the classical *grid world* problem (Sutton and Barto, 1998). The original version of this problem can be briefly described as follows: an agent wanders in a rectangular world starting from a random *initial* state with the aim of finding the *goal* state. In each state the agent is allowed to choose from four possible actions: "north", "south", "east" and "west". After an action was selected, the agent moves one step in that direction. There are some *mines* on the field, as well, that the agent should avoid. An *episode* ends if the agent finds the goal state or hits a mine. During our experiments, we applied randomly generated 10×10 grid worlds (thus, these MDPs had 100 states) with 10 mines. The *immediate-cost* of taking a (non-terminating) step was 5, a cost of hitting a mine was 100 and the cost of finding the goal state was -100.

In order to perform the experiment described by Table 1, we have applied the "RL-Glue" framework[2] which consists of open source softwares and aims at being a standard protocol for benchmarking and interconnecting reinforcement learning agents and environments.

We have analyzed an (ε, δ)-type version of grid world, where the problem formed an (ε, δ)-MDP. More precisely, we have investigated the case when for all time t, the transition-probabilities could vary by at most $\varepsilon \geq 0$ around the base transition-probability values and the immediate-costs could vary by at most $\delta \geq 0$ around the base cost values.

During our numerical experiments, the environment changed at each time-step. These changes were generated as follows. First, changes concerning the transition-probabilities are described. In our randomized grid worlds the agent was taken to a random surrounding state (no matter what action it chose) with probability η and this probability *changed* after each step. The new η was computed according to the *uniform* distribution, but its possible values were *bounded* by the values described in the first row of Table 1.

Similarly, the immediate-costs of the base MDP (cf. the first paragraph) were *perturbed* with a uniform random variable that changed at each time-step. Again, its (absolute) value was bounded by δ, which is presented in the first column of the table. The values shown were divided by 100 to achieve the same scale as the transition-probabilities have.

Table 1 was generated using an (optimistic) SARSA algorithm, namely, the current policy was evaluated by SARSA, then the policy was (optimistically) improved, more precisely, the *greedy* policy with respect to the achieved evaluation was calculated. That policy was also *soft*, namely, it made random *explorations* with probability 0.05. We have generated 1000 random grid worlds for each parameter pairs and performed 10 000 episodes in each of these generated worlds. The results

2. RL-Glue can be found at http://rlai.cs.ualberta.ca/RLBB/top.html.

Table 1: The (average) cumulative costs gathered by SARSA in varying grid worlds.

presented in the table were calculated by averaging the cumulative costs over all episodes and over all generated sample worlds.

The parameter analysis shown in Table 1 is indicative of the phenomenon that changes in the transition-probabilities have a much higher impact on the performance. Even large perturbations in the costs were tolerated by SARSA, but large variations in the transition-probabilities caused a high decrease in the performance. An explanation could be that large changes in the transitions cause the agent to loose control over the events, since it becomes very hard to predict the effects of the actions and, hence, to estimate the expected costs.

7. Conclusion

The theory of MDPs provide a general framework for modeling decision making in stochastic dynamic systems, if we know a function that describes the dynamics or we can simulate it, for example, with a suitable program. In some situations, however, the dynamics of the system may change, too. In theory, this change can be modeled with another (higher level) MDP, as well, but doing so would lead to models which are practically intractable.

In the paper we have argued that the optimal value function of a (discounted) MDP Lipschitz continuously depends on the transition-probability function and the immediate-cost function, therefore, small changes in the environment result only in small changes in the optimal value function. This result was already known for the case of transition-probabilities, but we have presented an improved estimation for this case, as well. A bound for changes in the discount factor was also proven, and it was demonstrated that, in general, this dependence was not Lipschitz continuous. Additionally, it was shown that changes in the discount rate could be traced back to changes in the immediate-cost function. The application of the Lipschitz property helps the theoretical treatment of changing environments or inaccurate models, for example, if the transition-probabilities or the costs are estimated statistically, only.

In order to theoretically analyze environmental changes, the framework of (ε,δ)-MDPs was introduced as a generalization of classical MDPs and ε-MDPs. In this quasi-stationary model the

transition-probability function and the immediate-cost function may change over time, but the cumulative changes must remain bounded by ε and δ, asymptotically.

Afterwards, we have investigated how RL methods could work in this kind of changing environment. We have presented a general theorem that estimated the asymptotic distance of a value function sequence from a fixed value function. This result was applied to deduce a convergence theorem for value function based algorithms that work in (ε, δ)-MDPs.

In order to demonstrate our approach, we have presented some numerical experiments, too. First, two simple iterative processes were shown, a "well-behaving" stochastic process and a "pathological", oscillating deterministic process. Later, the effects of environmental changes on Q-learning based flexible job-shop scheduling was experimentally studied. Finally, we have analyzed how SARSA could work in varying (ε, δ)-type grid world domains.

We can conclude that value function based RL algorithms can work in varying environments, at least if the changes remain bounded in the limit. The asymptotic distance of the generated value function sequence from the optimal value function of the base MDP is bounded for a large class of stochastic iterative algorithms. Moreover, this bound is proportional to the diameter of this set, for example, to parameters ε and δ in the case of (ε, δ)-MDPs. These results were illustrated through three classical RL methods: asynchronous value iteration, Q-learning and temporal difference learning policy evaluation. We showed, as well, that this approach could be applied to investigate the convergence of ADP methods.

There are many potential further research directions. Now, as a conclusion to the paper, we highlight some of them. First, analyzing the effects of environmental changes on the value function in case of the *expected average cost* optimization criterion would be interesting. A promising direction could be to investigate environments with non-bounded changes, for example, when the environment might *drift* over time. Naturally, this drift should also be sufficiently slow in order to give the opportunity to the learning algorithm to *track* the changes. Another possible direction could be the further analysis of the convergence results in case of applying *value function approximation*. The classical problem of *exploration* and *exploitation* should also be reinvestigated in changing environments. Finally, for practical reasons, it would be important to find *finite time bounds* for the convergence of stochastic iterative algorithms for (a potentially restricted class of) non-stationary environments.

Appendix A. Proofs

In this appendix the proofs of Theorems 11, 12, 13, 20 and Lemmas 14, 18 can be found.

Theorem 11 *Assume that two MDPs differ only in their transition-probability functions, denoted by p_1 and p_2. Let the corresponding optimal value functions be J_1^* and J_2^*, then*

$$\|J_1^* - J_2^*\|_\infty \leq \frac{\alpha \|g\|_\infty}{(1-\alpha)^2} \|p_1 - p_2\|_1 ,$$

where $\|\cdot\|_1$ is a norm on $f : \mathbb{X} \times \mathbb{A} \times \mathbb{X} \to \mathbb{R}$ type functions, for example, $f(x,a,y) = p(y|x,a)$,

$$\|f\|_1 = \max_{x,a} \sum_{y \in \mathbb{X}} |f(x,a,y)| .$$

Proof First, let us introduce a deterministic Markovian policy. For all state $x \in \mathbb{X}$:

$$\hat{\pi}(x) = \begin{cases} \arg\min\limits_{a \in \mathcal{A}(x)} \left[g(x,a) + \alpha \sum\limits_{y \in \mathbb{X}} p_1(y \mid x,a) J_1^*(y) \right] & \text{if } J_1^*(x) \leq J_2^*(x), \\ \arg\min\limits_{a \in \mathcal{A}(x)} \left[g(x,a) + \alpha \sum\limits_{y \in \mathbb{X}} p_2(y \mid x,a) J_2^*(y) \right] & \text{if } J_2^*(x) < J_1^*(x) \end{cases}$$

If the arg min is ambiguous then any action that takes the minimum can be selected. Using the Bellman optimality equation in the first step, $\|J_1^* - J_2^*\|_\infty$ can be estimated as follows,

$$\forall x \in \mathbb{X} : |J_1^*(x) - J_2^*(x)| =$$

$$= \left| \min_{a \in \mathcal{A}(x)} \left[g(x,a) + \alpha \sum_{y \in \mathbb{X}} p_1(y \mid x,a) J_1^*(y) \right] - \min_{a \in \mathcal{A}(x)} \left[g(x,a) + \alpha \sum_{y \in \mathbb{X}} p_2(y \mid x,a) J_2^*(y) \right] \right| \leq$$

$$\leq \left| g(x,\hat{\pi}(x)) + \alpha \sum_{y \in \mathbb{X}} p_1(y \mid x,\hat{\pi}(x)) J_1^*(y) - g(x,\hat{\pi}(x)) - \alpha \sum_{y \in \mathbb{X}} p_2(y \mid x,\hat{\pi}(x)) J_2^*(y) \right| ,$$

where we applied that $\forall f_1, f_2 : \mathcal{S} \to \mathbb{R}$ bounded functions such that $\min_s f_1(s) \leq \min_s f_2(s)$ and $\hat{s} = \arg\min_s f_1(s)$, we have $|\min_s f_1(s) - \min_s f_2(s)| \leq |f_1(\hat{s}) - f_2(\hat{s})|$. Then,

$$\forall x \in \mathbb{X} : |J_1^*(x) - J_2^*(x)| \leq \left| \alpha \sum_{y \in \mathbb{X}} p_1(y \mid x,\hat{\pi}(x)) J_1^*(y) - p_2(y \mid x,\hat{\pi}(x)) J_2^*(y) \right| =$$

$$= \left| \alpha \sum_{y \in \mathbb{X}} (p_1(y \mid x,\hat{\pi}(x)) - p_2(y \mid x,\hat{\pi}(x))) J_1^*(y) + \alpha \sum_{y \in \mathbb{X}} p_2(y \mid x,\hat{\pi}(x)) (J_1^*(y) - J_2^*(y)) \right| \leq$$

$$\leq \alpha \sum_{y \in \mathbb{X}} |(p_1(y \mid x,\hat{\pi}(x)) - p_2(y \mid x,\hat{\pi}(x))) J_1^*(y)| + \alpha \sum_{y \in \mathbb{X}} |p_2(y \mid x,\hat{\pi}(x)) (J_1^*(y) - J_2^*(y))| ,$$

where in the second step we have rewritten $p_1(y|x,\hat{\pi}(x)) J_1^*(y) - p_2(y|x,\hat{\pi}(x)) J_2^*(y)$ as

$$p_1(y|x,\hat{\pi}(x)) J_1^*(y) - p_2(y|x,\hat{\pi}(x)) J_2^*(y) =$$

$$= p_1(y|x,\hat{\pi}(x)) J_1^*(y) - p_2(y|x,\hat{\pi}(x)) J_1^*(y) + p_2(y|x,\hat{\pi}(x)) J_1^*(y) - p_2(y|x,\hat{\pi}(x)) J_2^*(y) =$$

$$= (p_1(y\,|\,x,\hat{\pi}(x)) - p_2(y\,|\,x,\hat{\pi}(x)))J_1^*(y) + p_2(y\,|\,x,\hat{\pi}(x))(J_1^*(y) - J_2^*(y)).$$

Now, let us recall (a special form of) *Hölder's inequality*: let v_1, v_2 be two vectors and $1 \leq q, r \leq \infty$ with $1/q + 1/r = 1$. Then, we have $\|v_1 v_2\|_{(1)} \leq \|v_1\|_{(q)} \|v_2\|_{(r)}$, where $\|\cdot\|_{(q)}$ denotes *vector* norm, for example, $\|v\|_{(q)} = (\sum_i |v_i|^q)^{1/q}$ and $\|v\|_{(\infty)} = \max_i |v_i| = \|v\|_\infty$. Here, we applied the unusual "(q)" notation to avoid confusion with the applied matrix norm. Notice that the first sum of the last estimation can be treated as the (1)-norm of $v_1 v_2$, where

$$v_1(y) = p_1(y \mid x,\hat{\pi}(x)) - p_2(y \mid x,\hat{\pi}(x))) \quad \text{and} \quad v_2(y) = J_1^*(y),$$

after which Hölder's inequality can be applied with $q = 1$ and $r = \infty$ to estimate the sum. A similar argument can be repeated in the case of the second sum with

$$v_1(y) = p_2(y \mid x,\hat{\pi}(x)) \quad \text{and} \quad v_2(y) = J_1^*(y) - J_2^*(y).$$

Then, after the two applications of Hölder's inequality, we have for all x that

$$|J_1^*(x) - J_2^*(x)| \leq \alpha \|p_1(\cdot \mid x,\hat{\pi}(x)) - p_2(\cdot \mid x,\hat{\pi}(x))\|_{(1)} \|J_1^*\|_\infty +$$

$$+ \alpha \|p_2(\cdot \mid x,\hat{\pi}(x))\|_{(1)} \|J_1^* - J_2^*\|_\infty,$$

since $\|J_1^*\|_\infty \leq \|g\|_\infty/(1-\alpha)$, $\|p_2(\cdot \mid x,\hat{\pi}(x))\|_{(1)} = 1$ and we have this estimation for all x,

$$\|J_1^* - J_2^*\|_\infty \leq \frac{\alpha\|g\|_\infty}{1-\alpha} \max_{x\in\mathbb{X}} \sum_{y\in\mathbb{X}} |\,p_1(y\,|\,x,\hat{\pi}(x)) - p_2(y\,|\,x,\hat{\pi}(x))\,| + \alpha\|J_1^* - J_2^*\|_\infty,$$

which formula can be overestimated, by taking the maximum over all actions, by

$$\|J_1^* - J_2^*\|_\infty \leq \frac{\alpha\|g\|_\infty}{1-\alpha} \|p_1 - p_2\|_1 + \alpha\|J_1^* - J_2^*\|_\infty,$$

from which the statement of the theorem immediately follows after rearrangement. ■

Theorem 12 *Assume that two discounted MDPs differ only in the immediate-cost functions, denoted by g_1 and g_2. Let the corresponding optimal value functions be J_1^* and J_2^*, then*

$$\|J_1^* - J_2^*\|_\infty \leq \frac{1}{1-\alpha} \|g_1 - g_2\|_\infty.$$

Proof First, let us introduce a deterministic Markovian policy. For all state $x \in \mathbb{X}$:

$$\hat{\pi}(x) = \begin{cases} \displaystyle\operatorname*{arg\,min}_{a\in\mathcal{A}(x)} \left[g_1(x,a) + \alpha \sum_{y\in\mathbb{X}} p(y \mid x,a) J_1^*(y) \right] & \text{if } J_1^*(x) \leq J_2^*(x), \\ \displaystyle\operatorname*{arg\,min}_{a\in\mathcal{A}(x)} \left[g_2(x,a) + \alpha \sum_{y\in\mathbb{X}} p(y \mid x,a) J_2^*(y) \right] & \text{if } J_2^*(x) < J_1^*(x). \end{cases}$$

If the arg min is ambiguous, then any action that takes the minimum can be selected. Using the Bellman optimality equation in the first step, $\|J_1^* - J_2^*\|_\infty$ can be estimated as follows,

$$\forall x \in \mathbb{X} : |J_1^*(x) - J_2^*(x)| =$$

$$= \left| \min_{a \in \mathcal{A}(x)} \left[g_1(x,a) + \alpha \sum_{y \in \mathbb{X}} p(y \mid x,a) J_1^*(y) \right] - \min_{a \in \mathcal{A}(x)} \left[g_2(x,a) + \alpha \sum_{y \in \mathbb{X}} p(y \mid x,a) J_2^*(y) \right] \right| \leq$$

$$\leq \left| g_1(x,\hat{\pi}(x)) + \alpha \sum_{y \in \mathbb{X}} p(y \mid x,\hat{\pi}(x)) J_1^*(y) - g_2(x,\hat{\pi}(x)) - \alpha \sum_{y \in \mathbb{X}} p(y \mid x,\hat{\pi}(x)) J_2^*(y) \right|,$$

where we applied that $\forall f_1, f_2 : \mathcal{S} \to \mathbb{R}$ bounded functions such that $\min_s f_1(s) \leq \min_s f_2(s)$ and $\hat{s} = \arg\min_s f_1(s)$, we have $|\min_s f_1(s) - \min_s f_2(s)| \leq |f_1(\hat{s}) - f_2(\hat{s})|$. Then,

$$\forall x \in \mathbb{X} : |J_1^*(x) - J_2^*(x)| \leq |g_1(x,\hat{\pi}(x)) - g_2(x,\hat{\pi}(x))| + \alpha \sum_{y \in \mathbb{X}} p(y \mid x,\hat{\pi}(x)) \, |J_1^*(y) - J_2^*(y)| \leq$$

$$\leq \|g_1 - g_2\|_\infty + \alpha \sum_{y \in \mathbb{X}} p(y \mid x,\hat{\pi}(x)) \, \|J_1^* - J_2^*\|_\infty =$$

$$= \|g_1 - g_2\|_\infty + \alpha \|J_1^* - J_2^*\|_\infty .$$

It is easy to see that if

$$\forall x \in \mathbb{X} : |J_1^*(x) - J_2^*(x)| \leq \|g_1 - g_2\|_\infty + \alpha \|J_1^* - J_2^*\|_\infty ,$$

then

$$\|J_1^* - J_2^*\|_\infty \leq \|g_1 - g_2\|_\infty + \alpha \|J_1^* - J_2^*\|_\infty ,$$

from which the statement of the theorem immediately follows after rearrangement. ■

Theorem 13 *Assume that two discounted MDPs differ only in the discount factors, denoted by* $\alpha_1, \alpha_2 \in [0,1)$. *Let the corresponding optimal value functions be* J_1^* *and* J_2^*, *then*

$$\|J_1^* - J_2^*\|_\infty \leq \frac{|\alpha_1 - \alpha_2|}{(1-\alpha_1)(1-\alpha_2)} \|g\|_\infty .$$

Proof Let π_i^* denote a greedy and deterministic policy based on value function J_i^*, where $i \in \{1,2\}$. Naturally, policy π_i^* is optimal if the discount rate is α_i (Theorem 6). Then, let us introduce a deterministic Markovian control policy $\hat{\pi}$ defined as

$$\hat{\pi}(x) = \begin{cases} \pi_1^*(x) & \text{if } J_1^*(x) \leq J_2^*(x), \\ \\ \pi_2^*(x) & \text{if } J_2^*(x) < J_1^*(x). \end{cases}$$

For any state x the difference of the two value functions can be estimated as follows,

$$|J_1^*(x) - J_2^*(x)| =$$

$$= \left| \min_{a\in\mathcal{A}(x)} \left[g(x,a) + \alpha_1 \sum_{y\in\mathbb{X}} p(y \mid x,a)\, J_1^*(y) \right] - \min_{a\in\mathcal{A}(x)} \left[g(x,a) + \alpha_2 \sum_{y\in\mathbb{X}} p(y \mid x,a)\, J_2^*(y) \right] \right| \leq$$

$$\leq \left| g(x,\hat{\pi}(x)) + \alpha_1 \sum_{y\in\mathbb{X}} p(y \mid x,\hat{\pi}(x))\, J_1^*(y) - g(x,\hat{\pi}(x)) - \alpha_2 \sum_{y\in\mathbb{X}} p(y \mid x,\hat{\pi}(x))\, J_2^*(y) \right|,$$

where we applied that $\forall\, f_1, f_2 : \mathcal{S} \to \mathbb{R}$ bounded functions such that $\min_s f_1(s) \leq \min_s f_2(s)$ and $\hat{s} = \arg\min_s f_1(s)$, we have $|\min_s f_1(s) - \min_s f_2(s)| \leq |f_1(\hat{s}) - f_2(\hat{s})|$. Then,

$$\forall x \in \mathbb{X} : |J_1^*(x) - J_2^*(x)| \leq \left| \sum_{y\in\mathbb{X}} p(y \mid x,\hat{\pi}(x)) \left(\alpha_1 J_1^*(y) - \alpha_2 J_2^*(y)\right) \right| \leq$$

$$\leq |\alpha_1 - \alpha_2| \frac{1}{1-\alpha_1} \|g\|_\infty + \alpha_2 \|J_1^* - J_2^*\|_\infty,$$

where in the last step we used the following estimation of $|\alpha_1 J_1^*(y) - \alpha_2 J_2^*(y)|$,

$$|\alpha_1 J_1^*(y) - \alpha_2 J_2^*(y)| = |\alpha_1 J_1^*(y) - \alpha_2 J_1^*(y) + \alpha_2 J_1^*(y) - \alpha_2 J_2^*(y)| \leq$$

$$\leq |\alpha_1 - \alpha_2|\, |J_1^*(y)| + \alpha_2\, |J_1^*(y) - J_2^*(y)| \leq |\alpha_1 - \alpha_2| \frac{1}{1-\alpha_1} \|g\|_\infty + \alpha_2 \|J_1^* - J_2^*\|_\infty,$$

where we applied the fact that for any state y we have,

$$|J_1^*(y)| \leq \sum_{t=0}^{\infty} \alpha_1^t \|g\|_\infty = \frac{1}{1-\alpha_1} \|g\|_\infty.$$

Because the estimation of $|J_1^*(x) - J_2^*(x)|$ is valid for all x, we have the following result

$$\|J_1^* - J_2^*\|_\infty \leq |\alpha_1 - \alpha_2| \frac{1}{1-\alpha_1} \|g\|_\infty + \alpha_2 \|J_1 - J_2\|_\infty,$$

from which the statement of the theorem immediately follows after rearrangement. ■

Lemma 14 *Assume that we have two discounted MDPs which differ only in the transition-probability functions or only in the immediate-cost functions or only in the discount factors. Let the corresponding optimal action-value functions be Q_1^* and Q_2^*, respectively. Then, the bounds for $\|J_1^* - J_2^*\|_\infty$ of Theorems 11, 12 and 13 are also bounds for $\|Q_1^* - Q_2^*\|_\infty$.*

Proof We will prove the theorem in three parts, depending on the changing components.
Case 1: Assume that the MDPs differ only in the transition functions, denoted by p_1 and p_2. We will prove the same estimation as in the case of Theorem 11, more precisely, that

$$\|Q_1^* - Q_2^*\|_\infty \leq \frac{\alpha \|g\|_\infty}{(1-\alpha)^2} \|p_1 - p_2\|_1.$$

For all state-action pair (x,a) we can estimate the absolute difference of Q_1^* and Q_2^* as

$$|Q_1^*(x,a) - Q_2^*(x,a)| =$$

$$= \left| g(x,a) + \alpha \sum_{y \in \mathbb{X}} p_1(y|x,a) J_1^*(y) - g(x,a) - \alpha \sum_{y \in \mathbb{X}} p_2(y|x,a) J_2^*(y) \right| \leq$$

$$\leq \left| \alpha \sum_{y \in \mathbb{X}} \left(p_1(y|x,a) J_1^*(y) - p_2(y|x,a) J_2^*(y) \right) \right|,$$

from which the proof continues in the same way as the proof of Theorem 11.
Case 2: Assume that the MDPs differ only in the immediate-cost functions, denoted by g_1 and g_2. We will prove the same estimation as in the case of Theorem 12, more precisely,

$$\|Q_1^* - Q_2^*\|_\infty \leq \frac{1}{1-\alpha} \|g_1 - g_2\|_\infty .$$

For all state-action pair (x,a) we can estimate the absolute difference of Q_1^* and Q_2^* as

$$|Q_1^*(x,a) - Q_2^*(x,a)| =$$

$$= \left| g_1(x,a) + \alpha \sum_{y \in \mathbb{X}} p(y|x,a) J_1^*(y) - g_2(x,a) - \alpha \sum_{y \in \mathbb{X}} p(y|x,a) J_2^*(y) \right| \leq$$

$$\leq \|g_1 - g_2\|_\infty + \left| \alpha \sum_{y \in \mathbb{X}} p(y|x,a) (J_1^*(y) - J_2^*(y)) \right| \leq \|g_1 - g_2\|_\infty + \alpha \|J_1^* - J_2^*\|_\infty .$$

The statement immediately follows after we apply Theorem 12 to estimate $\|J_1^* - J_2^*\|_\infty$.
Case 3: Assume that the MDPs differ only in the discount rates, denoted by α_1 and α_2. We will prove the same estimation as in the case of Theorem 13, more precisely, that

$$\|Q_1^* - Q_2^*\|_\infty \leq \frac{|\alpha_1 - \alpha_2|}{(1-\alpha_1)(1-\alpha_2)} \|g\|_\infty .$$

For all state-action pair (x,a) we can estimate the absolute difference of Q_1^* and Q_2^* as

$$|Q_1^*(x,a) - Q_2^*(x,a)| =$$

$$= \left| g(x,a) + \alpha_1 \sum_{y \in \mathbb{X}} p(y|x,a) J_1^*(y) - g(x,a) - \alpha_2 \sum_{y \in \mathbb{X}} p(y|x,a) J_2^*(y) \right| \leq$$

$$\leq \left| \alpha_1 \sum_{y \in \mathbb{X}} p(y|x,a) J_1^*(y) - \alpha_2 \sum_{y \in \mathbb{X}} p(y|x,a) J_2^*(y) \right| \leq |\alpha_1 - \alpha_2| \frac{1}{1-\alpha_1} \|g\|_\infty + \alpha_2 \|J_1^* - J_2^*\|_\infty ,$$

where in the last step we applied the same estimation as in the proof of Theorem 13. The statement immediately follows after we apply Theorem 13 to estimate $\|J_1^* - J_2^*\|_\infty$. ■

Lemma 18 *Assume that two discounted MDPs, $\mathcal{M}_1$ and $\mathcal{M}_2$, differ only in the discount factors, denoted by α_1 and α_2. Then, there exists an MDP, denoted by $\mathcal{M}_3$, such that it differs only in the immediate-cost function from $\mathcal{M}_1$, thus its discount factor is α_1, and it has the same optimal value function as $\mathcal{M}_2$. The immediate-cost function of $\mathcal{M}_3$ is*

$$\widehat{g}(x,a) = g(x,a) + (\alpha_2 - \alpha_1) \sum_{y \in \mathbb{X}} p(y|x,a) J_2^*(y),$$

where p is the probability-transition function of $\mathcal{M}_1$, $\mathcal{M}_2$ and $\mathcal{M}_3$; g is the immediate-cost function of $\mathcal{M}_1$ and $\mathcal{M}_2$; and $J_2^*(y)$ denotes the optimal cost-to-go function of $\mathcal{M}_2$.

Proof First of all, let us overview some general statements that will be used in the proof.

Recall from Bertsekas and Tsitsiklis (1996) that we can treat the solution (the optimal value function) of the infinite horizon problem as the limit of the finite horizon solutions. More precisely, the Bellman optimality equation for the n-stage (finite horizon) problem is

$$J_k^*(x) = \min_{a\in\mathcal{A}(x)} \Big[g(x,a) + \alpha \sum_{y\in\mathbb{X}} p(y \mid x,a)\, J_{k-1}^*(y) \Big],$$

for all $k \in \{1,\ldots,n\}$ and $x \in \mathbb{X}$. Note that by definition, we have $J_0^*(x) = 0$. Moreover,

$$\forall x \in \mathbb{X} : J^*(x) = J_\infty^*(x) = \lim_{n\to\infty} J_n^*(x).$$

Also recall that the n-stage optimal action value function is defined as

$$Q_k^*(x,a) = g(x,a) + \alpha \sum_{y\in\mathbb{X}} p(y|x,a) J_{k-1}^*(y),$$

for all x, a and $k \in \{1,\ldots,n\}$. We also have $Q_0^*(x,a) = 0$ and $J_n^*(x) = \min_a Q_n^*(x,a)$.

During the proof we will apply the solutions of suitable finite horizon problems, thus, in order to avoid notational confusions, let us denote the optimal state and action value functions of $\mathcal{M}_2$ and $\mathcal{M}_3$ by J^*, Q^* and $\hat{J}^*$, $\widehat{Q}^*$, respectively. The corresponding finite horizon optimal value functions will be denoted by J_n^*, Q_n^* and $\hat{J}_n^*$, $\widehat{Q}_n^*$, respectively, where n is the length of the horizon. We will show that for all state x and action a we have $Q^*(x,a) = \widehat{Q}^*(x,a)$, from which $J^* = \hat{J}^*$ follows. Let us define $\widehat{g}_n$ for all $n > 0$ by

$$\widehat{g}_n(x,a) = g(x,a) + (\alpha_2 - \alpha_1) \sum_{y\in\mathbb{X}} p(y|x,a) J_{n-1}^*(y).$$

We will apply induction on n. For the case of $n = 0$ we trivially have $Q_0^* = \widehat{Q}_0^*$, since both of them are constant zero functions. Now, assume that $Q_k^* = \widehat{Q}_k^*$ for $k \le n$, then

$$\widehat{Q}_{n+1}^*(x,a) = \widehat{g}_{n+1}(x,a) + \alpha_1 \sum_{y\in\mathbb{X}} p(y|x,a) \hat{J}_n^*(y) =$$

$$= g(x,a) + (\alpha_2 - \alpha_1) \sum_{y\in\mathbb{X}} p(y|x,a) J_n^*(y) + \alpha_1 \sum_{y\in\mathbb{X}} p(y|x,a) \hat{J}_n^*(y) =$$

$$= g(x,a) + \alpha_2 \sum_{y\in\mathbb{X}} p(y|x,a) J_n^*(y) + \alpha_1 \sum_{y\in\mathbb{X}} p(y|x,a) \big(\hat{J}_n^*(y) - J_n^*(y) \big) =$$

$$= g(x,a) + \alpha_2 \sum_{y\in\mathbb{X}} p(y|x,a) J_n^*(y) + \alpha_1 \sum_{y\in\mathbb{X}} p(y|x,a) \left(\min_{b\in\mathcal{A}(y)} \widehat{Q}_n^*(y,b) - \min_{b\in\mathcal{A}(y)} Q_n^*(y,b) \right) =$$

$$= g(x,a) + \alpha_2 \sum_{y\in\mathbb{X}} p(y|x,a) J_n^*(y) = Q_{n+1}^*(x,a).$$

We have proved that for all n: $Q_n^* = \widehat{Q}_n^*$. Consequently, $Q^*(x,a) = \lim_{n\to\infty} Q_n^*(x,a) = \lim_{n\to\infty} \widehat{Q}_n^*(x,a)$ $= \widehat{Q}^*(x,a)$ and, thus, $J^*(x) = \min_a Q^*(x,a) = \min_a \widehat{Q}^*(x,a) = \hat{J}^*(x)$. Finally, note that for the case

of the infinite horizon problem $\widehat{g}(x,a) = \lim_{n\to\infty} \widehat{g}_n(x,a)$. ■

Theorem 20 *Suppose that Assumptions 1-3 hold and let V_t be the sequence generated by*

$$V_{t+1}(x) = (1-\gamma_t(x))V_t(x) + \gamma_t(x)((K_tV_t)(x) + W_t(x)),$$

then, for any $V^*, V_0 \in \mathcal{V}$, the sequence V_t κ-approximates function V^* with

$$\kappa = \frac{4\rho}{1-\beta_0} \quad \textit{where} \quad \rho = \limsup_{t\to\infty} \|V_t^* - V^*\|_\infty.$$

The applied three main assumptions are as follows
Assumption 1 *There exits a constant $C > 0$ such that for all state x and time t, we have*

$$\mathbb{E}[W_t(x) \,|\, \mathcal{F}_t] = 0 \quad \textit{and} \quad \mathbb{E}\left[W_t^2(x) \,|\, \mathcal{F}_t\right] < C < \infty.$$

Assumption 2 *For all x and t, $0 \le \gamma_t(x) \le 1$, and we have with probability one*

$$\sum_{t=0}^{\infty} \gamma_t(x) = \infty \quad \textit{and} \quad \sum_{t=0}^{\infty} \gamma_t^2(x) < \infty.$$

Assumption 3 *For all t, operator $K_t : \mathcal{V} \to \mathcal{V}$ is a supremum norm contraction mapping with Lipschitz constant $\beta_t < 1$ and with fixed point V_t^*. Formally, for all $V_1, V_2 \in \mathcal{V}$,*

$$\|K_tV_1 - K_tV_2\|_\infty \le \beta_t \|V_1 - V_2\|_\infty.$$

Let us introduce a common Lipschitz constant $\beta_0 = \limsup_{t\to\infty} \beta_t$, and assume that $\beta_0 < 1$.

Proof During the proof, our main aim will be to apply Theorem 9, thus, we have to show that the assumptions of the theorem hold. Let us define operator H_t for all $V_a, V_b \in \mathcal{V}$ by

$$H_t(V_a, V_b)(x) = (1-\gamma_t(x))V_a(x) + \gamma_t(x)((K_tV_b)(x) + W_t(x)).$$

Applying this definition, first, we will show that $V'_{t+1} = H_t(V'_t, V^*)$ κ-approximates V^* for all V'_0. Because $\beta_t < 1$ for all t and $\limsup_{t\to\infty} \beta_t = \beta_0 < 1$, it follows that $\sup_t \beta_t = \widetilde{\beta} < 1$ and each K_t is $\widetilde{\beta}$ contraction. We know that $\limsup_{t\to\infty} \|V^* - V_t^*\|_\infty = \rho$, therefore, for all $\delta > 0$, there is an index t_0 such that for all $t \ge t_0$, we have that $\|V^* - V_t^*\|_\infty \le \rho + \delta$. Using these observations, we can estimate $\|K_tV^*\|_\infty$ for all $t > t_0$, as follows

$$\|K_tV^*\|_\infty = \|K_tV^* - V^* + V^*\|_\infty \le \|K_tV^* - V^*\|_\infty + \|V^*\|_\infty \le$$

$$\le \|K_tV^* - V_t^* + V_t^* - V^*\|_\infty + \|V^*\|_\infty \le \|K_tV^* - V_t^*\|_\infty + \|V_t^* - V^*\|_\infty + \|V^*\|_\infty \le$$

$$\le \|K_tV^* - K_tV_t^*\|_\infty + \rho + \delta + \|V^*\|_\infty \le \widetilde{\beta}\|V^* - V_t^*\|_\infty + \rho + \delta + \|V^*\|_\infty \le$$

$$\le (1+\widetilde{\beta})\rho + (1+\widetilde{\beta})\delta + \|V^*\|_\infty \le (1+\widetilde{\beta})\rho + 2\delta + \|V^*\|_\infty.$$

If we apply $\delta = (1-\widetilde{\beta})\rho/2$, then for sufficiently large t $(t \ge t_0)$ we have that

$$\|K_tV^*\|_\infty \le 2\rho + \|V^*\|_\infty.$$

Now, we can upper estimate $V'_{t+1} = H_t(V'_t, V^*)$, for all $x \in \mathcal{X}$, $V'_0 \in \mathcal{V}$ and $t \geq t_0$ by

$$V'_{t+1}(x) = H_t(V'_t, V^*)(x) = (1-\gamma_t(x))V'_t(x) + \gamma_t(x)((K_t V^*)(x) + W_t(x)) \leq$$

$$\leq (1-\gamma_t(x))V'_t(x) + \gamma_t(x)(\|K_t V^*\|_\infty + W_t(x)) \leq$$

$$\leq (1-\gamma_t(x))V'_t(x) + \gamma_t(x)(\|V^*\|_\infty + 2\rho + W_t(x)).$$

Let us define a new sequence for all $x \in \mathcal{X}$ by

$$\widetilde{V}_{t+1}(x) = \begin{cases} (1-\gamma_t(x))\widetilde{V}_t(x) + \gamma_t(x)(\|V^*\|_\infty + 2\rho + W_t(x)) & \text{if } t \geq t_0, \\ V'_t(x) & \text{if } t < t_0. \end{cases}$$

It is easy to see (for example, by induction from t_0) that for all time t and state x we have that $V'_t(x) \leq \widetilde{V}_t(x)$ with probability one, more precisely, for almost all $\omega \in \Omega$, where $\omega = \langle \omega_1, \omega_2, \dots \rangle$ drives the noise parameter $W_t(x) = w_t(x, \omega_t)$ in both V'_t and $\widetilde{V}_t$. Note that Ω is the sample space of the underlying probability measure space $\langle \Omega, \mathcal{F}, \mathbb{P} \rangle$.

Applying the "Conditional Averaging Lemma" of Szepesvári and Littman (1999), which is a variant of the Robbins-Monro Theorem and requires Assumptions 1 and 2, we get that $\widetilde{V}_t(x)$ converges with probability one to $2\rho + \|V^*\|_\infty$ for all $\widetilde{V}_0 \in \mathcal{V}$ and $x \in \mathcal{X}$. Therefore, because $V'_t(x) \leq \widetilde{V}_t(x)$ for all x and t with probability one, we have that the sequence $V'_t(x)$ κ-approximates $V^*(x)$ with $\kappa = 2\rho$ for all function $V'_0 \in \mathcal{V}$ and state $x \in \mathcal{X}$.

Now, let us turn to Conditions 1-4 of Theorem 9. For all x and t, we define functions $F_t(x)$ and $G_t(x)$ as $F_t(x) = \beta_t \gamma_t(x)$ and $G_t(x) = (1-\gamma_t(x))$. By Assumption 2, functions $F_t(x), G_t(x) \in [0,1]$ for all x and t. Condition 1 trivially follows from the definitions of G_t and H_t. For the proof of Condition 2, we need Assumption 3, namely that each operator K_t is a contraction with respect to β_t. Condition 3 is a consequence of Assumption 2 and the definition of G_t. Finally, we have Condition 4 for any $\varepsilon > 0$ and sufficiently large t by defining $\xi = \beta_0 + \varepsilon$. Applying Theorem 9 with $\kappa = 2\rho$, we get that V_t κ'-approximates V^* with $\kappa' = 4\rho/(1-\beta_0-\varepsilon)$. In the end, letting ε go to zero proves our statement. ■

Abstract

Harmonic analysis and diffusion on discrete data has been shown to lead to state-of-the-art algorithms for machine learning tasks, especially in the context of semi-supervised and transductive learning. The success of these algorithms rests on the assumption that the function(s) to be studied (learned, interpolated, etc.) are smooth with respect to the geometry of the data. In this paper we present a method for modifying the given geometry so the function(s) to be studied are smoother with respect to the modified geometry, and thus more amenable to treatment using harmonic analysis methods. Among the many possible applications, we consider the problems of image denoising and transductive classification. In both settings, our approach improves on standard diffusion based methods.

Keywords: diffusion processes, diffusion geometry, spectral graph theory, image denoising, transductive learning, semi-supervised learning

1. Introduction

Recently developed techniques in the analysis of data sets and machine learning use the geometry of the data set in order to study functions on it. In particular the idea of analyzing the data set and functions on it intrinsically has lead to novel algorithms with state-of-the-art performance in various problems in machine learning (Szummer and Jaakkola, 2001; Zhu et al., 2003; Zhou and Schlkopf, 2005; Belkin and Niyogi, 2003a; Mahadevan and Maggioni, 2007; Maggioni and Mhaskar, 2007). They are based on the construction of a diffusion, or an averaging operator K on the data set, dependent on its local, fine scale geometry. K, its powers, and the special bases associated to it, such as its eigenfunctions (Belkin and Niyogi, 2003a; Coifman et al., 2005a; Coifman and Lafon, 2006a) or its diffusion wavelets (Coifman and Maggioni, 2006) can be used to study the geometry of and analyze functions on the data set. Among other things, "diffusion analysis" allows us to introduce a notion of smoothness in discrete settings that preserves the relationships between smoothness,

sparsity in a "Fourier" basis, and evolution of heat that are well-known in Euclidean spaces (Zhou and Schlkopf, 2005).

One of the main contributions of this work is the observation that the geometry of the space is not the only important factor to be considered, but that the geometry and the properties of the function f to be studied (denoised/learned) should also affect the smoothing operation of the diffusion. We will therefore modify the geometry of a data set with features from f, and build K on the modified f-adapted data set. The reason for doing this is that perhaps f is not smooth with respect to the geometry of the space, but has structure that is well encoded in the features. Since the harmonic analysis tools we use are robust to complicated geometries, but are most useful on smooth functions, it is reasonable to let the geometry of the data set borrow some of the complexity of the function, and study a smoother function on a more irregular data set. In other words, we attempt to find the geometry so that the functions to be studied are as smooth as possible with respect to that geometry. On the one hand, the result is nonlinear in the sense that it depends on the input function f, in contrast with methods which consider the geometry of the data alone, independently of f. On the other hand, on the modified data set, the smoothing operator K will be linear, and very efficiently computable. One could generalize the constructions proposed to various types of processes (e.g., nonlinear diffusions).

The paper is organized as follows: in Section 2, we review the basic ideas of harmonic analysis on weighted graphs. In Section 3 we introduce the function-adapted diffusion approach, which aims to modify the geometry of a data set so that a function or class of functions which was non-smooth in the original geometry is smooth in the modified geometry, and thus amenable to the harmonic analysis in the new geometry. In Section 4 we demonstrate this approach in the context of the image denoising problem. In addition to giving easy to visualize examples of how the method works, we achieve state of the art results. In Section 5, we demonstrate the approach in the context of transductive learning. While here it is more difficult to interpret our method visually, we test it on a standard database, where it outperforms comparable "geometry only" methods on the majority of the data sets, and in many cases achieves state of the art results. We conclude by considering the under-performance of the method on some data sets, observing that in those examples (most of which are in fact the only artificial ones!), the geometry of the data suffices for learning the function of interests; and our method is superfluous.

2. Diffusion on Graphs Associated with Data-sets

An intrinsic analysis of a data set, modeled as a graph or a manifold, can be developed by considering a natural random walk K on it (Chung, 1997; Szummer and Jaakkola, 2001; Ng et al., 2001; Belkin and Niyogi, 2001; Zha et al., 2001; Lafon, 2004; Coifman et al., 2005a,b). The random walk allows to construct diffusion operators on the data set, as well as associated basis functions. For an initial condition δ_x, $K^t\delta_x(y)$ represents the probability of being at y at time t, conditioned on starting at x.

2.1 Setup and Notation

We consider the following general situation: the space is a finite weighted graph $G = (V,E,W)$, consisting of a set V (vertices), a subset E (edges) of $V \times V$, and a nonnegative function $W : E \to \mathbb{R}^+$ (weights). Without loss of generality we assume that there is an edge from x to $y \in V$, and write $x \sim y$, if and only if $W(x,y) > 0$. Notice that in this work W will usually be symmetric; that is

the edges will be undirected. The techniques we propose however do not require this property, and therefore can be used on data sets in which graph models with directed edges are natural.

We interpret the weight $W(x,y)$ as a measure of similarity between the vertices x and y. A natural filter acting on functions on V can be defined by normalization of the weight matrix as follows: let

$$d(x) = \sum_{y \in V} W(x,y)\,,$$

and let[1] the filter be

$$K(x,y) = d^{-1}(x)W(x,y)\,, \tag{1}$$

so that $\sum_{y\in V} K(x,y) = 1$, and so that multiplication Kf of a vector from the left is a local averaging operation, with locality measured by the similarities W. Multiplication by K can also be interpreted as a generalization of Parzen window type estimators to functions on graphs/manifolds. There are other ways of defining averaging operators. For example one could consider the heat kernel $e^{-t\mathcal{L}}$ where $\mathcal{L}$ is defined in (3) below, see also Chung (1997), or a bi-Markov matrix similar to W (Sinkhorn, 1964; Sinkhorn and Knopp, 1967; Soules, 1991; Linial et al., 1998; Shashua et al., 2005; Zass and Shashua, 2005).

In general K is not column-stochastic,[2] but the operation fK of multiplication on the right by a (row) vector can be thought of as a diffusion of the vector f. This filter can be iterated several times by considering the power K^t.

2.2 Graphs Associated with Data Sets

¿From a data set X we construct a graph G: the vertices of G are the data points in X, and weighted edges are constructed that connect nearby data points, with a weight that measures the similarity between data points. The first step is therefore defining these *local similarities*. This is a step which is data- and application-dependent. It is important to stress the attribute *local*. Similarities between far away data points are not required, and deemed unreliable, since they would not take into account the geometric structure of the data set. Local similarities are assumed to be more reliable, and non-local similarities will be inferred from local similarities through diffusion processes on the graph.

2.2.1 LOCAL SIMILARITIES

Local similarities are collected in a matrix W, whose rows and columns are indexed by X, and whose entry $W(x,y)$ is the similarity between x and y. In the examples we consider here, W will usually be symmetric, that is the edges will be undirected, but these assumptions are not necessary.

If the data set lies in $\mathbb{R}^d$, or in any other metric space with metric ρ, then the most standard construction is to choose a number ("local time") $\sigma > 0$ and let

$$W_\sigma(x,y) = h\left(\frac{\rho(x,y)^2}{\sigma}\right),$$

1. Note that $d(x) = 0$ if and only if x is not connected to any other vertex, in which case we trivially define $d^{-1}(x) = 0$, or simply remove x from the graph.
2. In particular cases K is a scalar multiple of a column-stochastic matrix, for example when D is a multiple of identity, which happens for example if G is regular and all the edges have the same weight.

for some function h with, say, exponential decay at infinity. A common choice is $h(a) = \exp(-a)$. The idea is that we expect that very close data points (with respect to ρ) will be similar, but do not want to assume that far away data points are necessarily different.

Let D be the diagonal matrix with entries given by d as in (2.1). Suppose the data set is, or lies on, a manifold in Euclidean space. In Lafon (2004), Belkin and Niyogi (2005), Hein et al. (2005), von Luxburg et al. (2004) and Singer (2006), it is proved that in this case, the choice of h in the construction of the weight matrix is in some asymptotic sense irrelevant. For a rather generic symmetric function h, say with exponential decay at infinity, $(I - D_\sigma^{-\frac{1}{2}} W_\sigma D_\sigma^{-\frac{1}{2}})/\sigma$, approaches the Laplacian on the manifold, at least in a weak sense, as the number of points goes to infinity and σ goes to zero. Thus this choice of weights is naturally related to the heat equation on the manifold. On the other hand, for many data sets, which either are far from asymptopia or simply do not lie on a manifold, the choice of weights can make a large difference and is not always easy. Even if we use Gaussian weights, the choice of the "local time parameter" σ can be nontrivial.

For each x, one usually limits the maximum number of points y such that $W(x,y) \neq 0$ (or non-negligible). Two common modifications of the construction above are to use either $\rho_\varepsilon(x,y)$ or $\rho_k(x,y)$ instead of ρ, where

$$\rho_\varepsilon(x,y) = \begin{cases} d(x,y) & \text{if } \rho(x,y) \leq \varepsilon; \\ \infty & \text{if } \rho(x,y) > \varepsilon \end{cases},$$

where usually ε is such that $h(\varepsilon^2/\sigma) << 1$, and

$$\rho_k(x,y) = \begin{cases} \rho(x,y) & \text{if } y \in n_k(x); \\ \infty & \text{otherwise.} \end{cases}$$

and $n_k(x)$ is the set of k nearest neighbors of x. This is for two reasons: one, often only very small distances give information about the data points, and two, it is usually only possible to work with very sparse matrices.[3] This truncation causes W to be not symmetric; if symmetry is desired, W may be averaged (arithmetically or geometrically) with its transpose.

A location-dependent approach for selecting the similarity measure is suggested in Zelnik-Manor and Perona (2004). A number m is fixed, and the distances at each point are scaled so the m-th nearest neighbor has distance 1; that is, we let $\rho_x(y,y') = \rho(y,y')/\rho(x,x_m)$, where x_m is the m-th nearest neighbor to x. Now ρ_x depends on x, so in order to make the weight matrix symmetric, they suggest to use the geometric mean of ρ_x and ρ_y in the argument of the exponential, that is, let

$$W_\sigma(x,y) = h\left(\frac{\rho_x(x,y)\rho_y(x,y)}{\sigma}\right), \tag{2}$$

with h, as above, decaying at infinity (typically, $h(a) = \exp(-a)$), or truncated at the k-th nearest neighbor. This is called the self-tuning weight matrix. There is still a timescale in the weights, but a global σ in the self-tuning weights corresponds to some location dependent choice of σ in the standard exponential weights.

3. However, methods of Fast Multipole of Fast Gauss type (Greengard and Rokhlin, 1988) may make it possible to work with dense matrices implicitly, with complexity proportional to the number of points. See Raykar et al. (2005) for a recent reference with applications to machine learning.

2.2.2 THE AVERAGING OPERATOR AND ITS POWERS

Multiplication by the normalized matrix K as in (1) can be iterated to generate a Markov process $\{K^t\}_{t\geq 0}$, and can be used to measure the strength of all the paths between two data points, or the likelihood of getting from one data point to the other if we constrain ourselves to only stepping between very similar data points. For example one defines the diffusion or spectral distance (Bérard et al., 1994; Coifman et al., 2005a; Coifman and Lafon, 2006a) by

$$\mathcal{D}^{(t)}(x,y) = ||K^t(x,\cdot) - K^t(y,\cdot)||_2 = \sqrt{\sum_{z\in X} |K^t(x,z) - K^t(y,z)|^2}\,.$$

The term diffusion distance was introduced in Lafon (2004), Coifman et al. (2005a) and Coifman and Lafon (2006a) and is suggested by the formula above, which expresses $\mathcal{D}^{(t)}$ as some similarity between the probability distributions $K^t(x,\cdot)$ and $K^t(y,\cdot)$, which are obtained by diffusion from x and y according to the diffusion process K. The term spectral distance was introduced in Bérard et al. (1994, see also references therein). It has recently inspired several algorithms in clustering, classification and learning (Belkin and Niyogi, 2003a, 2004; Lafon, 2004; Coifman et al., 2005a; Coifman and Lafon, 2006a; Mahadevan and Maggioni, 2005; Lafon and Lee, to appear, 2006; Maggioni and Mhaskar, 2007).

2.3 Harmonic Analysis

The eigenfunctions $\{\psi_i\}$ of K, satisfying

$$K\psi_i = \lambda_i \psi_i\,,$$

are are related,via multiplication by $D^{-\frac{1}{2}}$, to the eigenfunctions ϕ_i of the graph Laplacian (Chung, 1997), since

$$\mathcal{L} = D^{-\frac{1}{2}} W D^{-\frac{1}{2}} - I = D^{\frac{1}{2}} K D^{-\frac{1}{2}} - I\,. \tag{3}$$

They lead to a natural generalization of the Fourier analysis: any function $g \in \mathbb{L}^2(X)$ can be written as $g = \sum_{i\in I} \langle g, \phi_i\rangle \phi_i$, since $\{\phi_i\}$ is an orthonormal basis. The larger is i, the more oscillating the function ϕ_i is, with respect to the geometry given by W, and λ_i measures the frequency of ϕ_i. These eigenfunctions can be used for dimensionality reduction tasks (Lafon, 2004; Belkin and Niyogi, 2003a; Coifman and Lafon, 2006a; Coifman et al., 2005a; Jones et al., 2007a,b).

For a function g on G, define its gradient (Chung, 1997; Zhou and Schlkopf, 2005) as the function on the edges of G defined by

$$\nabla g(x,y) = W(x,y)\left(\frac{g(y)}{\sqrt{d(y)}} - \frac{g(x)}{\sqrt{d(x)}}\right) \tag{4}$$

if there is an edge e connecting x to y and 0 otherwise; then

$$||\nabla g(x)||^2 = \sum_{x\sim y} |\nabla g(x,y)|^2.$$

The smoothness of g can be measured by the Sobolev norm

$$||g||^2_{\mathcal{H}^1} = \sum_x |g(x)|^2 + \sum_x ||\nabla g(x)||^2\,. \tag{5}$$

The first term in this norm measures the size of the function g, and the second term measures the size of the gradient. The smaller $||g||_{\mathcal{H}^1}$, the smoother is g. Just as in the Euclidean case,

$$||g||^2_{\mathcal{H}^1} = ||g|^2_{\mathbb{L}^2(X,d)} - \langle g, \mathcal{L}g \rangle ;$$

thus projecting a function onto the first few terms of its expansion in the eigenfunctions of $\mathcal{L}$ is a smoothing operation.[4]

We see that the relationships between smoothness and frequency forming the core ideas of Euclidean harmonic analysis are remarkably resilient, persisting in very general geometries. These ideas have been applied to a wide range of tasks in the design of computer networks, in parallel computation, clustering (Ng et al., 2001; Belkin and Niyogi, 2001; Zelnik-Manor and Perona, 2004; Kannan et al., 2004; Coifman and Maggioni, 2007), manifold learning (Bérard et al., 1994; Belkin and Niyogi, 2001; Lafon, 2004; Coifman et al., 2005a; Coifman and Lafon, 2006a), image segmentation (Shi and Malik, 2000), classification (Coifman and Maggioni, 2007), regression and function approximation (Belkin and Niyogi, 2004; Mahadevan and Maggioni, 2005; Mahadevan et al., 2006; Mahadevan and Maggioni, 2007; Coifman and Maggioni, 2007).

2.4 Regularization by Diffusion

It is often useful to find the smoothest function $\tilde{f}$ on a data set X with geometry given by W, so that for a given f, $\tilde{f}$ is not too far from f; this task is encountered in problems of denoising and function extension. In the denoising problem, we are given a function $f + \eta$ from $X \to \mathbb{R}$, and η is Gaussian white noise of a given variance, or if one is ambitious, some other possibly stochastic contamination. We must find f. In the function extension or interpolation problem, a relatively large data set is given, but the values of f are known at only relatively few "labeled" points, and the task is to find f on the "unlabeled" points. Both tasks, without any a priori information on f, are impossible; the problems are underdetermined. On the other hand, it is often reasonable to assume f should be smooth, and so we are led to the problem of finding a smooth $\tilde{f}$ close to f.

In Euclidean space, a classical method of mollification is to run the heat equation for a short time with initial condition specified by f. It turns out that the heat equation makes perfect sense on a weighted graph: if f is a function on V, set $f_0 = f$, and $f_{k+1} = Kf$. If $g_k(x) = d^{\frac{1}{2}}(x) f_k(x)$,

$$g_{k+1} - g_k = \mathcal{L} g_k ,$$

so multiplication by K is a step in the evolution of the (density normalized) heat equation. Furthermore, a quick calculation shows this is the gradient descent for the smoothness energy functional $\sum ||\nabla g||^2$. We can thus do "harmonic" interpolation on X by iterating K (Zhu et al., 2003).

We can design more general mollifiers using an expansion on the eigenfunctions $\{\psi_i\}$ of K. For the rest of this section, suppose all inner products are taken against the measure d, that is, $\langle a, b \rangle = \sum a(x)b(x)d(x)$, and so ψ are orthonormal. Then $f = \sum \langle f, \psi_i \rangle \psi_i$ and one can define $\tilde{f}$, a smoothed version of f, by

$$\tilde{f} = \sum_i \alpha_i \langle f, \psi_i \rangle \psi_i$$

4. However it is well known that if f does not have uniform smoothness everywhere, the approximation by eigenfunctions is poor not only in regions of lesser smoothness, but the poor approximation spills to regions of smoothness as well. This lack of localization can be avoided with the multiscale constructions in Coifman and Maggioni (2006) and Maggioni and Mhaskar (2007).

for some sequence $\{\alpha_i\}$ which tends to 0 as $i \to +\infty$; in the interpolation problem, we can attempt to estimate the inner products $\langle f, \psi_i \rangle$, perhaps by least squares. Typical examples for α_i are:

(i) $\alpha_i = 1$ if $i < I$, and 0 otherwise (pure low-pass filter); I usually depends on a priori information on η, for example on the variance of η. This is a band-limited projection (with band I), see for example Belkin (2003).

(ii) $\alpha_i = \lambda_i^t$ for some $t > 0$, this corresponds to setting $\tilde{f} = K^t(f)$, that is, kernel smoothing on the data set, with a data-dependent kernel (Smola and Kondor, 2003; Zhou and Schlkopf, 2005; Chapelle et al., 2006).

(iii) $\alpha_i = P(\lambda_i)$, for some polynomial (or rational function) P, generalizing (ii). See, for example, Maggioni and Mhaskar (2007)

As mentioned, one can interpret $K^t f$ as evolving a heat equation on the graph with an initial condition specified by f. If we would like to balance smoothing by K with fidelity to the original f, we can choose $\beta > 0$ and set $f_0 = f$ and $f_{t+1} = (K f_t + \beta f)/(1+\beta)$; the original function is treated as a heat source. This corresponds at equilibrium to

(iv) $\alpha_i = \beta/(1+\beta-\lambda_i)$.

One can also consider families of nonlinear mollifiers, of the form

$$\tilde{f} = \sum_i m(\langle f, \psi_i \rangle)\psi_i \,,$$

where for example m is a (soft-)thresholding function (Donoho and Johnstone, 1994). In fact, m may be made even dependent on i. While these techniques are classical and well-understood in Euclidean space (mostly in view of applications to signal processing), it is only recently that research in their application to the analysis of functions on data sets has begun (in view of applications to learning tasks, see in particular Maggioni and Mhaskar 2007).

All of these techniques clearly have a regularization effect. This can be easily measured in terms of the Sobolev norm defined in (5): the methods above correspond to removing or damping the components of f (or $f+\eta$) in the subspace spanned by high-frequency ψ_i, which are the ones with larger Sobolev norm.

3. Function-adapted Kernels

The methods above are based on the idea that the function f to be recovered should be smooth with respect to W, but it can happen that an interesting function on data is not smooth with respect to the given geometry on that data. In this case we cannot directly bring to bear the full power of the methods described above. On the other hand, we have seen that these methods are well defined on any weighted graph. We thus propose to modify the geometry of W so that the function(s) to be recovered are as smooth as possible in the modified geometry. Even when f is not smooth, the geometry of W and f can interact in a structured way. We will attempt to incorporate the geometry of the function f (or a family of functions F) in the construction of the weights W; the hope is that we can convert structure to smoothness, and apply the methods of harmonic analysis to a smoother function on a rougher data set. In other words, we want our regularizer to take averages between

points where f has similar structure, in addition to being near to each other in terms of the given geometry of the data.

The simplest version of this idea is to only choose nonzero weights between points on the same level set of f. Then $||\nabla f||$ (with respect to W) is zero everywhere, and the function to be recovered is as smooth as possible. Of course knowing the level sets of f is far too much to ask for in practice. For example, in the function extension problem, if f has only a few values (e.g., for a classification task), knowing the level sets of f would be equivalent to solving the problem.

If we had some estimate $\tilde{f}$ for f, we could set

$$W^f(x,y) = \exp\left(-\frac{||x-y||^2}{\sigma_1} - \frac{|\tilde{f}(x)-\tilde{f}(y)|^2}{\sigma_2}\right), \tag{6}$$

so that when $\sigma_2 << \sigma_1$, the associated averaging kernel K will average locally, but much more along the (estimated) level sets of f than across them, because points on different level sets now have very weak or no affinity. This is related to ideas in Yaroslavsky (1985); Smith and Brady (1995) and Coifman et al. (2005a).

The estimate $\tilde{f}$ of f is just a simple example of a feature map. More generally, we set

$$W^f(x,y) = h_1\left(-\frac{\rho_1(x,y)^2}{\sigma_1}\right) h_2\left(-\frac{\rho_2(\mathcal{F}(f)(x),\mathcal{F}(f)(y))^2}{\sigma_2}\right), \tag{7}$$

where $\mathcal{F}(f)(x)$ is a set of features associated with f, evaluated at the data point x, ρ_1 is a metric on the data set, ρ_2 is a metric on the set of features, h_1 and h_2 are (usually exponentially) decaying functions, and σ_1 and σ_2 are "local time" parameters in data and feature space respectively. Such a similarity is usually further restricted as described at the end of Section 2.2.1. The idea here is to be less ambitious than (6), and posit affinity between points where we strongly believe f to have the same structure, and not necessarily between every point on an (estimated) level set. The averaging matrix K^f associated with W^f can then be used for regularizing, denoising and learning tasks, as described above. We call such a kernel a function-adapted kernel.

The way the function f affects the construction of K^f will be application- and data- specific, as we shall see in the applications to image denoising and graph transductive learning. For example, in the application to image denoising, $\mathcal{F}(f)(x)$ may be a vector of filter responses applied to the image f at location x. In the application to transductive classification, we are given C functions χ_i, defined by $\chi_i(x) = 1$ if x is labeled as a point in class i, and 0 otherwise (either the point is not labeled, or it is not in class i). We set $f = (\chi_i)_{i=1}^N$. Then $\mathcal{F}(f)(x)$ can be obtained by evaluating $K^t(\chi_i)$ at x, where K is a diffusion operator which only depends on the data set, and not on the χ_i's. In all applications, our idea is simply to to try to choose similarities, with the limited information about the function(s) to be recovered that we are given, so that the function(s) are as regular as possible with respect to the chosen similarities.

4. Application I: Denoising of Images

We apply function-adapted kernels to the task of denoising images. Not only this will be helpful to gain intuition about the ideas in Section 3 in a setting where our methods are easily visualized, but it also leads to state-of-art results.

Gray-scale images are often modeled as real-valued functions, or distributions, on Q, a fine discretization of the square $[0,1]^2$, and they are often analyzed, denoised, compressed, inpainted, deblurred as such, see for example Tschumperle (2002), Perona and Malik (1990), Rudin et al. (1992),

Chan and Shen (2005), Perona and Malik (1990), Tomasi and Manduchi (1998), Elad (2002), Boult et al. (1993), Chin and Yeh (1983), Davis and Rosenfeld (1978), Graham (1961), Huang et al. (1979), Lee (1980), Yin et al. (1996) and references therein. It is well known that images are not smooth as functions from Q to $\mathbb{R}$, and in fact the interesting and most important features are often exactly the non-smooth parts of f. Thus Fourier analysis and the heat equation on Q are not ideally suited for images; much of the work referenced above aims to find partial differential equations whose evolution smooths images without blurring edges and textures.

With the approach described in Section 3, unlike with many PDE-based image processing methods, the machinery of smoothing is divorced from the task of feature extraction. We build a graph $G(I)$ whose vertices are the pixels of the image and whose weights are adapted to the image structure, and use the diffusion on the graph with a fidelity term, as described in Section 2.4 to smooth the image, *considered as a function on the graph*. If we are able to encode image structure in the geometry of the graph in such a way that the image is actually smooth as a function on its graph, then the harmonic analysis on the graph will be well-suited for denoising that image. Of course, we have shifted part of the problem to feature extraction, but we will see that very simple and intuitive techniques produce state of the art results.

4.1 Image-adapted Graphs and Diffusion Kernels

To build the image-adapted graph we first associate a feature vector to each location x in the image I, defined on a square Q. A simple choice of $d+2$ dimensional feature vectors is obtained by setting two of the coordinates of the feature vector to be scaled versions of the coordinates of the corresponding pixel in the image αx, where $\alpha \geq 0$ is a scalar, and $x \in Q$. The remaining d features are the responses to convolution with d different filters $g_1, \cdots, g_d$, evaluated at location x. More formally, we pick a d-vector $g = (g_1, \cdots, g_d)$ of filters (i.e., real valued functions on Q), fix $\alpha \geq 0$, and map Q into $\mathbb{R}^{d+2}$ by a *feature map*

$$\begin{aligned} \mathcal{F}_{g,\alpha}(I) : Q &\to \mathbb{R}^{d+2} \\ x &\mapsto (\alpha x, f * g_1(x), \cdots, f * g_d(x)) \end{aligned}$$

This is an extremely flexible construction, and there are many interesting choices for the filters $\{g_i\}$. One could take a few wavelets or curvelets at different scales, or edge filters, or patches of texture, or some measure of local statistics. Also note there are many other choices of feature maps that are not obtained by convolution, see Section 4.1.2 for examples.

The graph $G(I)$ will have vertices given by $\mathcal{F}_{g,\alpha}(x)$, $x \in Q$. To obtain the weighted edges, set

$$\rho(x,y) = \rho_{g,\alpha}(x,y) = ||\mathcal{F}_{g,\alpha}(f)(x) - \mathcal{F}_{g,\alpha}(f)(y)||,$$

where $||\cdot||$ is a norm (e.g., Euclidean) in $\mathbb{R}^{d+2}$. The parameter α specifies the amount of weight to give to the original 2-d space coordinates of the pixels, and may be 0. Alternatively, instead of using a weight α, one can choose sets $S = S(x) \subset Q$ so that

$$\rho(x,y) = d_{g,S}(x,y) = \begin{cases} \rho_{g,0}(x,y) & \text{if } y \in S(x); \\ \infty & \text{otherwise.} \end{cases} . \tag{8}$$

In the discrete case, if we choose $S(x)$ to be the n nearest neighbors of x in the 2 space coordinates: we will write $\rho_{g,n}$, and if the filters are understood, just ρ_n.

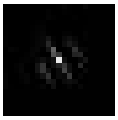

Figure 1: Above: image of Lena, with two locations highlighted. Left: row of the diffusion kernel corresponding to the upper-left highlighted area in the above image. Right: row of the diffusion kernel corresponding to the bottom-left highlighted area in the above image. The diffusion kernel averages according to different patterns in different locations. The averaging pattern on the right is also "non-local", in the sense that the averaging occurs along well-separated stripes, corresponding to the hair in the original picture.

For a fixed choice of metric ρ as above, and a "local time" parameter σ, we construct the similarity matrix W_σ as described in Section 2.2.1, and the associated diffusion kernel K as in (1).

In Figure 3 we explore the local geometry in patch space by projecting the set of patches around a given patch onto the principal components of the set of patches itself. Geometric structures of the set of patches, dependent on local geometry of the image (e.g., texture vs. edge) are apparent. The key feature of these figures is that the gray level intensity value is *smooth* as a function from the set of patches to $\mathbb{R}$, even when the intensity is not smooth in the original spatial coordinates.

We now describe some interesting choices for the feature maps $\mathcal{F}(I)$.

4.1.1 PATCH GRAPH

Let g_N be the set of N^2 filters $\{g_{i,j}\}_{i,j=1,\ldots,N}$, where $g_{i,j}$ is a $N \times N$ matrix with 1 in the i,j entry and 0 elsewhere. Then $\mathcal{F}_{g_N,0}$ is the set of patches of the image embedded in N^2 dimensions. The diffusion one gets from this choice of filters is the NL-means filter of Buades et al. (2005a). "NL"

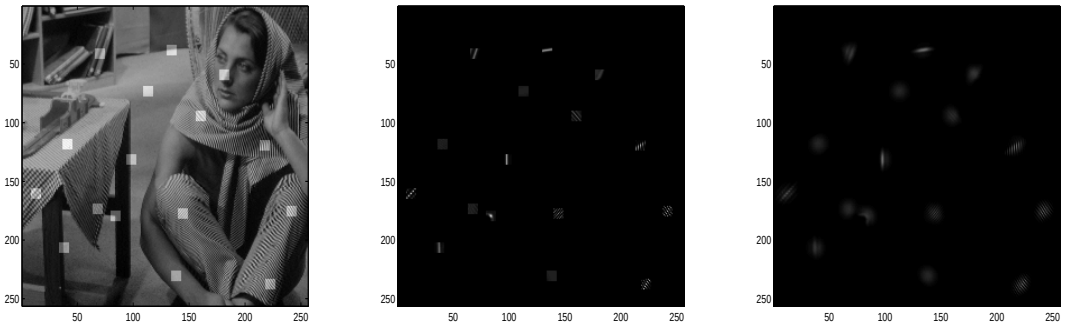

Figure 2: Left to right: image of Barbara, with several locations p_i highlighted; $K^t(p_i,\cdot)$, for $t = 1,2$.

stands for Non-Local; in the paper, they proposed setting $\alpha = 0$. In a later paper they add some locality constraints; see Buades et al. (2005b) and Mahmoudi (2005). We wish to emphasize that smoothing with the NL-means filter is not, in any sort of reasonable limit, a 2-*d* PDE; rather, it is the heat equation on the set of patches of the image!

Note the embedding into 5×5 patches is the same embedding (up to a rotation) as into 5×5 DCT coordinates, and so the weight matrices constructed from these embeddings are the same. On the other hand, if we attenuate small filter responses, the weight matrices for the two filter families will be different.

4.1.2 BOOTSTRAPPING A DENOISER; OR DENOISED IMAGES GRAPH

Different denoising methods often pick up different parts of the image structure, and create different characteristic artifacts. Suppose we have obtained denoised images $f_1,...,f_d$, from a noisy image f. To make use of the various sensitivities, and rid ourselves of the artifacts, we could embed pixels $x \in Q$ into $\mathbb{R}^{d+2}$ by $x \mapsto (\alpha x, f_1(x),...,f_d(x))$. In other words we interpret $(f_i(x))_{i=1,...,d}$ as a feature vector at x. This method is an alternative to "cycle spinning"(Coifman and Donoho, 1995), that is, simply averaging the different denoisings.

In practice, we have found that a better choice of feature vector is $f_{\sigma(1)}(x),...,f_{\sigma(d)}(x)$, where σ is a random permutation of $\{1,...,d\}$ depending on x. The idea is to mix up the artifacts from the various denoisings. Note that this would not affect standard averaging, since $\sum f_i(x) = \sum f_{\sigma(i)}$.

4.2 Image Graph Denoising

Once we have the graph W and normalized diffusion K, we use K to denoise the image. The obvious bijection from pixels to vertices in the image graph induces a correspondence between functions on pixels (such as the original image) and functions on the vertices of the graph. In particular the original image can be viewed as a function I on $G(I)$. The functions K^tI are smoothed versions of I with respect to the geometry of $G(I)$. If the graph was simply the standard grid on Q, then K would be nothing other than a discretization of the standard two-dimensional heat kernel, and K^tI would be the classical smoothing of I induced by the Euclidean two-dimensional heat kernel, associated with the classical Gaussian scale space (we refer the reader to Witkin, 1983; Koenderink,

1984; Lindeberg, 1994, and references therein). In our context K^t is associated with a scale space induced by $G(I)$, which is thus a nonlinear scale space (in the sense that it depends on the original

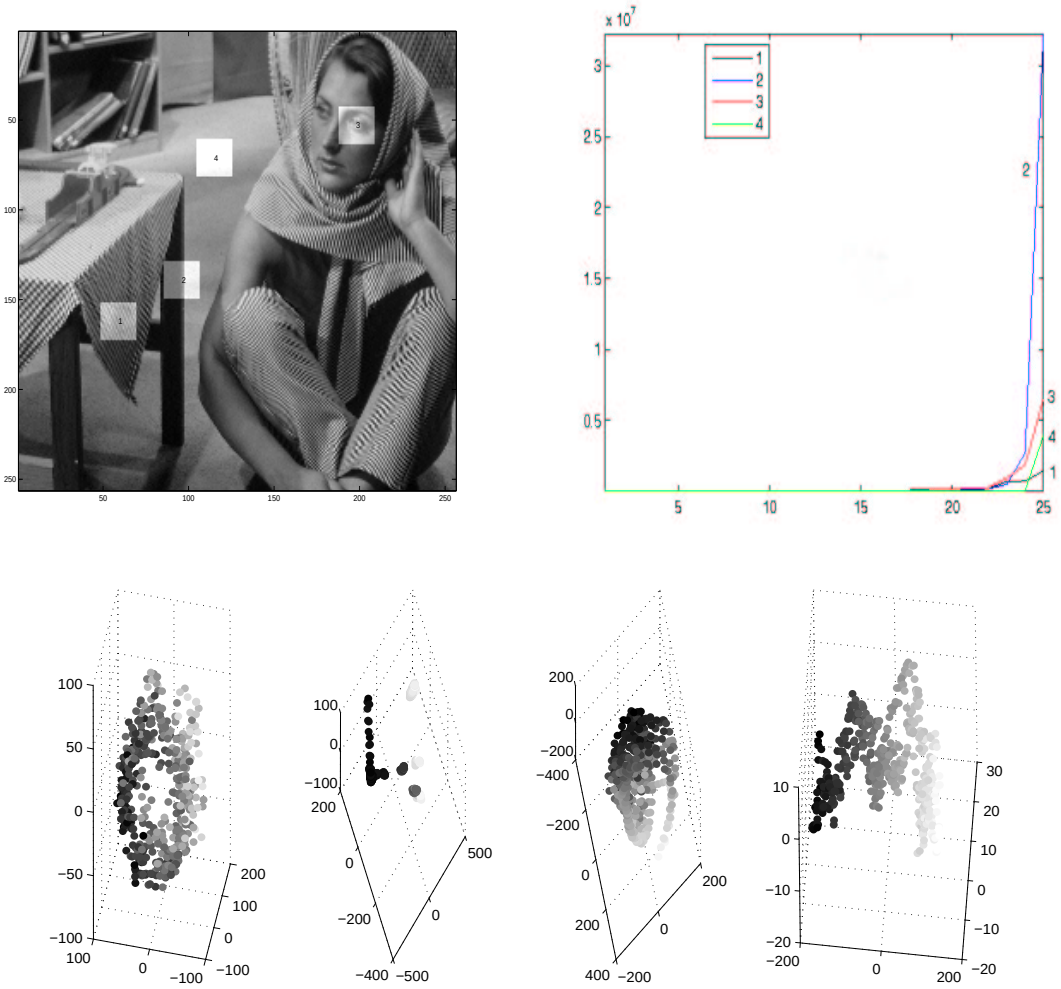

Figure 3: Top left: image of Barbara, with 4 square 10×10 pixel regions highlighted. The 5×5 patches in each region are considered as 25 dimensional vectors, and top right we plot the singular values of their covariance matrix. At the bottom, we project the 25-dimensional points in each region on their top 3 principal components, and the color is the value of the image at each point. In region 1, note how the (approximate) periodicity of the texture in region 1 is reflected in the tubular shape of the projection; in region 2, the portions of the image on different sides of the edge are disconnected in the feature space, and note the higher dimensionality, as measured by the singular values; for region 3, note the higher dimensionality (slower decay of the singular values) compared to regions 1 and 4; for region 4 note the very small dimensionality. Most importantly, note that in each region, the gray level pixel value is smooth as a function of the patches.

image I). In fact $G(I)$, as described above, is often a point cloud in high-dimensional space, where closeness in those high-dimensional space represents similarity of collections of pixels, and/or of their features, in the original two-dimensional domain of I.

We can balance smoothing by K with fidelity to the original noisy function by setting $f_{t+1} = (Kf_t + \beta f)/(1+\beta)$ where $\beta > 0$ is a parameter to be chosen, and large β corresponds to less smoothing and more fidelity to the noisy image. This is a standard technique in PDE based image processing, see Chan and Shen (2005) and references therein. If we consider iteration of K as evolving a heat equation, the fidelity term sets the noisy function as a heat source, with strength determined by β. Note that even though when we smooth in this way, the steady state is no longer the constant function, we still do not usually wish to smooth to equilibrium. We refer the reader to Figure 4 for a summary of the algorithm proposed.

$\tilde{I} \leftarrow$ `DenoiseImage`(I,t)

// Input:
// I : an image
// t : amount of denoising

// Output:
// $\tilde{I}$: a denoised version of I.

1. Construct a graph G associated with I, in any of the ways discussed in Section 4.
2. Compute the associated I-adapted diffusion operator K^I.
3. set $\tilde{I} \leftarrow (K^I)^t I$.

Figure 4: Pseudo-code for denoising an image

4.3 Examples

Figure 5 displays examples of denoising with a diffusion on an image graph. On the top left of the figure we have the noisy image f_0; the noise is $N(0,.0244)$. On the top right of Figure 5, we denoise the image using a 7×7 NL-means type patch embedding as described in Section 4.1.1. We set

$$W(k,j) = e^{-\rho_{81}^{\sim}(k,j)^2/.3}$$

where $\rho_{81}^{\sim}$ is the distance in the embedding, restricted to 81 point balls in the 2-d metric; that is we take $S(k)$ in Equation (8) to be the 81 nearest pixels to pixel k in the 2-d metric. We then normalize $K = D^{-1}W$ and denoise the image by applying K three times with a fidelity term of .07; that is, $f_{t+1} = (Kf_t + .07f_0)/(1.07)$, and the image displayed is f_3. The parameters were chosen by hand.

In the bottom row of Figure 5: on the bottom left, we sum 9 curvelet denoisings. Each curvelet denoisings is a reconstruction of the noisy image f_0 shifted either 1, 2, or 4 pixels in the vertical and/or horizontal directions, using only coefficients with magnitudes greater than 3σ. To demonstrate bootstrapping, or cycle spinning by diffusion, we embed each pixel in $\mathbb{R}^9$ using the 9 curvelet denoisings as coordinates. We set

$$W(k,j) = e^{-\rho_{81}^{\sim}(k,j)^2/.03}$$

Figure 5: 1) Lena with Gaussian noise added. 2) Denoising using a 7×7 patch graph. 3) Denoising using hard thresholding of curvelet coefficients. The image is a simple average over 9 denoisings with different grid shifts. 4) Denoising with a diffusion built from the 9 curvelet denoisings.

where $\tilde{\rho_{81}}$ is the distance in the embedding, and again we take $S(k)$ in Equation (8) to be the 81 nearest pixels to pixel k in the 2-d metric. We then normalize $K = D^{-1}W$ and denoise the image by applying K ten times with a fidelity term of .1; that is $f_{t+1} = (Kf_t + .1f_0)/(1.1)$, and f_{10} is displayed. The results are on the bottom right of Figure 5. We are able to greatly reduce the artifacts from a simple average of the curvelet denoisings.

5. Application II: Graph Transductive Learning

We apply function adapted approach to the transductive learning problem, and give experimental evidence demonstrating that using function adapted weights can improve diffusion based classifiers.

In a transductive learning problem one is given a few "labeled" examples $\tilde{X} \times \tilde{F} = \{(x_1, y_1), \ldots, (x_p, y_p)\}$ and a large number of "unlabeled" examples $X \setminus \tilde{X} = \{x_{p+1}, \ldots, x_n\}$. The goal is to estimate the conditional distributions $F(y|x)$ associated with each available example x (labeled or unlabeled).

For example $\tilde{F}$ may correspond to labels for the points $\tilde{X}$, or the result of a measurement at the points in $\tilde{X}$. The goal is to extend $\tilde{F}$ to a function F defined on the whole X, that is consistent with unseen labels/measurements at points in $X \setminus \tilde{X}$.

This framework is of interest in applications where it is easy to collect samples, that is, X is large, however it is expensive to assign a label or make a measurement at X, so only a few labels/measurements are available, namely at the points in $\tilde{X}$. The points in $X \setminus \tilde{X}$, albeit unlabeled, can be used to infer properties of the structure of the space (or underlying process/probability distribution) that is potentially useful in order to extend $\tilde{F}$ to F. Data sets with internal structures or geometry are in fact ubiquitous.

If F is smooth with respect to the data, an intrinsic analysis on the data set, such as the one possible by the use of diffusion processes and the associated Fourier and multi-scale analyses, fits very well in the transductive learning framework. In several papers a diffusion process constructed on X has been used for finding F directly (Zhou and Schlkopf, 2005; Zhu et al., 2003; Kondor and Lafferty, 2002) and indirectly, by using adapted basis functions on X constructed from the diffusion, such as the eigenfunctions of the Laplacian (Coifman and Lafon, 2006a,b; Lafon, 2004; Coifman et al., 2005a,b; Belkin and Niyogi, 2003b; Maggioni and Mhaskar, 2007), or diffusion wavelets (Coifman and Maggioni, 2006; Mahadevan and Maggioni, 2007; Maggioni and Mahadevan, 2006; Mahadevan and Maggioni, 2005; Maggioni and Mahadevan, 2005).

We will try to modify the geometry of the unlabeled data so that F is as smooth as possible with respect to the modified geometry. We will use the function adapted approach to try to learn the correct modification.

5.1 Diffusion for Classification

We consider here the case of classification, that is, F takes only a small number of values (compared to the cardinality of X), say $\{1, \ldots, k\}$. Let C_i, $i \in \{1, \ldots k\}$, be the classes, let C_i^{lab} be the labeled data points in the ith class, that is, $C_i = \{x \in \tilde{X} : \tilde{F} = i\}$, and let χ_i^{lab} be the characteristic function of those C_i, that is, $\chi_i^{lab}(x) = 1$ if $x \in C_i$, and $\chi_i^{lab}(x) = 0$ otherwise.

A simple classification algorithm can be obtained as follows (Szummer and Jaakkola, 2001):

(i) Build a geometric diffusion K on the graph defined by the data points X, as described in Section 2.2.1.

(ii) Use a power of K to smooth the functions χ_i^{lab}, exactly as in the denoising algorithm described above, obtaining functions $\overline{\chi_i^{lab}}$:

$$\overline{\chi_i^{lab}} = K^t \chi_i^{lab} .$$

The parameter t can be chosen by cross-validation.

(iii) Assign each point x to the class

$$\mathrm{argmax}_i \overline{\chi_i^{lab}}(x) .$$

This algorithm takes into account the influence of the labeled points on the unlabeled point to be classified, where the measure of influence is based on the weighted connectivity of the whole data set. If we average with a power of the kernel we have constructed, we count the number and strength of all the paths of length t to the various classes from a given data point. As a consequence, this method is more resistant to noise than, for example, a simple nearest neighbors (or also a geodesic nearest neighbors) method, as changing the location or class of a small number of data points does not change the structure of the whole network, while it can change the class label of a few nearest neighbors.

For each i, the "initial condition" for the heat flow given by χ_i^{lab} considers all the unlabeled points to be the same as labeled points not in C_i. Since we are solving many one-vs-all problems, this is reasonable; but one also may want to set the initial condition $\chi_i^{lab}(x) = 1$ for $x \in C_i^{lab}$, $\chi_i^{lab}(x) = -1$ for $x \in C_j^{lab}$, $j \neq i$, and $\chi_i^{lab}(x) = 0$ for all other x. It can be very useful to change the initial condition to a boundary condition by resetting the values of the labeled points after each application of the kernel. For large powers, this is equivalent to the harmonic classifier of Zhu et al. (2003), where the χ_i^{lab} is extended to the "harmonic" function with given boundary values on the labeled set. Just as in the image denoising examples, it is often the case that one does not want to run such a harmonic classifier to equilibrium, and we may want to find the correct number of iterations of smoothing by K and updating the boundary values by cross validation.

We can also use the eigenfunctions of K (which are also those of the Laplacian $\mathcal{L}$) to extend the classes. Belkin (2003) suggests using least squares fitting in the embedding defined by the first few eigenfunctions $\phi_1, \ldots, \phi_N$ of K. Since the values at the unlabeled points are unknown, we regress only to the labeled points; so for each χ_i^{lab}, we need to solve

$$\operatorname{argmin}_{\{a_l\}} \sum_{x \text{ labeled}} \left| \sum_{l=1}^{N} a_{il} \phi_l(x) - \chi_i^{lab}(x) \right|^2,$$

and extend the χ_i^{lab} to

$$\overline{\chi_i^{lab}} = \sum_{l=1}^{N} a_{il} \phi_i.$$

The parameter N controls the bias-variance tradeoff: smaller N implies larger bias of the model (larger smoothness)[5] and decreases the variance, while larger N has the opposite effect. Large N thus corresponds to small t in the iteration of K.

5.2 Function Adapted Diffusion for Classification

If the structure of the classes is very simple with respect to the geometry of the data set, then smoothness with respect to this geometry is precisely what is necessary to generalize from the labeled data. However, it is possible that the classes have additional structure on top of the underlying data set, which will not be preserved by smoothing geometrically. In particular at the boundaries between classes we would like to filter in such a way that the "edges" of the class function are preserved. We will modify the diffusion so it flows faster along class boundaries and slower across them, by using function-adapted kernels as in (7). Of course, we do not know the class boundaries: the func-

5. On the other hand, extending with small numbers of eigenfunctions creates "ripples"; that is, the Gibbs phenomenon. Techniques for avoiding the Gibbs phenomenon are discussed in Maggioni and Mhaskar (2007).

$F \leftarrow$ `ClassifyWithAdaptedDiffusion`$(X, \tilde{X}, \{\chi_i\}_{i=1,\ldots,N}, t_1, \beta, t_2)$

// Input:
// $X := \{x_i\}$: a data set
// $\tilde{X}$: a subset of X, representing the labeled set
// $\{\chi_i\}_{i=1,\ldots,N}$: set of characteristic functions of the classes, defined on $\tilde{X}$
// β : weight of the tuning parameter

// Output:
// C : function on X, such that $C(x)$ is the class to which $x \in X$ is estimated to belong.

1. Construct a weighted graph G associated with X, in any of the ways discussed.
2. Compute the associated diffusion operator K as in (1).
3. Compute guesses at the soft class functions $\overline{\chi_i}$ using any of the methods in Section 5.1, or any other method, and for multi-class problems, set
$$c_i(x) = \frac{\overline{\chi_i}(x)}{\sum_i |\overline{\chi_i(x)}|}.$$
4. Using the c_i as features, or $\overline{\chi_i}$ for two class problems, construct a new graph with kernel K' from the similarities as in Equation (7), with $\sigma_2 = \beta\sigma_1$.
5. Finally, find $C(x)$ using any of the methods in Section 5.1 and the kernel K'

Figure 6: Pseudo-code for learning of a function based on diffusion on graphs

tions $\{\chi_i\}$ are initially given on a (typically small) subset $\tilde{X}$ of X, and hence a similarity cannot be immediately defined in a way similar to (7).

We use a bootstrapping technique. We first use one of the algorithms above, which only uses similarities between data points ("geometry"), to generate the functions $\overline{\chi_i}$. We then use these functions to design a function-adapted kernel, by setting

$$\mathcal{F}(\{\chi_i\})(x) := (c_i(x))_{i=1,\ldots,k},$$

and then define a kernel as in (7). Here the c_i's are normalized confidence functions defined by

$$c_i(x) = \frac{\overline{\chi_i}(x)}{\sum_i |\overline{\chi_i(x)}|}.$$

In this way, if several classes claim a data point with some confidence, the diffusion will tend to average more among other points which have the same ownership situation when determining the value of a function at that data point. The normalization, besides having a clear probabilistic interpretation when the $\overline{\chi_i}$ are positive, also achieves the effect of not slowing the diffusion when there is only one possible class that a point could be in, for example, if a data point is surrounded by points of a single class, but is relatively far from all of them.

We summarize the algorithm in Figure 6. In the examples below we simply let ρ_2 be the metric of $\mathbb{R}^k$, and also let $h_2(a) = h_1(a) = e^{-a}$. The ratio β between σ_2 and σ_1, however, is important,

since it measures the trade-off between the importance given to the geometry of X and that of the set of estimates $\{(\overline{\chi_i}(x))_{i=1,\ldots,k}\}_{x\in X} \subseteq \mathbb{R}^k$.

We wish to emphasize the similarity between this technique and those described in Section 4 and especially Section 4.1.2. We allow the geometry of the data set to absorb some of the complexity of the classes, and use diffusion analysis techniques on the modified data set. The parallel with image denoising should not be unexpected: the goal of a function-adapted kernel is to strengthen averaging along level lines, and this is as desirable in image denoising as in transductive learning.

We remark that even if the c_i's are good estimates of the classes, they are not necessarily good choices for extra coordinates: for example, consider a two class problem, and a function c which has the correct sign on each class, but oscillates wildly. On the other hand, functions which are poor estimates of the classes could be excellent extra coordinates as long as they oscillate slowly parallel to the class boundaries. Our experience suggests, consistently with these considerations, that the safest choices for extra coordinates are very smooth estimates of the classes. In particular, of the three methods of class extension mentioned above, the eigenfunction method is often not a good choice for extra coordinates because of oscillation phenomena; see the examples in Section 5.4.

5.3 Relationship Between Our Methods and Previous Work

In Coifman et al. (2005a) the idea of using the estimated classes to warp the diffusion is introduced. They suggest, for each class C_n, building the modified weight matrix $W_n(i,j) = W(i,j)\overline{\chi_n^{lab}}(i)\overline{\chi_n^{lab}}(j)$, normalizing each W_n, and using the W_n to diffuse the classes. Our approach refines and generalizes theirs, by collecting all the class information into a modification of the metric used to build the kernel, rather than modifying the kernel directly. The tradeoff between geometry of the data and geometry of the (estimated/diffused) labels is made explicit and controllable.

In Zhu et al. (2003) it is proposed to adjust the graph weights to reflect prior knowledge. However, their approach is different than the one presented here. Suppose we have a two class problem. They add to each node of the graph a "dongle" node with transition probability β, which they leave as a parameter to be determined. They then run the harmonic classifier (Zhu et al., 2003) with the confidence function (ranging from 1 to -1) from a prior classifier as the boundary conditions on all the dongle nodes. Thus their method sets a tension between the *values* of the prior classifier and the harmonic classifier. Our method does not suggest values for the soft classes based on the prior classifier; rather, it uses this information to suggest modifications to the graph weights between unlabeled points.

5.4 Examples

We present experiments that demonstrate the use of function-adapted weights for transductive classification. We find that on many standard benchmark data sets, classification rate is improved using function-adapted weights instead of "geometry only" weights in diffusion based classifiers.

We use the data sets of Chapelle et al. (2006) and the first 10,000 images in the MNIST data set. At the time this article was written, the respective data sets are available at `http://www.kyb.tuebingen.mpg.de/ssl-book/benchmarks.html` and `http://yann.lecun.com/exdb/mnist/`, with an extensive review of the performance of existing algorithms available at `http://www.kyb.tuebingen.mpg.de/ssl-book/benchmarks.pdf`, and at `http://yann.lecun.com/exdb/mnist/`.

All the data sets were reduced to 50 dimensions by principal components analysis. In addition, we smooth the MNIST images by convolving 2 times with an averaging filter (a 3×3 all ones matrix). The convolutions are necessary if we want the MNIST data set to resemble a Riemannian manifold; this is because if one takes an image with sharp edges and considers a smooth family of smooth diffeomorphisms of $[0,1] \times [0,1]$, the set of images obtained under the family of diffeomorphisms is not necessarily a (differentiable) manifold (see Donoho and Grimes 2002, and also Wakin et al. 2005). However, if the image does not have edges, then the family of morphed images is a manifold.[6]

We do the following:

x1. Choose 100 points as labeled. Each of the benchmark data sets of Chapelle et al., has 12 splits into 100 labeled and 1400 unlabeled points; we use these splits. In the MNIST data set we label points 1001 through 1100 for the first split, 1101 to 1200 for the second split, etc, and used 12 splits in total. Denote the labeled points by L, let C_i the ith class, and let χ_i^{lab} be 1 on the labeled points in the ith class, -1 on the labeled points of the other classes, and 0 elsewhere.

x2. Construct a Gaussian kernel W with k nearest neighbors, $\sigma = 1$, and normalized so the jth neighbor determines unit distance in the self tuning normalization (Equation 2), where $\{k, j\}$ is one of $\{9,4\}$, $\{13,9\}$, $\{15,9\}$, or $\{21,15\}$.

x3. Classify unlabeled points x by $\sup_i \overline{\chi_i^{lab}}(x)$, where $\overline{\chi_i^{lab}}(x)$ are constructed using the harmonic classifier with the number of iterations chosen by leave-20-out cross validation from 1 to 250. More explicitly: set $g_i^0 = \chi_i^{lab}$. Set $g_i^N(x) = (Kg_i^{N-1})(x)$ if $x \notin L$, $g_i^N(x) = 1$ if $x \in C_i \bigcap L$, and $g_i^N(x) = 0$ if $x \in L \backslash C_i$, and K is W normalized to be averaging. Finally, set $\overline{\chi_i^{lab}} = g_i^N(x)$, where N is chosen by leave-10-out cross validation between 1 and 250 (C_i and L are of course reduced for the cross validation).

x4. Classify unlabeled points x by $\sup_i \overline{\chi_i^{lab}}(x)$, where the $\overline{\chi_i^{lab}}(x)$ are constructed using least squares regression in the (graph Laplacian normalized) eigenfunction embedding, with the number of eigenfunctions cross validated; that is, for each χ_i^{lab}, we solve

$$\text{argmin}_{\{a_l\}} \sum_{x \text{ labeled}} \left| \sum_{l=1}^{N} a_{il} \phi_l(x) - \chi_i(x) \right|^2,$$

and extend the χ_i^{lab} to

$$\overline{\chi_i^{lab}} = \sum_{l=1}^{N} a_{il} \phi_i.$$

The ϕ are the eigenfunctions of $\mathcal{L}$, which is W normalized as a graph Laplacian, and N is chosen by leave-10-out cross validation.

6. For the most simple example, consider a set of $n \times n$ images where each image has a single pixel set to 1, and every other pixel set to 0. As we translate the on pixel across the grid, the difference between each image and its neighbor is in a new direction in R^{n^2}, and thus there is no reasonable tangent. The same thing is true for translates of a more complicated binary image, and translates of any image with an edge. One could complain that this is an artifact of the discrete grid, but it is easy to convince yourself that the set of translates of a characteristic function in $L^2(\mathbb{R})$ does not have a tangent anywhere- the tangent direction of the curve defined by the translates of a function is exactly the derivative of the function.

x5. Classify unlabeled points x by $\sup_i \overline{\chi_i^{lab}}(x)$, where $\overline{\chi_i^{lab}}(x)$ are constructed by smoothing χ_i^{lab} with K. More explicitly: set $g_i^0 = \chi_i^{lab}$. Set $g_i^N = W g_i^{N-1}$, where K is W normalized to be averaging; and finally, let $\overline{\chi_i^{lab}} = g_i^N(x)$, where N is chosen by leave-10-out cross validation between 1 and 250 (C_i and L are of course reduced for the cross validation).

We also classify the unlabeled points using a function-adapted kernel. Using the $\overline{\chi_i^{lab}}$ from the harmonic classifier at steady state ($N = 250$), we do the following:

x6. If the problem has more than two classes, set

$$c_i(x) = \frac{g_i^{250}(x)}{\sum_i |g_i^{250}(x)|},$$

else, set $c_i(x) = g_i^{250}(x)$

x7. Using the c_i as extra coordinates, build a new weights $\tilde{W}$. The extra coordinates are normalized to have average norm equal to the average norm of the original spatial coordinates; and then multiplied by the factor β, where β is determined by cross validation from $\{1,2,4,8\}$. The modified weights are constructed using the nearest neighbors from the original weight matrix, exactly as in the image processing examples.

x8. Use the function dependent $\tilde{K}$ to estimate the classes as in (x3).

x9. Use the function dependent $\tilde{L}$ to estimate the classes as in (x4).

x10. Use the function dependent $\tilde{K}$ to estimate the classes as in (x5).

We also repeat these experiments using the smoothed classes as an initial guess, and using the eigenfunction extended classes as initial guess. The results are reported in the Figures 7, 8, and 9. Excepting the data sets g241c, gc241n, and BCI, there is an almost universal improvement in classification rate using function-adapted weights instead of "geometry only" weights over all choices of parameters and all methods of initial soft class estimation.

In addition to showing that function adapted weights often improve classification using diffusion based methods, the results we obtain are very competitive and in many cases better than all other methods listed in the extensive comparative results presented in Chapelle et al. (2006), also available at `http://www.kyb.tuebingen.mpg.de/ssl-book/benchmarks.pdf`. In Figure 10 we attempt a comparison. For every data set, we report the performance of the best classifier (with model selection, and cross-validated performance) among all the ones considered in Chapelle et al. (2006). We also report the performance of our best classifier, among the ones we considered, corresponding to different choices of the two parameters for the self-tuning nearest-neighbor graph and initial smoothing (but with other parameters cross-validated). This comparison is unfair in many respects, for us in that we give the best choice over the two graph parameters (out of the four pairs we tested) and choice of initial class estimation (three tested), and against us considering the large number of algorithms listed in Chapelle et al. (2006). Nevertheless it demonstrates that the proposed algorithms on 3 out of 7 data sets can outperform all the algorithms considered in Chapelle et al. (2006).

Figure 7: Various classification error percentages. Each pair of columns corresponds to a smoothing method; the right column in each pair uses function adapted weights, with c_i determined by the harmonic classifier. KS stands for kernel smoothing as in (x5), FAKS for function adapted kernel smoothing as in (x10), HC for harmonic classifier as in (x3), FAHC for function adapted harmonic classifier as in (x8), EF for eigenfunctions as in (x4), and FAEF for function adapted eigenfunctions as in (x9). The Gaussian kernel had k neighbors, and the jth neighbor determined unit distance in the self-tuning construction, where counterclockwise, from the top left, $\{k, j\}$ is $\{9,4\}$, $\{13,9\}$, $\{15,9\}$, and $\{21,15\}$. Notice that excepting the data sets g241c, gc241n, and BCI, there is an almost universal improvement in classification error with function-adapted weights.

6. Some Comments on the Benchmarks where Our Methods Do Not Work Well

If the class structure is trivial with respect to the geometry of the data as presented, then anisotropy will be unhelpful. This is the case for two of the benchmark data sets, g241c and g241n. In g241c, which has been constructed by generating two Gaussian clouds, and labeling each point by which cloud it came from, the best possible strategy (knowing the generative model) is to assign a point

Figure 10: Classification errors, in percent. In the rightmost column we chose, for each data set, the best performing method with model selection, among all those discussed in Chapelle et al. (2006). In each of the remaining columns we report the performance of each of the smoothing methods described above, but with the best settings of parameters for constructing the nearest neighbor graph and type of initial class guesses, among those considered in other tables (but all other smoothing parameters, including those for the initial guesses, cross validated). The aim of this rather unfair comparison is to highlight the potential of the methods on the different data sets.

to the cluster center it is nearest to. The boundary between the classes is exactly at the bottleneck between the two clusters; in other words, the geometry/metric of the data as initially presented leads to the optimal classifier, and thus modifying the geometry by the cluster guesses can only do harm. This is clearly visible if one looks at the eigenfunctions of the data set: the sign of the second eigenfunction at a given point is an excellent guess as to which cluster that point belongs to, and in fact in our experiments, often two was the optimal number of eigenfunctions. See figure 11. g241n

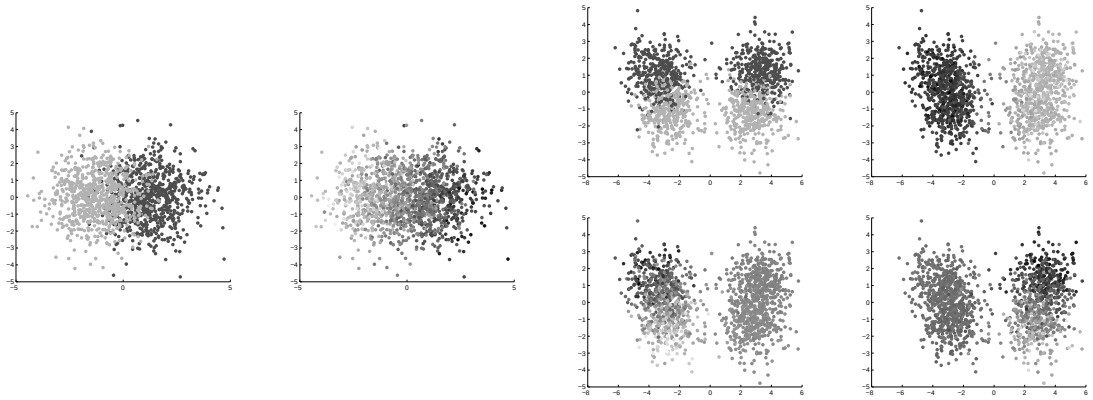

Figure 11: Panel on the left. On the left the lighter and darker points are the two classes for g241c. On the right is the second eigenfunction. Panel on the right. On the top left the lighter and darker points are the two classes for g241n. On the top right is the second eigenfunction, then on the bottom the third and fourth eigenfunctions.

is very similar; it is generated by four Gaussians. However, two pairs of centers are close together, and the pairs are relatively farther apart. The classes split across the two fine scale clusters in each coarse scale cluster as in g241c. In this data set, the ideal strategy is to decide which coarse cluster a point is in, and then the problem is exactly as above. In particular, the optimal strategy is given by the geometry of the data as presented. This is again reflected in the simplicity of the classes with respect to eigenfunctions 2, 3, and 4; see figure 11.

While in some sense these situations are very reasonable, it is our experience that in many natural problems the geometry of the data is not so simple with respect to the classes, and function-adapted kernels help build better classifiers.

Our method also was not useful for the BCI example. Here the problem was simply that the initial guess at the classes was too poor.

7. Computational Considerations

Let N be the cardinality of the data set X, which is endowed with some metric ρ. The first and most computationally intensive part of the algorithms proposed is the construction of the graph and corresponding weights. The approach we use is direct, in the sense that we explicitly store the similarity matrix W. For each point $x \in X$, we need to find the points in an ε-ball, or the k nearest neighbors of x. This problem can be solved trivially, for any metric ρ, in $O(dN^2)$ computations. It is of course highly desirable to reduce this cost, and this requires more efficient ways of computing near (or

nearest) neighbors. This problem is known to be hard even in Euclidean space $\mathbb{R}^d$, as d increases. The literature on the subject is vast, rather than a long list of papers, we point the interested reader to Datar et al. (2004) and references therein. The very short summary is that for approximate versions of the k-nearest neighbor problem, there exist algorithms which are subquadratic in N, and in fact pretty close to linear. The neighbor search is in fact the most expensive part of the algorithm: once for each point x we know its neighbors, we compute the similarities W (this is $O(k)$ for the k neighbors of each point), and create the $N \times N$ sparse matrix W (which contains kN non-zero entries). The computation of K from W is also trivial, requiring $O(N)$ with a very small constant. Apply K^t to a function f on X is very fast as well (for $t << N$, as is the case in the algorithm we propose), because of the sparsity of K, and takes $O(tkN)$ computations.

This should be compared with the $O(N^2)$ or $O(N^3)$ algorithms needed for other kernel methods, involving the computations of many eigenfunctions of the kernel, or of the Green's function $(I - K)^{-1}$.

Note that in most of the image denoising applications we have presented, because of the 2-d locality constraints we put on the neighbor searches, the number of operation is linear in the number N of pixels, with a rather small constant. In higher dimensions, for all of our examples, we use the nearest neighbor searcher provided in the TSTool package, available at `http://www.physik3.gwdg.de/tstool/`. The entire processing of an image as in the examples 256×256 takes about 7 seconds on a laptop with a 2.2Ghz dual core Intel processor (the code is not parallelized though, so it runs on one core only), and 2Gb of RAM (the memory used during processing is approximately 200Mb).

8. Future Work

We mention several directions for further study. The first one is to use a transductive learning approach to tackle image processing problems like denoising and inpainting. One has at one's disposal an endless supply of clean images to use as the "unlabeled data", and it seems that there is much to be gained by using the structure of this data.

The second one is to more closely mimic the function regularization in image processing in the context of transductive learning. In this paper, our diffusions regularize in big steps; also our method is linear (on a modified space). Even though there is no differential structure on our data sets, it seems that by using small time increments and using some sort of constrained nearest neighbor search so that we do not have to rebuild the whole graph after each matrix iteration, we can use truly nonlinear diffusions to regularize our class functions.

Another research direction is towards understanding how to construct and use efficiently basis functions which are associated to function-adapted diffusion kernels. The use of the low-frequency eigenfunctions of the operator, and the associated Fourier analysis of functions on the set has been considered in several works, as cited above, while the construction and use of multiscale basis functions, which correspond to a generalized wavelet analysis on data sets (Coifman and Maggioni, 2006; Szlam et al., 2005; Maggioni et al., 2005), has been used so far for approximation problems in machine learning (Maggioni and Mahadevan, 2006; Mahadevan and Maggioni, 2007) but has potential in many other applications. One can consider the approach that uses diffusion kernels directly, as in this paper, as a sort of "PDE approach" (even if in fact the discreteness and roughness of the sets considered usually brings us quite afar from PDEs on continua), while one can investigate "dual" approaches based on representations and bases functions.

9. Conclusions

We have introduced a general approach for associating graphs and diffusion processes to data sets and functions on such data sets. This framework is very flexible, and we have shown two particular applications, denoising of images and transductive learning, which traditionally are considered very different and have been tackled with very different techniques. We show that in fact they are very similar problems and results at least as good as the state-of-the-art can be obtained within the single framework of function-adapted diffusion kernels.

Acknowledgments

The authors would like to thank Francis Woolfe and Triet Le for helpful suggestions on how to improve the manuscript, and to James C. Bremer and Yoel Shkolnisky for developing code for some of the algorithms. MM is grateful for partial support by NSF DMS-0650413 and ONR N00014-07-1-0625 313-4224.

Nearly Uniform Validation Improves Compression-Based Error Bounds

Eric Bax BAXHOME@YAHOO.COM
PO Box 60543
Pasadena, CA 91116-6543

Editor: Manfred Warmuth

Abstract

This paper develops bounds on out-of-sample error rates for support vector machines (SVMs). The bounds are based on the numbers of support vectors in the SVMs rather than on VC dimension. The bounds developed here improve on support vector counting bounds derived using Littlestone and Warmuth's compression-based bounding technique.

Keywords: compression, error bound, support vector machine, nearly uniform

1. Introduction

The error bounds developed in this paper are based on the number of support vectors in an SVM. Littlestone and Warmuth (Littlestone and Warmuth, 1986; Floyd and Warmuth, 1995) pioneered error bounds of this type. Their method derives error bounds based on how few training examples are needed to represent a classifier that is consistent with all training examples. Hence, bounds derived using their method are called compression-based bounds.

Compression-based bounds apply to SVMs because producing an SVM involves determining which training examples are "border" examples of each class and then ignoring "interior" examples. The number of border examples can be a small fraction of the number of training examples. Discarding the interior examples and training on the border examples alone produces the same SVM. So SVM training itself is a method to reconstruct the classifier based on a subset of the training data. For more details on applying compression-based bounds to SVMs, refer to Cristianini and Shawe-Taylor (2000) and von Luxburg et al. (2004). For information on applying compression-based bounds to some other classifiers, refer to Littlestone and Warmuth (1986), Floyd and Warmuth (1995), Marchand and Shawe-Taylor (2001) and Marchand and Sokolova (2005).

Compression-based bounds are effective when a small subset of the available examples can represent a classifier that is consistent with all available examples. Proofs of effectiveness for compression-based bounds use uniform validation over a set of classifiers that includes the consistent classifier. The validation is uniform in the sense that no classifier in the set may be misvalidated.

The bounds introduced in this paper apply when multiple subsets of the available examples can represent the same consistent classifier. (Support vector machines meet this condition.) Proofs of effectiveness for the new bounds use validation over a set of classifiers that includes several copies of the consistent classifier. So the validation need not be strictly uniform over the set of classifiers; the proofs can tolerate any number of misvalidated classifiers less than the number of copies of the classifier of interest and must still validate that classifier. Hence, the error bounds are said to be *nearly uniform*. Nearly uniform error bounds are introduced in Bax (1997).

This paper is organized as follows. Section 2 sets up definitions, notation, and goals. Section 3 gives an error bound for validation of a classifier. Section 4 presents a bound on the probability of several simultaneous events, which is the basis for nearly uniform error bounds. Section 5 describes nearly uniform error bounds. Section 6 applies nearly uniform error bounds to compression-based bounding. Section 7 analyzes the error bounds. Section 8 applies the error bounds. Section 9 discusses possibilities for future research.

2. Definitions, Notation, and Goals

Let $C = Z_1, \ldots, Z_m$ be a sequence of examples drawn i.i.d. from a joint input-label distribution D, with labels in $\{0,1\}$. Let $Z = (X, Y)$, where X is the input, and Y is the class label. Let g be a *classifier*, that is, a function from the input space to class labels. Define the *error* of g:

$$E_D(g) = P_D(g(X) \neq Y),$$

where the probability is over distribution D.

Let V be a sequence of examples. Define the *empirical error* of g on V:

$$E_V(g) = P_V(g(X) \neq Y),$$

where the probability is uniform over the examples in V. If a classifier has empirical error zero, then the classifier is said to be *consistent* with V.

The goal is to use the examples in C to develop a classifier g^* that is consistent with C and to produce a PAC (probably approximately correct) bound on the error. This paper focuses on producing the error bound for training methods that can develop g^* using subsets of the examples in C, called compression training algorithms. These methods include training support vector machines (SVMs) and perceptrons.

3. Validation of a Consistent Classifier

Theorem 1 *Let V be a sequence of examples drawn i.i.d. from D, and let g be a classifier developed independently of the examples in V. Then*

$$P[E_V(g) = 0 \wedge E_D(g) \geq \varepsilon] \leq (1-\varepsilon)^{|V|}.$$

Proof The LHS is

$$= P[E_V(g) = 0 | E_D(g) \geq \varepsilon] P[E_D(g) \geq \varepsilon]. \quad (1)$$

The second probability in (1) is at most one, so this is

$$\leq P[E_V(g) = 0 | E_D(g) \geq \varepsilon]. \quad (2)$$

If the error is at least ε, then the probability of correctly classifying each example in V is at most 1-ε, so (2) is

$$\leq (1-\varepsilon)^{|V|}.$$

■

The set V is called the set of *validation examples*. Theorem 1 cannot be applied directly to g^* with $V = C$ to compute an error bound, because g^* is developed using the examples in C. To validate g^*, we can use Theorem 1 indirectly, performing uniform validation over a set of classifiers that includes g^*, with validation for each classifier based on examples not used to develop the classifier. Since the set of classifiers includes g^*, uniform validation over the set implies validation of g^*.

In this paper, we use *nearly uniform* validation to validate g^*. We use a multi-set of classifiers that has several copies of g^*, and we perform validation over the classifiers, allowing fewer failed validations than the number of copies of g^*. This nearly uniform validation implies validation of g^*.

4. Probability of Several Simultaneous Events

Nearly uniform validation is based on a bound on the probability of several simultaneous events. Let $A_1, \ldots, A_n$ be subsets of a universal set U. Let $P(A_i)$ be the probability that an element drawn at random from U is a member of set A_i.

Theorem 2

$$P\left[\bigcup_{S \subseteq \{1,\ldots,n\} \wedge |S|=k} \left(\bigcap_{i \in S} A_i\right)\right] \leq \frac{1}{k}[P(A_1) + \ldots + P(A_n)],$$

that is, the probability that a random $u \in U$ is in at least k sets from $A_1, \ldots, A_n$ is at most the sum of probabilities for the sets, divided by k.

Proof The LHS of Theorem 2 is

$$P\left[I(A_1) + \ldots + I(A_n) \geq k\right], \tag{3}$$

where I is the indicator function:

$$I(A_i) = \begin{cases} 1 \text{ if } u \in A_i \\ 0 \text{ otherwise} \end{cases}.$$

By Markov's inequality, (3) is

$$\leq \frac{1}{k} E\left[I(A_1) + \ldots + I(A_n)\right].$$

By linearity of expectation, the RHS is

$$= \frac{1}{k}\left[EI(A_1) + \ldots + EI(A_n)\right],$$

which is

$$= \frac{1}{k}\left[P(A_1) + \ldots + P(A_n)\right].$$

■

Note that setting $k = 1$ gives the well-known sum bound on the probability of a union:

$$P\left[A_1 \cup \ldots \cup A_n\right] \leq P(A_1) + \ldots + P(A_n).$$

5. Nearly Uniform Validation

Consider the probability that at least k classifiers from a set of n classifiers are consistent with their validation examples and yet all have error at least ε.

Theorem 3 *Let $g_1, \ldots, g_n$ be a sequence of classifiers. Let $V_1, \ldots, V_n$ be validation sets, with each classifier g_i developed independently of validation set V_i. Let $|V| = |V_1| = \cdots = |V_n|$. Then*

$$P[\exists S \subseteq \{1,...,n\} \wedge |S| = k : \forall i \in S : (E_{V_i}(g_i) = 0 \wedge E_D(g_i) \geq \varepsilon)] \leq \frac{1}{k} n (1-\varepsilon)^{|V|},$$

where the probability is over validation sets, with the examples within each validation set drawn i.i.d. according to D, but without requiring any independence between validation sets. For instance, with a set of examples, each classifier could be the result of training on a subset of the examples, and each validation set could be the examples not used to train the corresponding classifier.

Proof We will apply Theorem 2. Define

$$\forall i \in \{1,...,n\} : A_i = \{(V_1,...,V_n) | (E_{V_i}(g_i) = 0 \wedge E_D(g_i) \geq \varepsilon)\},$$

that is, A_i is the set of validation set sequences for which g_i is consistent with V_i and yet the error of g_i is at least ε. Then the LHS of Theorem 3 is equal to the LHS of Theorem 2. So, by Theorem 2, the LHS of Theorem 3 is

$$\leq \frac{1}{k}[P(A_1) + ... + P(A_n)]. \tag{4}$$

By Theorem 1

$$\forall i \in \{1,...,n\} : P(A_i) \leq (1-\varepsilon)^{|V|}. \tag{5}$$

Substituting (5) into (4) completes the proof. ■

6. Sample Compression and Nearly Uniform Validation

This section begins with some definitions and notation. Next, Section 6.1 reviews sample compression bounds based on uniform validation. These are the compression bounds found in previous work. Then Section 6.2 develops new sample compression bounds. The new bounds are based on nearly uniform validation.

Recall that $C = Z_1, \ldots, Z_m$ is the sequence of examples available for training. For $T \subseteq \{1, \ldots, m\}$, define *g(T)* to be the classifier represented by the examples in C that are indexed by T, under some scheme for representing classifiers. (An example scheme is to train a classifier on the examples used for representation.) Define *V(T)* to be the subsequence of examples in C not indexed by T. Let

$$E_D(T) = E_D(g(T)),$$

and let

$$E_V(T) = E_{V(T)}(g(T)).$$

6.1 Review of Uniform Sample Compression Bounds

Define *compression index set H* to be a minimum-sized subset of $\{1, \ldots, m\}$ such that

$$E_V(H) = 0,$$

that is, *g(H)* is consistent with the examples in C not indexed by H. Note that any method to represent such a classifier by the examples indexed by H can be extended to represent a classifier that is consistent with all examples in C by the examples indexed by H—simply augment the classifier with the examples indexed by H, use a lookup to classify those examples correctly, and apply the original classifier to any input not in those examples. Hence, the bounds developed here also apply under the condition that H indexes a minimum-sized subset of examples in C that represent a classifier that is consistent with C.

Theorem 4 *Choose an integer $h \in \{1, \ldots, m\}$, independently of the examples in C. Identify a compression index set H. Let g*=g(H). Then*

$$P\left[E_D(g*) \geq \varepsilon \wedge |H| = h\right] \leq \left(\begin{array}{c} m \\ h \end{array} \right) (1-\varepsilon)^{m-h},$$

where the probability is over random draws of $C = Z_1, \ldots, Z_m$.

Proof Assume $|H|=h$; otherwise the probability in Theorem 4 is zero, and the proof is done. By the definition of H,

$$E_D(g*) \geq \varepsilon \Rightarrow (E_V(H) = 0 \wedge E_D(H) \geq \varepsilon).$$

So

$$P\left[E_D(g*) \geq \varepsilon\right] \leq P\left[E_V(H) = 0 \wedge E_D(H) \geq \varepsilon\right].$$

Since H depends on the examples in C, Theorem 3 does not apply directly. So use uniform validation over the set of classifiers represented by size-h subsets of C to validate $g(H)$ using Theorem 3. (This set of classifiers is chosen independently of C, and it includes $g(H)$.)

Let $g_1, \ldots, g_n$ be the classifiers represented by size-h subsets of C. Since $g(H) \in \{g_1, \ldots, g_n\}$,

$$P[E_V(H) = 0 \wedge E_D(H) \geq \varepsilon] \leq P[\exists g_i \in \{g_1, ..., g_n\} : (E_{V_i}(g_i) = 0 \wedge E_D(g_i) \geq \varepsilon)].$$

Apply Theorem 3 to the RHS. Set k=1 in Theorem 3 to bound the probability of at least one misvalidation, and note that

$$n = \left(\begin{array}{c} m \\ h \end{array} \right).$$

Then Theorem 3 implies

$$P[\exists g_i \in \{g_1, ..., g_n\} : (E_{V_i}(g_i) = 0 \wedge E_D(g_i) \geq \varepsilon)] \leq \left(\begin{array}{c} m \\ h \end{array} \right) (1-\varepsilon)^{m-h}.$$

■

In Theorem 4, we must choose h independently of C. The following theorem allows us to choose h based on C.

Theorem 5 *Let*

$$\delta(m,h,\varepsilon) = \left(\begin{array}{c} m \\ h \end{array} \right) (1-\varepsilon)^{m-h}.$$

Let $\varepsilon(m, h, \delta)$ *be the value of* ε *such that* $\delta=\delta(m, h, \varepsilon)$*:*

$$\varepsilon(m,h,\delta) = 1 - \left(\frac{\delta}{\left(\begin{array}{c} m \\ h \end{array} \right)} \right)^{\frac{1}{m-h}}.$$

Select δ*. Identify a compression index set H. Let g*=g(H). Then, with probability at least 1-*δ*,*

$$E_D(g*) \leq \varepsilon(m, |H|, \frac{\delta}{m}),$$

where the probability is over random draws of $C = Z_1, \ldots, Z_m$*.*

Proof By Theorem 4, for each $h \in \{1, \ldots, m\}$,

$$P[E_D(g*) \geq \varepsilon(m,h,\frac{\delta}{m}) \wedge h = |H|] \leq \frac{\delta}{m}.$$

Using the sum bound on the probability of a union:

$$P[\exists h \in \{1,...,m\} : E_D(g*) \geq \varepsilon(m,h,\frac{\delta}{m}) \wedge h = |H|] \leq \delta.$$

So

$$P[\forall h \in \{1,...,m\} : E_D(g*) \leq \varepsilon(m,h,\frac{\delta}{m}) \vee h \neq |H|] \geq 1-\delta.$$

■

6.2 Nearly Uniform Sample Compression Bounds for SVMs

Now consider a case where multiple subsets of the examples in C all represent the same consistent classifier. Under this condition, we can use nearly uniform validation to derive new error bounds. This section focuses on a special case of this condition, a case that applies to SVM training.

Define *retained set* $R \subseteq \{1, \ldots, m\}$ to be a minimum-sized set such that for some classifier g^*,

$$E_{V(R)}(g^*) = 0 \wedge \forall \{1,...,m\} \supseteq Q \supseteq R : g(Q) = g^*.$$

In other words, every superset of R represents the same classifier, g*, which is consistent with the examples in C not indexed by R. For example, in support vector machine training, R can be the set of support vectors in a support vector machine produced by training on all examples in C. (To ensure that the training algorithm produces the same SVM for different supersets of R, assume that the training algorithm breaks ties to determine which SVM to return in a nonrandom way that does not depend on which examples beyond R are in the training set. For example, the algorithm could

form a candidate set consisting of all SVMs with a minimum number of support vectors among those that minimize the algorithm's training objective function. Then the algorithm could return the candidate SVM with the lexicographically earliest bit-string representation.)

Theorem 6 *Choose an integer $q \in \{1, \ldots, m\}$, independently of the examples in C. Identify a retained set $R \subseteq C$ and an associated classifier g^*. Let $r=|R|$. Then*

$$P[E_D(g^*) \geq \varepsilon \wedge q \geq r] \leq \left(\begin{array}{c} m-r \\ q-r \end{array} \right)^{-1} \left(\begin{array}{c} m \\ q \end{array} \right) (1-\varepsilon)^{m-q},$$

where the probability is over random draws of $C = Z_1, \ldots, Z_m$.

Proof Assume $q = r$; otherwise the probability in Theorem 6 is zero, and the proof is done. By the definition of R,

$$E_D(g^*) \geq \varepsilon \Rightarrow \forall \{1, ..., m\} \supseteq Q \supseteq R \text{ s.t. } |Q| = q : (E_V(Q) = 0 \wedge E_D(Q) \geq \varepsilon).$$

So

$$P[E_D(g^*) \geq \varepsilon] \leq P[\forall \{1, ..., m\} \supseteq Q \supseteq R \text{ s.t. } |Q| = q : (E_V(Q) = 0 \wedge E_D(Q) \geq \varepsilon)]. \quad (6)$$

Since R depends on the examples in C, Theorem 3 does not apply directly. So use nearly uniform validation over the set of classifiers represented by size-q subsets of C to validate g^* using Theorem 3. This set of classifiers is chosen independently of C, and it includes at least k instances of g^*, where

$$k = |\{ Q | \{1, ...m\} \supseteq Q \supseteq R \wedge |Q| = q\}| = \left(\begin{array}{c} m-r \\ q-r \end{array} \right).$$

Let $g_1, \ldots, g_n$ be the classifiers represented by size-q subsets of C. Since $g_1, \ldots, g_n$ contains at least k instances of g^*, the RHS of (6) is

$$\leq P[\exists S \subseteq \{1, ..., n\} \wedge |S| = k : \forall i \in S : (E_{V_i}(g_i) = 0 \wedge E_D(g_i) \geq \varepsilon)]. \quad (7)$$

Apply Theorem 3, noting that

$$n = \left(\begin{array}{c} m \\ q \end{array} \right).$$

Then Theorem 3 implies that (7) is

$$\leq \left(\begin{array}{c} m-r \\ q-r \end{array} \right)^{-1} \left(\begin{array}{c} m \\ q \end{array} \right) (1-\varepsilon)^{m-q}.$$

■

In Theorem 6, we must choose q independently of C, and hence without reference to r. So, in Theorem 6, the value of q cannot be optimized with respect to r. Also, if $q < r$, then the theorem does not produce an error bound. The following theorem allows us to choose q based on r.

Theorem 7 *Let*

$$\delta(m,r,q,\varepsilon) = \left(\begin{array}{c} m-r \\ q-r \end{array} \right)^{-1} \left(\begin{array}{c} m \\ q \end{array} \right) (1-\varepsilon)^{m-q}.$$

Let $\varepsilon(m, r, q, \delta)$ *be the value of* ε *such that* $\delta=\delta(m, r, q, \varepsilon)$*:*

$$\varepsilon(m,r,q,\delta) = 1 - \left(\frac{\delta}{\left(\begin{array}{c} m-r \\ q-r \end{array} \right)^{-1} \left(\begin{array}{c} m \\ q \end{array} \right)} \right)^{\frac{1}{m-q}}.$$

Select δ *and a set* $W = \{q_1, \ldots, q_w\}$ *of candidates for q, independently of C. Use C to identify a retained set R and an associated classifier g*. Let* $r=|R|$*. Then, with probability at least 1-*δ*,*

$$E_D(g^*) \leq \min_{q \in W \text{ s.t. } q \geq r} \varepsilon(m,r,q,\frac{\delta}{w}),$$

where the probability is over random draws of $C = Z_1, \ldots, Z_m$*.*

Proof By Theorem 6, for each $q \in W$,

$$P[E_D(g^*) \geq \varepsilon(m,r,q,\frac{\delta}{w}) \wedge q \geq r] \leq \frac{\delta}{w}.$$

Using the sum bound on the probability of a union:

$$P[\exists q \in W : E_D(g^*) \geq \varepsilon(m,r,q,\frac{\delta}{w}) \wedge q \geq r] \leq \delta.$$

So

$$P[\forall q \in W : E_D(g^*) \leq \varepsilon(m,r,q,\frac{\delta}{w}) \vee q < r] \geq 1-\delta.$$

■

Note that setting $q = r$ and $W = \{1, \ldots, m\}$ in Theorem 7 gives the compression error bound from Theorem 5, which is the bound from the literature (Littlestone and Warmuth, 1986; Cristianini and Shawe-Taylor, 2000; Langford, 2005). In the next two sections, we examine how different choices of q and W affect the error bound.

7. Analysis

This section analyzes optimal choices of q and analyzes how strongly the error bound depends on different factors. To determine optimal choices for q, we analyze how probability of bound failure δ changes as q increases. To compare the influence of different factors, we use some approximations for the bound ε. Also, we compare choosing q to maximize the number of examples used for validation to choosing q to maximize the number of copies of g^* in the nearly uniform validation.

7.1 Optimal *q* Based on *m*, *r* and ε

In this section, we examine which values of q minimize $\delta(m,r,q,\varepsilon)$. For some background, note that increasing q increases the fraction of classifiers in the nearly uniform validation that match g^*, but it decreases the number of validation examples for each classifier. The minimum for q is r, which produces only one classifier that matches g^* and leaves m-r examples for validation. The maximum for q is m, making g^* the only classifier involved in uniform validation, but leaving no validation examples.

For fixed m, r, and ε, we want to determine values of q that minimize $\delta(m,r,q,\varepsilon)$. Let

$$p(q) = \delta(m,r,q,\varepsilon).$$

Compare values of $p(q)$ for successive values of $q \in [r,m]$, examining the ratio $p(q+1)/p(q)$. If this ratio is less than one, then increasing q improves the error bound. Writing the ratio in terms of factorials and canceling terms yields

$$p(q+1)/p(q) = (1-\frac{r}{q+1})(1-\varepsilon)^{-1}. \tag{8}$$

The RHS increases with q. So an optimal value of q is the integer that is the floor of the value that makes the RHS of (8) one. Setting the RHS equal to one and solving for q produces

$$q_{opt} = \left\lfloor \frac{r}{\varepsilon} - 1 \right\rfloor,$$

making the optimal validation set size

$$m - q_{opt} = m - \left\lfloor \frac{r}{\varepsilon} - 1 \right\rfloor.$$

For example, with SVM training, if 5% of the training examples are support vectors, and the error bound is $\varepsilon = 10\%$, then the optimal choice for q is one less than half the number of training examples.

7.2 How Error Bound ε Depends on m, r, q, and δ

To explore how the error bound $\varepsilon(m,r,q,\delta/w)$ in Theorem 7 depends on m, r, q, ,δ, and w, we will use the following pair of approximations:

$$\left(\begin{array}{c} n \\ k \end{array} \right) \approx \left(\frac{en}{k} \right)^k,$$

which follows from Stirling's approximation (Feller, 1968, p. 52), and

$$(1-a)^b \approx e^{-ab}.$$

Apply these approximations to

$$\frac{\delta}{w} = \left(\begin{array}{c} m-r \\ q-r \end{array} \right)^{-1} \left(\begin{array}{c} m \\ q \end{array} \right) (1-\varepsilon)^{m-q}, \tag{9}$$

producing

$$\frac{\delta}{w} \approx \left(\frac{e(m-r)}{q-r}\right)^{-(q-r)} \left(\frac{em}{q}\right)^{q} e^{-\varepsilon(m-q)}.$$

Solve for ε:

$$\varepsilon(m,r,q,\frac{\delta}{w}) \approx \frac{1}{m-q}\left[-(q-r)\ln\frac{e(m-r)}{q-r} + q\ln\frac{em}{q} + \ln\frac{w}{\delta}\right]. \tag{10}$$

The error bound is linear in the inverse of the number of validation examples *m* - *q*, approximately linear in *q* - *r* and in *q*, logarithmic in the number *w* of candidates for *q*, and logarithmic in the inverse of δ. (Setting *q* = *r* and *w* = *m* in (10) gives the bound from Cristianini and Shawe-Taylor 2000, p. 70.)

To compare error bounds based on uniform validation to bounds based on nearly uniform validation, compare ε(*m*,*r*,*q*,δ/*w*) with *q* = *r*, which produces a single copy of *g** in the set of classifiers being validated, to ε(*m*,*r*,*q*,δ/*w*) with *q* = (*m*+*r*)/2, which maximizes the number of copies of *g** in the set of classifiers being validated.

For *q* = *r*, use (10):

$$\varepsilon(m,r,r,\frac{\delta}{w}) \approx \frac{1}{m-r}\left[r\ln\frac{em}{r} + \ln\frac{w}{\delta}\right]. \tag{11}$$

For *q* = (*m*+*r*)/2, start from (9):

$$\frac{\delta}{w} = \begin{pmatrix} m-r \\ \frac{1}{2}(m+r)-r \end{pmatrix}^{-1} \begin{pmatrix} m \\ \frac{1}{2}(m+r) \end{pmatrix} (1-\varepsilon)^{m-(m+r)/2}.$$

Combining terms shows that this is

$$= \begin{pmatrix} m-r \\ \frac{1}{2}(m-r) \end{pmatrix}^{-1} \begin{pmatrix} m \\ \frac{1}{2}(m+r) \end{pmatrix} (1-\varepsilon)^{(m-r)/2}.$$

The first combination counts the number of copies of *g** in the set of classifiers to be validated. We chose *q* to make this the coefficient of the central (i.e., largest) term of a binomial distribution. Using the bounds for the central and near-central terms of the binomial distribution from Feller (1968, p. 180), shows this to be

$$\approx \sqrt{1-\frac{r}{m}}2^{r}e^{-(m-r)\varepsilon/2}..$$

For *r*<<*m*, the first term is close to one, so ignore it. Then

$$\frac{\delta}{w} \approx e^{r\ln 2-(m-r)\varepsilon/2}..$$

Solve for ε:

$$\varepsilon(m,r,\frac{m+r}{2},\frac{\delta}{w}) \approx \frac{2}{m-r}\left(r\ln 2 + \ln\frac{w}{\delta}\right). \tag{12}$$

Compare (11) to (12):

$$\varepsilon(m,r,r,\frac{\delta}{w}) : \varepsilon(m,r,\frac{m+r}{2},\frac{\delta}{w}) \approx \frac{1}{m-r}\left[r\ln\frac{em}{r}+\ln\frac{w}{\delta}\right] : \frac{2}{m-r}\left(r\ln 2+\ln\frac{w}{\delta}\right).$$

Terms $\ln(w/\delta)$ tend to be small compared to the rest of the sums in parentheses, so ignore them. Then divide both sides of the ratio by $r/(m\text{-}r)$ to get:

$$\approx \ln\frac{em}{r} : \ln 4,$$

which is

$$= \ln m - \ln r + 1 : \ln 4.$$

For example, if there are m = 1024 training examples and r = 64 support vectors, then the ratio is 3:1, indicating that using nearly uniform validation improves the bound by a factor of about three.

8. Tests

This section presents results of tests applying Theorem 7 to compare uniform error bounds to some nearly uniform bounds. We compare the bound methods:

1. **Uniform** – Use $q = r$ and $W = \{1, \ldots, m\}$. This is the compression-based bound from the literature.

2. **Full** – Use the optimal q in $W = \{1, \ldots, m\}$. This is the straightforward nearly uniform bound.

3. **Sample** – Use the optimal q in $W = \{m/11, 2m/11, \ldots, 10m/11\}$, that is, use 10 equally-spaced candidates for q. This limits the candidates for q, making $w = 10$ in the error bound instead of $w = m$, but optimizing over fewer choices for q.

4. **Center** – Use $q = m/2$. So $W = \{m/2\}$, and $w = 1$.

For all tests, $\delta = 0.01$, and bounds are produced by applying Theorem 7. Each table in this section shows error bounds produced by various methods for a set of problems. For each problem, the best error bound is shown in bold. In parentheses after the bounds are values of q that produced the bounds. For methods Full and Sample, q_{min} is the value of $q \in W$ that minimizes $\varepsilon(m, r, q, \delta/w)$ in Theorem 7. For the other methods, the value of q shown is the only choice.

8.1 Error Bounds for SVMs Trained on Real-World Data Sets

This subsection applies the bound methods to actual data sets for which SVMs have been developed:

1. **Netclass** – SVMs were trained to recognize which of several generative graph models best describe a graph of the neural network of c. elegans (Middendorf et al., 2004). There are m = 800 training examples and r = 51 support vectors.

2. **Genex** – SVMs were trained to classify microarray gene expression data (Brown et al., 1999). There are m = 1097 training examples and r = 216 support vectors.

				Bound Method		
Data	***m***	***r***	**Uniform (*q*)**	**Full (q_{min})**	**Sample (q_{min})**	**Center (*q*)**
Netclass	800	51	23.2% (51)	11.2% (440)	10.0% (509)	**9.8%** (400)
Genex	1097	216	46.5% (216)	25.8% (810)	**24.3%** (897)	28.1% (548)
Dig1	787	355	71.9% (355)	53.5% (648)	**52.1%** (715)	65.6% (393)

Table 1: Error Bounds for Real-World Data Sets

		Bound Method		
r	**Uniform (q)**	**Full (q_{min})**	**Sample (q_{min})**	**Center (q)**
5	25.0% (5)	19.7% (21)	17.1% (27)	**15.0%** (50)
10	35.6% (10)	27.2% (33)	24.5% (36)	**21.3%** (50)
20	50.9% (20)	39.8% (50)	36.9% (54)	**34.1%** (50)

Table 2: Error Bounds for m = 100 Examples

3. **Dig1** – An SVM was trained for digit recognition (Langford 2005). There are m = 787 training examples and r = 355 support vectors.

Method Center produces the best bound for problem Netclass, and method Sample produces the best bound for the other problems. For the first two problems (Netclass and Genex), all methods based on nearly uniform bounds produce about the same bounds, and they are about half the error bound produced by uniform validation. For Dig1, the bounds produced by methods Full and Sample are much better than those produced by uniform validation, but still not good enough to be of any use in practice.

Why are compression bounds for Dig1 so ineffective? Compression bounds are based on the idea that if a classifier is based on only a few training examples and still performs well on the rest, then that is evidence that the classifier performs well in general. For Dig1, the size of the retained set, r, is about half of the number of training examples m. The retained set is composed of training examples used in the classifier and of training examples for which the classifier errs. Consider the following scenario: each class label is equally likely, and we simply choose g^* to be the function that returns the most common label in the training set regardless of the input. Then the retained set consists of all training examples with the least common label, which is most likely a little less than half the training examples. In this case, the true error rate is 50%, and r is about half of m. Since our compression bounds are based on r and m, the bounds cannot distinguish this scenario from the case of Dig1. Hence, compression bounds rely heavily on having few retained examples relative to the number of training examples.

8.2 Error Bounds for m = 1000 Examples

This section explores error bounds produced by the different methods over a range of training set sizes m and retained set sizes r. These tests give a sense of how data set sizes and ratios of r to m affect bounds.

As in Section 8.1, the most effective bound methods in Tables 2 to 4 are Sample and Center. Comparing methods within rows shows that the nearly uniform methods produce better bounds than the uniform methods, with the nearly uniform methods producing bounds that are about half

		Bound Method		
r	**Uniform (q)**	**Full (q_{min})**	**Sample (q_{min})**	**Center (q)**
50	19.5% (50)	9.0% (480)	7.9% (636)	**7.7%** (500)
100	30.9% (100)	15.1% (620)	**13.8%** (727)	14.6% (500)
200	47.0% (200)	26.4% (742)	**24.9%** (818)	28.5% (500)

Table 3: Error Bounds for m = 1000 Examples

		Bound Method		
r	**Uniform (q)**	**Full (q_{min})**	**Sample (q_{min})**	**Center (q)**
50	11.7% (50)	4.6% (895)	4.0% (1090)	**3.9%** (1000)
100	19.2% (100)	7.7% (1209)	**7.0%** (1454)	7.3% (1000)
200	30.6% (200)	13.6% (1374)	**12.7%** (1454)	14.2% (1000)

Table 4: Error Bounds for m = 2000 Examples

the bounds for the uniform method when the ratio r:m is about 1:10. The advantage of using nearly uniform methods is more pronounced for smaller ratios of r:m.

Comparing Table 2 to Table 3 cell-by-cell shows the effect of increasing problem size by a factor of 10 while keeping ratios r:m the same. In general, the bounds improve as problem size increases, and the improvement is greater for smaller r:m ratios. The same kind of comparison is possible between Table 3 and Table 4 by comparing the first two rows of Table 3 to the last two rows of Table 4. This comparison shows the same general trends.

9. Discussion

This section outlines several possible directions for future work. One possibility is to improve the bounds by treating training examples for which g^* errs differently from training examples that comprise g^*. Right now, these examples are combined in the retained set R. Let R_E be the set of training errors for g^*, and let R^* be the set of examples used to form g^*. Suppose training on any superset of R^* yields g^*, that is, including some training errors from R_E does not disrupt training. Then R^* can be used in place of R to form a new error bound on g*. Of course, we need to use validation of non-consistent classifiers in the proposed bound, since validation sets would contain examples that cause empirical error. For example, we could use the bounds based on Binomial Tail Inversion (Langford, 2005).

The error bounds in this paper are based on uniform validation over different validation sets resulting from partitions of all available data into training and validation sets. Lack of knowledge of the joint distribution of misvalidations forces us to take the worst-case joint distributions as bases for the bounds. The worst-case bound is often applied when many validations all use the same examples; better bounds apply when the validations are all based on example sets drawn independently of each other. For each pair of partitions into training and validation sets, the validation sets have an intersection of shared examples, and the non-intersection examples are drawn independently of each other. Perhaps it is possible to use some information about the patterns of shared and independent examples among the different validation sets to constrain the joint distribution of misvalidations in a way that improves the uniform error bounds.

It would be useful to extend the results of this paper to other classifiers that have compression-based bounds, including set covering machines (SCMs) (Marchand and Shawe-Taylor 2001) and decision list machines (DLMs) (Marchand and Sokolova 2005). The challenge is to efficiently identify a retained set under the present training methods for SCMs and DLMs, that is, identify a small subset of training examples such that training on any superset that is a subset of the training examples produces the same classifier. A solution may be to modify the training algorithms in some way to make it easy to identify a small retained set after training.

An alternative approach is to empirically estimate the fraction of trainings on subsets of training data (and perhaps on strings of side information) that produce the same classifier as the classifier g^* trained on all available data. Use sampling over subsets of training data (and strings of side information) to estimate the fraction. Then form an error bound that uses the estimated fraction as the basis for nearly uniform validation. Include a term in the error bound to account for the possibility of over-estimating the fraction of trainings that produce g^*.

Finally, it should be possible to apply this empirical approach to nearly uniform validation in a transductive setting, where the inputs of examples to be classified are known. Each classifier g that agrees with g^* on all examples to be classified could be considered equivalent to g^*. This procedure is similar to empirically determining VC dimension for specific data sets, as described by Vapnik (1998).

Acknowledgments

Thanks to John Langford for extremely helpful advice, encouragement, and data. Thanks to Mario Marchand for encouragement, pointers to relevant literature, and feedback on presentation. Thanks to Manfred Warmuth and three anonymous referees for many helpful suggestions. Thanks to Lance Williams and Dan Ruderman for discussions that led to this paper and for feedback on several versions of the results. Thanks to Danny Hillis and everyone at Applied Minds for encouragement and support to pursue this research.

Abstract

We consider the problem of learning accurate models from multiple sources of "nearby" data. Given distinct samples from multiple data sources and estimates of the dissimilarities between these sources, we provide a general theory of which samples should be used to learn models for each source. This theory is applicable in a broad decision-theoretic learning framework, and yields general results for classification and regression. A key component of our approach is the development of approximate triangle inequalities for expected loss, which may be of independent interest. We discuss the related problem of learning parameters of a distribution from multiple data sources. Finally, we illustrate our theory through a series of synthetic simulations.

Keywords: error bounds, multi-task learning

1. Introduction

We introduce and analyze a theoretical model for the problem of learning from multiple sources of "nearby" data. As a hypothetical example of where such problems might arise, consider the following scenario: For each web user in a large population, we wish to learn a classifier for what sites that user is likely to find "interesting." Assuming we have at least a small amount of labeled data for each user (as might be obtained either through direct feedback, or via indirect means such as click-throughs following a search), one approach would be to apply standard learning algorithms to each user's data in isolation. However, if there are natural and accessible measures of similarity between the interests of pairs of users (as might be obtained through their mutual labelings of common web sites), an appealing alternative is to *aggregate* the data of "nearby" users when learning a classifier for each particular user. This alternative is intuitively subject to a trade-off between the increased sample size and how different the aggregated users are.

We treat this problem in some generality and provide a bound addressing the aforementioned trade-off. In our model there are K unknown data sources, with source i generating a distinct sample S_i of n_i observations. We assume we are given only the samples S_i, and a *disparity*[1] matrix D whose entry $D(i,j)$ bounds the difference between source i and source j. Given these inputs, we wish to

*. A preliminary version of this work appeared in *Advances in Neural Information Processing Systems 19* (Crammer et al., 2007).

1. We avoid using the term distance since our results include settings in which the underlying loss measures may not be formal distances.

decide which subset of the samples S_j will result in the best model for each source i. Our framework includes settings in which the sources produce data for classification, regression, and density estimation (and more generally any additive-loss learning problem obeying certain conditions).

Our main result is a general theorem establishing a bound on the expected loss incurred by using all data sources within a given disparity of the target source. Optimization of this bound then yields a recommended subset of the data to be used in learning a model of each source. Our bound clearly expresses a trade-off between three quantities: the sample size used (which increases as we include data from more distant models), a weighted average of the disparities of the sources whose data is used, and a model complexity term. It can be applied to any learning setting in which the underlying loss function obeys an *approximate* triangle inequality, and in which the class of hypothesis models under consideration obeys uniform convergence of empirical estimates of loss to expectations. For classification problems, the standard triangle inequality holds. For regression we prove a 2-approximation to the triangle inequality. Uniform convergence bounds for the settings we consider may be obtained via standard data-independent model complexity measures such as VC dimension and pseudo-dimension, or via more recent measures such as Rademacher complexity.

Recent work by Crammer et al. (2006) examines the considerably more limited problem of learning a model when all data sources are corrupted versions of a *single, fixed* source, for instance when each data source provides noisy samples of a fixed binary function, but with varying levels of noise. In the current work, the labels on each source may be entirely unrelated to those on other source except as constrained by the bounds on disparities, requiring us to develop new techniques. Blitzer et al. (2007) study the related problem of training classifiers using multiple sources of data drawn from different *underlying* domains but labeled using identical or similar labeling functions. Wu and Dietterich (2004) study similar problems experimentally in the context of SVMs. The framework examined here can also be viewed in the context of multi-task learning, or as a type of transfer learning (Baxter, 1995; Ben-David, 2003; Maurer, 2005).

In Section 2 we introduce a decision-theoretic framework for probabilistic learning that includes classification, regression, and many other settings as special cases, and then give our multiple source generalization of this model. In Section 3 we provide our main result, which is a general bound on the expected loss incurred by using all data within a given disparity of a target source. Section 4 discusses the most simple application of this bound to binary classification using VC theory. In Section 5, we give applications of our general theory to classification and regression using Rademacher complexity, and show more generally how the theory can be applied for any Lipschitz loss function. In Section 6 we discuss how to empirically estimate the disparity matrix from data. In Section 7, we discuss the related problem of learning parameters of a distribution from multiple data sources. Finally, in Section 8, we illustrate the theory through synthetic simulations.

2. Learning Models

Before detailing our multiple-source learning model, we first introduce a standard decision-theoretic learning framework in which our goal is to find a model minimizing a generalized notion of empirical loss (Haussler, 1992). Let the *hypothesis class* $\mathcal{H}$ be a set of models (which might be classifiers, real-valued functions, densities, etc.), and let f be the *target model*, which may or may not lie in the class $\mathcal{H}$. Let z be a (generalized) data point or observation. For instance, in (noise-free) classification and regression, z will consist of a pair $\langle x,y\rangle$ where $y = f(x)$. We assume that the target model f induces some underlying distribution P_f over observations z. In the case of classification

or regression, P_f is induced by drawing the inputs x according to some underlying distribution P, and then setting $y = f(x)$ (possibly corrupted by noise).

Each setting we consider has an associated *loss function* $\mathcal{L}(h,z)$. For example, in classification we typically consider the 0/1 loss: $\mathcal{L}(h,\langle x,y\rangle) = 0$ if $h(x) = y$, and 1 otherwise. In regression we might consider the squared loss function $\mathcal{L}(h,\langle x,y\rangle) = (y-h(x))^2$. In each case, we are interested in the expected loss of a model g_2 on target g_1, $e(g_1,g_2) = \mathrm{E}_{z\sim P_{g_1}}[\mathcal{L}(g_2,z)]$. Expected loss is not necessarily symmetric.

In our multiple source model, we are presented with K distinct mutually independent samples or *sources* of data $S_1,\ldots,S_K$, and a symmetric $K\times K$ matrix D. Each source S_i contains n_i observations that are generated from a fixed and unknown model f_i, and D satisfies $\max(e(f_i,f_j),e(f_j,f_i)) \leq D(i,j)$. When D is unknown, it often can be estimated from a small amount of data; see Section 6 for more details. Our goal is to decide which sources S_j to use in order to learn the best approximation (in terms of expected loss) to each f_i.

While we are interested in accomplishing this goal for each f_i, it suffices and is convenient to examine the problem from the perspective of a fixed f_i. Thus without loss of generality let us suppose that we are given sources $S_1,\ldots,S_K$ of size $n_1,\ldots,n_K$ from models $f_1,\ldots,f_K$ such that $\varepsilon_1 \equiv D(1,1) \leq \varepsilon_2 \equiv D(1,2) \leq \cdots \leq \varepsilon_K \equiv D(1,K)$, and our goal is to learn f_1. Here we have simply taken the problem in the preceding paragraph, focused on the problem for f_1, and reordered the other models according to our estimations or their proximity to f_1. To highlight the distinguished role of the target f_1 we shall denote it f. We denote the observations in S_j by $z_1^j,\ldots,z_{n_j}^j$. In all cases we will analyze, for any $k \leq K$, the hypothesis $\hat{h}_k$ minimizing the empirical loss $\hat{e}_k(h)$ on the first k sources $S_1,\ldots,S_k$, that is

$$\hat{h}_k = \operatorname*{argmin}_{h\in\mathcal{H}} \hat{e}_k(h) = \operatorname*{argmin}_{h\in\mathcal{H}} \frac{1}{n_{1:k}} \sum_{j=1}^{k}\sum_{i=1}^{n_j} \mathcal{L}(h,z_i^j) \ ,$$

where $n_{1:k} = n_1 + \cdots + n_k$. We also denote the expected error of function h with respect to the first k sources of data as

$$e_k(h) = \mathrm{E}\left[\hat{e}_k(h)\right] = \sum_{i=1}^{k}\left(\frac{n_i}{n_{1:k}}\right) e(f_i,h).$$

3. General Theory for the Multiple Source Problem

In this section we provide the first of our main results: a general bound on the expected loss of the model minimizing the empirical loss on the nearest k sources. Optimization of this bound leads to a recommended set of sources to incorporate when learning $f = f_1$. The key ingredients needed to apply this bound are an approximate triangle inequality and a uniform convergence bound, which we define below. In the subsequent sections we demonstrate that these ingredients can indeed be provided for a variety of natural learning problems.

Definition 1 *For $\alpha \geq 1$, we say that the α-**triangle inequality** holds for a class of models $\mathcal{F}$ and expected loss function e if for all $g_1,g_2,g_3 \in \mathcal{F}$ we have*

$$e(g_1,g_2) \leq \alpha(e(g_1,g_3)+e(g_3,g_2)).$$

The parameter $\alpha \geq 1$ is a constant that depends on $\mathcal{F}$ and e.

The choice $\alpha = 1$ yields the standard triangle inequality. We note that the restriction to models in the class $\mathcal{F}$ may in some cases be quite weak—for instance, when $\mathcal{F}$ is all possible classifiers or real-valued functions with bounded range—or stronger, as in densities from the exponential family. Our results will require only that the unknown *source* models $f_1, \ldots, f_K$ lie in $\mathcal{F}$, even when our *hypothesis* models are chosen from some possibly much more restricted class $\mathcal{H} \subseteq \mathcal{F}$. For now we simply leave $\mathcal{F}$ as a parameter of the definition.

Definition 2 *A **uniform convergence bound** for a hypothesis space $\mathcal{H}$ and loss function $\mathcal{L}$ is a bound that states that for any $0 < \delta < 1$, with probability at least $1 - \delta$ for any $h \in \mathcal{H}$*

$$|\hat{e}(h) - e(h)| \leq \beta(n, \delta) \ ,$$

where $\hat{e}(h) = \frac{1}{n}\sum_{i=1}^{n} \mathcal{L}(h, z_i)$ for n observations $z_1, \ldots, z_n$ generated independently according to distributions $P_1, \ldots P_n$, and $e(h) = \mathrm{E}[\hat{e}(h)]$ where the expectation is taken with respect to $z_1, \ldots, z_n$. Here β is a function of the number of observations n and the confidence δ, and depends on $\mathcal{H}$ and $\mathcal{L}$.

This definition simply asserts that for every model in $\mathcal{H}$, its empirical loss on a sample of size n and the expectation of this loss will be "close" when $\beta(n, \delta)$ is small. In general the function β will incorporate standard measures of the complexity of $\mathcal{H}$, and will be a decreasing function of the sample size n, as in the classical $O(\sqrt{d/n})$ bounds of VC theory. Our bounds will be derived from the rich literature on uniform convergence. The only twist to our setting is the fact that the observations are no longer necessarily identically distributed, since they are generated from multiple sources. However, generalizing the standard uniform convergence results to this setting is mostly straightforward as we will see in the upcoming sections on applications of the bound.

We are now ready to present our general bound.

Theorem 3 *Let e be the expected loss function for loss $\mathcal{L}$, and let $\mathcal{F}$ be a class of models for which the α-triangle inequality holds with respect to e. Let $\mathcal{H} \subseteq \mathcal{F}$ be a class of hypothesis models for which there is a uniform convergence bound β for $\mathcal{L}$. Let K, $f = f_1, f_2, \ldots, f_K \in \mathcal{F}$, $\{\varepsilon_i\}_{i=1}^{K}$, $\{n_i\}_{i=1}^{K}$, and $\hat{h}_k$ be defined as above. For any δ such that $0 < \delta < 1$, with probability at least $1 - \delta$, for any $k \in \{1, \ldots, K\}$*

$$e(f, \hat{h}_k) \leq \alpha^2 \min_{h \in \mathcal{H}} \{e(f, h)\} + (\alpha + \alpha^2) \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) \varepsilon_i + 2\alpha\beta(n_{1:k}, \delta/2K) \ .$$

Before providing the proof, let us examine the bound of Theorem 3, which expresses a natural and intuitive trade-off. The first term in the bound is simply the *approximation error*, the residual loss that we incur by limiting our hypothesis model to fall in the restricted class $\mathcal{H}$. The second term is a weighted sum of the disparities of the $k \leq K$ models whose data is used with respect to the target model $f = f_1$. We expect this term to *increase* as we increase k to include more distant sources. The final term is determined by the uniform convergence bound. We expect this term to *decrease* with added sources due to the increased sample size. All three terms are influenced by the strength of the approximate triangle inequality that we have, as quantified by α.

The bound given in Theorem 3 can be loose, but provides an upper bound necessary for optimization and suggests a natural choice for the number of sources k^* to use to estimate the target

f:

$$k^* = \operatorname*{argmin}_k \left((\alpha+\alpha^2) \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) \varepsilon_i + 2\alpha\beta(n_{1:k}, \delta/2K) \right).$$

Theorem 3 and this optimization make the implicit assumption that the best subset of sources to use will be a prefix of the sources—that is, that we should not "skip" a nearby source in favor of more distant ones. This assumption will be true for typical data-independent uniform convergence such as VC dimension bounds, and will be true on average for data-dependent bounds, where we expect uniform convergence bounds to improve with increased sample size.

We now give the proof of Theorem 3.

Proof: (Theorem 3) By Definition 1, for any $h \in \mathcal{H}$, any $k \in \{1, \ldots K\}$, and any $i \in \{1, \ldots, k\}$,

$$\left(\frac{n_i}{n_{1:k}} \right) e(f,h) \leq \left(\frac{n_i}{n_{1:k}} \right) (\alpha e(f, f_i) + \alpha e(f_i, h)) \ .$$

Summing over all $i \in \{1, \ldots, k\}$, we find

$$\begin{aligned} e(f,h) &\leq \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) (\alpha e(f, f_i) + \alpha e(f_i, h)) \\ &= \alpha \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) e(f, f_i) + \alpha \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) e(f_i, h) \leq \alpha \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) \varepsilon_i + \alpha e_k(h) \ . \end{aligned}$$

In the first line above we have used the α-triangle inequality to deliberately introduce a weighted summation involving the f_i. In the second line, we have broken up the summation using the fact that $e(f, f_i) \leq \varepsilon_i$ and the definition of $e_k(h)$. Notice that the first summation is a weighted average of the expected loss of each f_i, while the second summation is the expected loss of h on the data. Using the uniform convergence bound, we may assert that with high probability $e_k(h) \leq \hat{e}_k(h) + \beta(n_{1:k}, \delta/2K)$, and with high probability

$$\hat{e}_k(\hat{h}_k) = \min_{h \in \mathcal{H}} \{\hat{e}_k(h)\} \leq \min_{h \in \mathcal{H}} \left\{ \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) e(f_i, h) + \beta(n_{1:k}, \delta/2K) \right\} \ .$$

Putting these pieces together, we find that with high probability

$$\begin{aligned} e(f, \hat{h}_k) &\leq \alpha \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) \varepsilon_i + 2\alpha\beta(n_{1:k}, \delta/2K) + \alpha \min_{h \in \mathcal{H}} \left\{ \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) e(f_i, h) \right\} \\ &\leq \alpha \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) \varepsilon_i + 2\alpha\beta(n_{1:k}, \delta/2K) \\ &\quad + \alpha \min_{h \in \mathcal{H}} \left\{ \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) \alpha e(f_i, f) + \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) \alpha e(f, h) \right\} \\ &= (\alpha+\alpha^2) \sum_{i=1}^{k} \left(\frac{n_i}{n_{1:k}} \right) \varepsilon_i + 2\alpha\beta(n_{1:k}, \delta/2K) + \alpha^2 \min_{h \in \mathcal{H}} \{e(f,h)\} \ . \end{aligned}$$

■

4. Simple Application to Binary Classification

We demonstrate the applicability of the general theory given by Theorem 3 to several standard learning settings. As a warm-up, we begin with the most straightforward application, classification using VC bounds.

In (noise-free) binary classification, we assume that our target model is a fixed, unknown and arbitrary function f from some input set $\mathcal{X}$ to $\{0,1\}$, and that there is a fixed and unknown distribution P on the $\mathcal{X}$. Note that the distribution P over input does not depend on the target function f. The observations are of the form $z = \langle x, y\rangle$ where $y \in \{0,1\}$. The loss function $\mathcal{L}(h, \langle x, y\rangle)$ is defined as 0 if $y = h(x)$ and 1 otherwise, and the corresponding expected loss is $e(g_1, g_2) = \mathrm{E}_{\langle x,y\rangle \sim P_{g_1}}\left[\mathcal{L}(g_2, \langle x, y\rangle)\right] = \Pr_{x\sim P}[g_1(x) \neq g_2(x)]$.

For 0/1 loss it is well-known and easy to see that the (standard) 1-triangle inequality holds. Classical VC theory (Vapnik, 1998) provides us with uniform convergence as follows.

Lemma 4 *Let $\mathcal{H} : \mathcal{X} \to \{0,1\}$ be a class of functions with VC dimension d, and let $\mathcal{L}(h, \langle x, y\rangle) = |y - h(x)|$ be the 0/1-loss. The following function β is a uniform convergence bound for $\mathcal{H}$ and $\mathcal{L}$ when $n \geq d/2$:*

$$\beta(n, \delta) = \sqrt{\frac{8(d \ln(2en/d) + \ln(4/\delta))}{n}} \; .$$

The proof is analogous to the standard proof of uniform convergence using the VC Dimension (see, for example, Chapters 2–4 of Anthony and Bartlett (1999)), requiring only minor modifications to the symmetrization argument to handle the fact that the samples need not be uniformly distributed. It relies heavily on Hoeffding's inequality (Hoeffding, 1963), stated here for completeness.

Lemma 5 (Hoeffding's Inequality) *Let X be a set, $D_1, \cdots, D_m$ be probability distributions on X, and $f_1, \cdots, f_m$ be real-valued functions on X such that $f_i : X \to [a_i, b_i]$ for $i = 1, \cdots, m$. Then*

$$\Pr\left(\left|\left(\frac{1}{m}\sum_{i=1}^{m} f_i(x_i)\right) - \left(\frac{1}{m}\sum_{i=1}^{m} E_{x\sim D_i}[f_i(x)]\right)\right| \geq \varepsilon\right) \leq 2\exp\left(\frac{-2\varepsilon^2 m^2}{\sum_{i=1}^{m}(b_i - a_i)^2}\right) \; ,$$

where the probability is over the sequence of values x_i distributed according to D_i for all $i = 1, \cdots, m$.

With Lemma 4 in place, the conditions of Theorem 3 are easily satisfied, yielding the following result.

Theorem 6 *Let $\mathcal{F}$ be the set of all functions from an input set $\mathcal{X}$ into $\{0,1\}$ and let d be the VC dimension of $\mathcal{H} \subseteq \mathcal{F}$. Let e be the expected 0/1 loss. Let K, $f = f_1, f_2, \ldots, f_K \in \mathcal{F}$, $\{\varepsilon_i\}_{i=1}^K$, $\{n_i\}_{i=1}^K$, and $\hat{h}_k$ be defined as above in the multi-source learning model, and assume that $n_1 \geq d/2$. For any δ such that $0 < \delta < 1$, with probability at least $1 - \delta$, for any $k \in \{1, \ldots, K\}$*

$$e(f, \hat{h}_k) \leq \min_{h\in\mathcal{H}}\{e(f,h)\} + 2\sum_{i=1}^{k}\left(\frac{n_i}{n_{1:k}}\right)\varepsilon_i + \sqrt{\frac{32\left(d\ln\left(2en_{1:k}/d\right) + \ln\left(8K/\delta\right)\right)}{n_{1:k}}} \; .$$

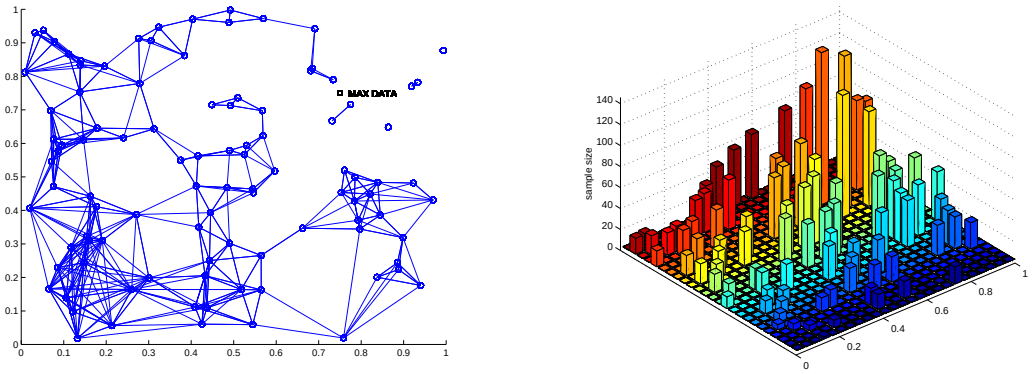

Figure 1: Visual illustration of Theorem 6.

In Figure 1 we provide a visual illustration of the behavior of Theorem 3 applied to a simple classification problem. In this problem there are $K = 100$ classifiers, each classifier f_i for $i = 1 \ldots 100$ is defined by 2 parameters represented by a point in the unit square, such that the expected disagreement rate between two such classifiers is proportional the L_1 distance between their parameters.[2] We chose the 100 parameter vectors f_i uniformly at random from the unit square (the circles in the left panel). To generate varying source sizes, we let n_i decrease with the distance of f_i from a chosen "central" point at $(0.75, 0.75)$ (marked "MAX DATA" in the left panel); the resulting source sizes for each model are shown in the bar plot in the right panel, where the origin $(0,0)$ is in the near corner, $(1,1)$ in the far corner, and the source sizes clearly peak near $(0.75, 0.75)$. For every function f_i we used Theorem 6 to find the best sources j to be used to estimate its parameters. The undirected graph on the left includes an edge between f_i and f_j if and only if the data from f_j is used to learn f_i and/or the converse.

The graph simultaneously displays the geometry implicit in Theorem 6 as well as its adaptivity to local circumstances. Near the central point, the graph is sparse and the edges quite short, corresponding to the fact that for such models we have enough direct data (represented with high bars in the right panel) that it is not advantageous to include data from distant models. Far from the central point the graph becomes dense and the edges long, as we are required to aggregate a larger neighborhood to learn the optimal model. In addition, decisions are affected locally by how many models are "nearby" a given model, when there are many close functions f_j to a given f_i there is no need to use "far" models, but when the neighborhood of a function is not populated with many examples, there is a need for data from models far-away.

5. Bounds Using Rademacher Complexity

Given the interest in tighter, potentially data-dependent convergence bounds (such as maximum margin bounds, PAC-Bayes, and others) in recent years, it is natural to ask how our multi-source theory can exploit these modern bounds. We examine one specific case here using Rademacher

2. It is easy to create simple input distributions and classifiers that generate exactly this geometry. Let the input x be a pair $x = (p,b)$ where $p \in [0,1], b \in \{0,1\}$ and let the hypothesis class consist of functions defined as pairs of thresholds $f = (t_1, t_2)$ where $f(x) = 1$ if and only if ($p > t_1$ and $b = 0$) or ($p > t_2$ and $b = 1$). The distribution of $x = (p,b)$ is a product of a uniform distribution for p and a fair coin for b.

complexity (Bartlett and Mendelson, 2002; Bartlett et al., 2002; Koltchinskii, 2001; Koltchinskii and Panchenko, 2000); analogs can be derived in a similar manner for other complexity measures. We start by deriving bounds for settings in which generic Lipschitz loss functions are used, and then discuss specific applications to classification and to regression with squared loss.

5.1 Rademacher Complexity and General Lipschitz-loss Bounds

If $\mathcal{H}$ is a class of functions mapping from a set $\mathcal{X}$ to $\mathbb{R}$, the *empirical Rademacher complexity* of $\mathcal{H}$ on a fixed set of observations $x_1,\ldots,x_n$ is defined as

$$\hat{R}_n(\mathcal{H}) = \mathrm{E}\left[\sup_{h\in\mathcal{H}}\left|\frac{2}{n}\sum_{i=1}^{n}\sigma_i h(x_i)\right|\right] ,$$

where the expectation is taken with respect to independent uniform $\{\pm 1\}$-valued random variables $\sigma_1,\ldots,\sigma_n$. The *Rademacher complexity* for n observations can then be defined as $R_n(\mathcal{H}) = \mathrm{E}\left[\hat{R}_n(\mathcal{H})\right]$ where the expectation is with respect to observations $x_1,\ldots,x_n$. In the standard setting, $x_1,\ldots,x_n$ are drawn i.i.d. from a fixed distribution. In our setting, these observations will still be independent, but not necessarily identically distributed. We will show that the standard uniform convergence results still hold for this modified definition of Rademacher complexity.

Consider any setting in which each generalized data point $z = \langle x,y\rangle$ for some $x \in \mathcal{X}$ and $y \in \mathcal{Y}$ with $y = f(x)$. A *cost function* for the loss $\mathcal{L}$ is a function $\phi(y,a) : \mathbb{R} \to \mathbb{R}$ such that $\mathcal{L}(h,\langle x,y\rangle) = \phi(y,h(x))$ for all $x \in \mathcal{X}$, $y \in \mathcal{Y}$, and $h \in \mathcal{H}$. We will consider cost functions ϕ that are Lipschitz in the second parameter. Define $\phi'(y,a) = \phi(y,a) - \phi(y,0)$. Note that if ϕ is Lipschitz in the second parameter with constant L then ϕ' is also Lipschitz in the second parameter with the same constant L.

Lemma 8 below gives a uniform convergence bound for any loss function with a corresponding Lipschitz cost function. The proof of this lemma is in Appendix A. It is analogous to the proof of Theorem 8 in Bartlett and Mendelson (2002), which makes a similar claim in the i.i.d. setting, and uses the following lemma from Bartlett and Mendelson (2002).

Lemma 7 *If $\phi : \mathbb{R} \to \mathbb{R}$ is Lipschitz with constant L and $\phi(0) = 0$, then $R_n(\phi \circ \mathcal{H}) \leq 2LR_n(\mathcal{H})$.*

Lemma 8 *Let $\mathcal{L}$ be a loss function bounded in $[0,1]$, and $\phi : \mathbb{R} \to \mathbb{R}$ a cost function such that $\mathcal{L}(f,\langle x,y\rangle) = \phi(y,f(x))$ where ϕ is Lipschitz in the second parameter with constant L. Let $\mathcal{H} : \mathcal{X} \to \mathcal{Y}$ be a class of functions and let $\{\langle x_i,y_i\rangle\}_{i=1}^n$ be sampled independently according to some probability distributed P. For any n, for any $0 < \delta < 1$, with probability $1-\delta$ over samples of length n, every $h \in \mathcal{H}$ satisfies*

$$\beta(n,\delta) = 2LR_n(\mathcal{H}) + \sqrt{\frac{2\ln(2/\delta)}{n}} .$$

5.2 Application to Classification Using Rademacher Complexity

Theorem 9 below follows from the application of Theorem 3 using the 1-triangle inequality and an application of Lemma 8 with

$$\phi(y,a) = \begin{cases} 1 & \text{if } ya \leq 0, \\ 1-ya & \text{if } 0 < ya \leq 1, \\ 0 & \text{if } ya > 1. \end{cases}$$

Notice first that if $\mathcal{L}$ is the 0/1 loss, then for all $x \in \mathcal{X}$, $y \in \{-1,1\}$, and $h \in \mathcal{X} \to \{-1,1\}$, $\mathcal{L}(h,\langle x,y\rangle) = \phi(y,h(x))$, and furthermore that ϕ is Lipschitz with constant 1, so Lemma 8 can be applied immediately.

Theorem 9 *Let $\mathcal{F}$ be a set of functions from an input set $\mathcal{X}$ into {-1,1} and let $R_{n_{1:k}}(\mathcal{H})$ be the Rademacher complexity of $\mathcal{H} \subseteq \mathcal{F}$ on the first k sources of data. Let e be the expected 0/1 loss. Let K, $f = f_1, f_2, \ldots, f_K \in \mathcal{F}$, $\{\varepsilon_i\}_{i=1}^K$, $\{n_i\}_{i=1}^K$, and $\hat{h}_k$ be defined as in the multi-source learning model. For any δ such that $0 < \delta < 1$, with probability at least $1-\delta$, for any $k \in \{1,\ldots,K\}$*

$$e(f,\hat{h}_k) \leq \min_{h\in\mathcal{H}}\{e(f,h)\} + 2\sum_{i=1}^{k}\left(\frac{n_i}{n_{1:k}}\right)\varepsilon_i + 2\sqrt{\frac{2\ln(4K/\delta)}{n_{1:k}}} + 4R_{n_{1:k}}(\mathcal{H}) \; .$$

Before moving on, let us briefly examine the behavior of this bound. Similarly to the VC-based bound given in Theorem 6, as k increases and more sources of data are combined, the second term will grow while the third will shrink. The behavior of the final term $R_{n_{1:k}}(\mathcal{H})$, however, is less predictable and may grow or shrink as more sources of data are combined.

Note that for the special case of classification with 0/1 loss, it is possible to get tighter bounds with better dependence on $R_{n_{1:k}}$ by using a more careful analysis than the one in the proof of Lemma 8. Such bounds are given in an earlier version of this paper (Crammer et al., 2007); we choose not to present these alternate bounds here to simplify presentation.

5.3 Regression

We now turn to (noise-free) regression with squared loss. Here our target model f is any function from an input class $\mathcal{X}$ into some bounded subset of $\mathbb{R}$. (Frequently we will have $\mathcal{X} \subseteq \mathbb{R}^d$, but this is not required.) Our loss function is $\mathcal{L}(h,\langle x,y\rangle) = (y-h(x))^2$, and the expected loss is thus $e(g_1,g_2) = \mathrm{E}_{\langle x,y\rangle\sim P_{g_1}}\left[\mathcal{L}(g_2,\langle x,y\rangle)\right] = \mathrm{E}_{x\sim P}\left[(g_1(x)-g_2(x))^2\right]$.

For regression it is known that the standard 1-triangle inequality does not hold. However, a 2-triangle inequality does hold and is stated in the following lemma.

Lemma 10 *Given any three functions $g_1, g_2, g_3 : \mathcal{X} \to \mathbb{R}$, a fixed and unknown distribution P on the inputs $\mathcal{X}$, and the expected loss $e(g_1,g_2) = \mathrm{E}_{x\sim P}\left[(g_1(x)-g_2(x))^2\right]$,*

$$e(g_1,g_2) \leq 2\left(e(g_1,g_3)+e(g_3,g_1)\right).$$

Proof: By Jensen's inequality and the convexity of $x \mapsto x^2$, for any g_1, g_2, and g_3,

$$\begin{aligned} e(g_1,g_2) &= \mathrm{E}_{x\sim P}\left[(g_1(x)-g_2(x))^2\right] \\ &= \mathrm{E}_{x\sim P}\left[4\left(\frac{1}{2}(g_1(x)-g_3(x)) + \frac{1}{2}(g_3(x)-g_2(x))\right)^2\right] \\ &\leq \mathrm{E}_{x\sim P}\left[2(g_1(x)-g_3(x))^2 + 2(g_3(x)-g_2(x))^2\right] = 2\left(e(g_1,g_3)+e(g_3,g_1)\right) \; . \end{aligned}$$

■

We can derive a uniform convergence bound for squared loss using Rademacher complexity as long as the region $\mathcal{Y}$ is bounded.

Lemma 11 *Let $\mathcal{H} : \mathcal{X} \to [-B,B]$ be a class of functions, and let $\mathcal{L}(h,\langle x,y\rangle) = (y-h(x))^2$ be the squared loss. The following function β is a uniform convergence bound for $\mathcal{H}$ and $\mathcal{L}$:*

$$\beta(n,\delta) = 8BR_n(\mathcal{H}) + 4B^2\sqrt{\frac{2\ln(2/\delta)}{n}}\ .$$

Proof: We cannot apply Lemma 8 directly using the squared loss function, since it may output values outside of the range $[0,1]$. Instead, we apply the Lemma 8 using the alternate loss function $\mathcal{L}'(h,\langle x,y\rangle) = \phi(y,h(x))$ where

$$\phi(y,a) = \begin{cases} \frac{1}{4B^2}(y+B)^2 & \text{if } a < -B, \\ \frac{1}{4B^2}(y-a)^2 & \text{if } -B \le a \le B, \\ \frac{1}{4B^2}(y+B)^2 & \text{if } a > B. \end{cases}$$

It is easy to see that ϕ always outputs values in the range $[0,1]$. Furthermore, for any $y \in [-B,B]$, ϕ is Lipschitz in the second parameter with parameter $1/B$. For any $[a,b] \in [-B,B]$,

$$\begin{aligned} |\phi(y,a)-\phi(y,b)| &= \frac{1}{4B^2}\left|(y-a)^2-(y-b)^2\right| = \frac{1}{4B^2}\left|a^2-b^2+2y(b-a)\right| \\ &\le \frac{1}{4B^2}\left|a^2-b^2\right| + \frac{1}{2B^2}\left|y(a-b)\right| \\ &\le \frac{1}{4B^2}\left|a+b\right|\left|a-b\right| + \frac{1}{2B^2}\left|y(a-b)\right| \le \frac{1}{B}\left|a-b\right|\ . \end{aligned}$$

Applying Lemma 8 gives a uniform convergence bound of $(2/B)R_n(\mathcal{H}) + \sqrt{2\ln(2/\delta)/n}$ for $\mathcal{L}'$. Scaling by $4B^2$ yields the bound for $\mathcal{L}$. ■

Combining this with Lemma 10 and applying Theorem 3 yields the following.

Theorem 12 *Let $\mathcal{F}$ be the set of functions from $\mathcal{X}$ into $[-B,B]$, and $\mathcal{H} \subseteq \mathcal{F}$. Let e be the expected squared loss. Let K, $f = f_1, f_2, \ldots, f_K \in \mathcal{F}$, $\{\varepsilon_i\}_{i=1}^K$, $\{n_i\}_{i=1}^K$, and $\hat{h}_k$ be defined as in the multi-source learning model. For any δ such that $0 < \delta < 1$, with probability at least $1-\delta$, for any $k \in \{1,\ldots,K\}$*

$$e(f,\hat{h}_k) \le 4\min_{h\in\mathcal{H}}\{e(f,h)\} + 6\sum_{i=1}^{k}\left(\frac{n_i}{n_{1:k}}\right)\varepsilon_i + 32BR_{n_{1:k}}(\mathcal{H}) + 16B^2\sqrt{\frac{2\ln(4K/\delta)}{n_{1:k}}}\ .$$

5.4 Remarks on the Use of Data-Dependent Complexity Measures

The following lemma, which relates the true Rademacher complexity of a function class to its empirical Rademacher complexity, follows directly from Theorem 11 of Bartlett and Mendelson (2002), the proof of which does not require samples to be identically distributed.

Lemma 13 *Let $\mathcal{H}$ be a class of functions mapping to $[-1,1]$. For any integer n, for any $0 < \delta < 1$, with probability $1-\delta$,*

$$\left|R_n(\mathcal{H}) - \hat{R}_n(\mathcal{H})\right| \le \sqrt{\frac{8\ln(2/\delta)}{n}}.$$

This lemma immediately allows us to replace $R_n(\mathcal{H})$ with that data-dependent quantity $\hat{R}_n$ in any of the bounds above for only a small penalty.

While the use of data-dependent complexity measures can be expected to yield more accurate bounds and thus better decisions about the number k^* of sources to use, it is not without its costs in comparison to the more standard data-independent approaches. In particular, in principle the optimization of a data-dependent version of the bound given in Theorem 9 to choose k^* may actually involve running the learning algorithm on all possible prefixes of the sources, since we cannot know the data-dependent complexity term for each prefix without doing so. In contrast, the data-independent bounds can be computed and optimized for k^* without examining the data at all, and the learning performed only once on the first k^* sources. This is especially useful in the case that labels are not free but must be purchased at a price.

6. Estimating the Disparity Matrix

A potential drawback of the theory presented here is the need to estimate the disparity matrix D when it is unknown. However, it is often the case that this matrix can be estimated with many fewer labeled samples than are required for learning. In this section, we discuss how D can be estimated in the classification setting.

As before, consider the scenario in which each target function is a fixed, unknown and arbitrary function from some input set $\mathcal{X}$ to $\{-1,1\}$, and assume that there is a fixed and unknown distribution P over $\mathcal{X}$. Suppose we are given m data points labeled by a pair of functions f_i and f_j, and let $\hat{e}(f_i,f_j)$ be the fraction of points on which the labels disagree. By Hoeffding's inequality, with probability $1-\delta'$,

$$|\hat{e}(f_i,f_j)-e(f_i,f_j)| \leq \sqrt{\frac{\ln(2/\delta')}{2m}}\ .$$

Thus in order to approximate $e(f_i,f_j)$ with an error no more than ε, only $\ln(2/\delta')/(2\varepsilon^2)$ commonly labeled points are needed. Applying the union bound gives us the following lemma.

Lemma 14 *Let $\mathcal{F}$ be a set of functions from $\mathcal{X}$ into $\{-1,1\}$, and suppose $f_1,\ldots,f_K \in \mathcal{F}$. Let e be the expected 0/1 loss. Suppose that for each pair $i,j \in \{1,\cdots,K\}$, there exist $m_{i,j} \geq m_0$ examples distributed according to P commonly labeled by f_i and f_j, where*

$$m_0 = \frac{2\ln(K)+\ln(2/\delta)}{2\varepsilon^2}$$

for any δ such that $0 \leq \delta \leq 1$, and let $\hat{e}(f_i,f_j)$ be the fraction of commonly labeled examples on which f_i and f_j disagree. Then with probability $1-\delta$, for all $i,j \in \{1,\cdots,K\}$, $|\hat{e}(f_i,f_j)-e(f_i,f_j)| \leq \varepsilon$.

Using the lemma we set the upper bound on the mutual error $e(f_i,f_j)$ between the pair of function f_i and f_j to be $D_{i,j} = \hat{e}(f_i,f_j)+\varepsilon$. With probability at least $1-\delta$ these bound holds simultaneously for all i,j.

Note that in general, $\log(K)$ will be significantly smaller than the dimension d of $\mathcal{H}$. Thus many fewer labeled examples are required to estimate the disparity matrix than to actually learn the best function in the class.

The assumption that there exist commonly labeled points for each pair of functions is natural in many settings. Consider, for example, the problem of predicting whether or not users will enjoy

certain movies using ratings from other users. It is often the case that pairs of users will have seen many of the same movies. These commonly rated movies can be used to determine how similar each pair of users are, while ratings of additional movies can be reserved to learn the prediction functions.

7. Estimating the Parameters of a Distribution

We now proceed with the study of the related problem of estimating the unknown parameters of a distribution from multiple sources of data. As in the previous sections, we provide a bound on the diversity of an estimator based on the first k sources from the target. Up until this point, we have measured the diversity between two functions by using the expected value of a loss function. The loss is a function of two *specific* observations. Thus, although two functions may not agree on many points, the diversity between them could be zero (if the measure of their disagreement points is zero). In this section we use a more direct way to measure the diversity between two functions by computing the distance between the parameters used to specify these distributions.

Before stating the problem formally we provide with some illustrative examples for intuition.

Example 1 *We wish to estimate the bias θ of a coin given K sources of training observations $N_1,...,N_K$. Each source N_k contains n_k outcomes of flips of a coin with bias θ_k. The only information we are given is that $\theta_k \in [\theta-\varepsilon_k, \theta+\varepsilon_k]$.*

In the next example we consider the simple generalization to the multinomial distribution, which involves more than a single parameter.

Example 2 *We wish to estimate the probability $\Theta^{(p)}$ of a die to fall on its pth side (out of D possible outcomes) given K sources of training observations $N_1,...,N_K$. Each source N_k contains n_k outcomes using a die with parameters $\Theta_k^{(p)}$. The only information provided is a bound on the ℓ_∞ distance between the parameter sets, $\max_p |\Theta_k^{(p)} - \Theta^{(p)}| = \|\Theta_k - \Theta\|_\infty \leq \varepsilon_k$.*

Formally, let $\Pr[X|\Theta]$ be a parametric family of distributions such that $X \in \mathbb{R}^d$ and $\Theta \in \mathbb{R}^D$. We assume that there exists a vector function Ψ such that

$$\mathrm{E}\left[\Psi^{(p)}(X)\right] = \Theta^{(p)} \qquad \text{for } p = 1,\ldots,D\,.$$

This assumption is met, for example, by any member of the exponential family. In the two examples we have discussed, the function Ψ is simply an identity or indicator. This function is useful because it allows us to estimate the parameters of the distribution from data. Let $X_1,\cdots,X_n$ be a sequence of n i.i.d. samples from such a distribution, where the function Ψ is known. Then the estimator obtained by the method of moments is given by the empirical mean

$$\hat{\Theta} = \frac{1}{n}\sum_{i=1}^{n}\Psi(X_i)\,.$$

In our setting, we wish to estimate the parameters Θ of a parametric distribution $\Pr[X|\Theta]$ given K sources of training observations $N_1,...,N_K$. Each source N_k contains n_k outcomes from a distribution with parameters Θ_k, that is, $\Pr[X|\Theta_k]$. The only information we are given is a bound on the ℓ_∞ distance between the parameter sets, $\|\Theta - \Theta_k\|_\infty \leq \varepsilon_k$.

We first bound the deviation of this estimation from the true parameters using Hoeffding's inequality. Fix the value of the index $p = 1,\ldots,D$. We assume that there exist A and $B > 0$ such that,

$$\Psi^{(p)}(X_i) \in [A, A+B] \quad \text{for } i = 1,\ldots,n\ .$$

Then,

$$\Pr\left[\left|\mathrm{E}\left[\hat{\Theta}^{(p)}\right] - \hat{\Theta}^{(p)}\right| \geq \varepsilon\right] \leq 2\exp\left(-2\frac{n\varepsilon^2}{B^2}\right)\ .$$

Setting the right hand-side of the inequality equal to δ and solving for ε, we get

$$\Pr\left[\left|\mathrm{E}\left[\hat{\Theta}^{(p)}\right] - \hat{\Theta}^{(p)}\right| \geq \sqrt{\frac{B^2\ln(\frac{2}{\delta})}{2n}}\right] \leq \delta\ .$$

We can use the union bound to bound on this difference for all D parameters at once and get

$$\Pr\left[\exists p\ :\ \left|\mathrm{E}\left[\hat{\Theta}^{(p)}\right] - \hat{\Theta}^{(p)}\right| \geq \sqrt{\frac{B^2\ln(\frac{2D}{\delta})}{2n}}\right] \leq \sum_{p=1}^{D}\frac{\delta}{D} = \delta\ .$$

This proves the following lemma.

Lemma 15 *Let $X_1,\ldots,X_n$ be a sequence of i.i.d. random variables. Let $\hat{\Theta} = \frac{1}{n}\sum_{i=1}^{n}\Psi(X_i)$ and $\Theta = \mathrm{E}\left[\hat{\Theta}\right]$, where both $\hat{\Theta}$ and Θ are D-dimensional vectors. Assume that $\Psi^{(p)}(X_i) \in [A, A+B]$ for $i = 1,\ldots,n$, $p = 1,\ldots,D$, for some A and $B > 0$. Then, for any $\delta \in (0,1)$ the following bound holds.*

$$\Pr\left[\|\Theta - \hat{\Theta}\|_\infty \geq \sqrt{\frac{B^2\ln(\frac{2D}{\delta})}{2n}}\right] \leq \delta\ .$$

We now turn our attention to the problem of choosing the best sources. We define the estimator using the first k sources to be,

$$\hat{\Theta}_k = \frac{1}{n_{1:k}}\sum_{i=1}^{k}\sum_{X\in N_i}\Psi(X)\ ,$$

where as before $n_{1:k} = \sum_{i=1}^{k} n_i$. We denote the expectation of this estimate by

$$\bar{\Theta}_k = \mathrm{E}\left[\hat{\Theta}_k\right] = \frac{1}{n_{1:k}}\sum_{i=1}^{k} n_i\Theta_i\ .$$

We now bound the deviation of the estimate $\hat{\Theta}_k$ from the true set of parameters Θ using the expectation $\bar{\Theta}_k$,

$$\begin{aligned}
\|\Theta - \hat{\Theta}_k\|_\infty &= \|\Theta - \bar{\Theta}_k + \bar{\Theta}_k - \hat{\Theta}_k\|_\infty \\
&\leq \|\Theta - \bar{\Theta}_k\|_\infty + \|\bar{\Theta}_k - \hat{\Theta}_k\|_\infty \\
&\leq \sum_{i=1}^{k}\frac{n_i\|\Theta - \Theta_i\|_\infty}{n_{1:k}} + \|\bar{\Theta}_k - \hat{\Theta}_k\|_\infty \\
&\leq \sum_{i=1}^{k}\frac{n_i}{n_{1:k}}\varepsilon_k + \|\bar{\Theta}_k - \hat{\Theta}_k\|_\infty\ .
\end{aligned}$$

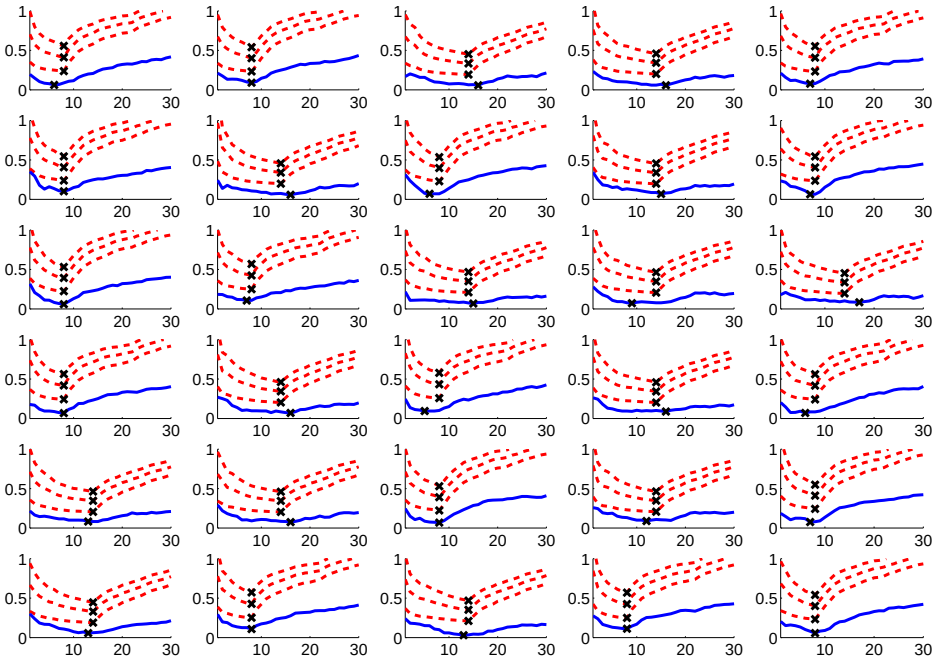

Figure 2: Simulation of the multiple source error bounds.

Let $B = \max_{k=1\ldots K} \sup_X \|\Psi(X)\|_\infty$. We can then use Lemma 15 to bound the second term above, yielding the following theorem.

Theorem 16 *Let $\hat{\Theta}_k$ be the estimate of Θ obtained by using only the data from the first k sources, where both $\hat{\Theta}$ and Θ are D-dimensional vectors. Assume that $-B \leq \Psi^{(p)}(X_i) \leq B$. Then for any $\delta > 0$, with probability $\geq 1-\delta$ we have*

$$\|\Theta - \hat{\Theta}_k\|_\infty \leq \sum_{i=1}^{k} \frac{n_i}{n_{1:k}} \varepsilon_i + \sqrt{\frac{4B^2 \ln(\frac{2DK}{\delta})}{2n_{1:k}}}$$

simultaneously for all $k = 1, \ldots, K$.

As we did with Theorem 3, we can convert Theorem 16 into an algorithm for selecting data sources. Given the K sources of data we simply compute the bounds provided by these theorems for each prefix of the sources of length k and select the subset of sources that yields the smallest bound. A bound for the special case of Example 1 was developed and presented in previous work (Crammer et al., 2006). That bound has the same form as the bound given here in Theorem 16 but with better constants.

8. Synthetic Simulations

In this section, we illustrate the bounds of our main theorem through a simple synthetic simulation. Our hypothesis class $\mathcal{H}$ consists of all linear separators through the origin in 15 dimensions. The

goal is to learn thirty classifiers from this class using only limited amounts of data. These data points are drawn uniformly at random from inside the 15-dimensional unit sphere. In this restricted setting, it is easy to calculate the disparity between two functions. Representing each function f by a unit weight vector w such that $f(x) = \text{sign}(w \cdot x)$, the distance between functions w and w' is simply θ/π where $\theta = \arccos(w \cdot w')$ is the angle between w and w'.

In each simulation we ran, the linear classifiers were generated as follows. First, three base classifiers were generated by choosing weight vectors uniformly at random from the surface of the 15-dimensional sphere. Each of the thirty classifiers was then generated by randomly choosing one of the base classifiers, perturbing each coordinate of its weight vector, and renormalizing the perturbed weights.

The number of training samples available for each function was generated from a Poisson distribution with a mean of 8. Each data instance was then sampled from inside the 15-dimensional unit sphere via rejection sampling and labeled by the corresponding classifier, and 500 test samples for each function were generated in the same manner.

To predict the optimal set of training data sources to use for each model, we calculated an approximation of the multiple-source VC bound for classification. It is well known that the constants in the VC-based uniform convergence bounds are not tight. Thus for the purpose of illustrating how these bounds might be used in practice, we have chosen to show approximations of our bounds with a variety of constants. In particular, we have chosen to approximate the bound with

$$2\sum_{i=1}^{k}\left(\frac{n_k}{n_{1:K}}\right)\varepsilon_k + C\sqrt{\frac{(d\ln(2en_{1:K}/d)+\ln(8K/\delta))}{n_{1:K}}}$$

with $\delta = 0.001$ for different values of C. These approximations yield curves that are closer in shape and magnitude to the actual error than a curve generated using the precise, overly conservative constants of Theorem 6.

The set of plots shown in Figure 2 illustrates the results of a single multiple source simulation. (Results from repeated versions of this experiment and experiments with different source sizes were similar.) Each individual plot represents a particular target function. On the x axis is the number of data sources used in training. On the y axis is error. The solid blue curves show test error of a model trained using logistic regression. Dashed red curves show our multiple source error bound with C set to $1/4$ in the lowest curve, $1/2$ in the middle curve, and $1/\sqrt{2}$ in the highest curve. The $\times$ on each curve marks the minimum value.

These plots clearly show the trade-off that exists. When too few sources are used, there is not enough data available to learn a 15-dimensional function. When too many sources are used, the labels on the training data often will not correspond to the labels that would have been assigned by the target function. The optimal amount of data lies somewhere in between.

Although the VC bounds remain loose even after constants have been dropped, the bounds tend to maintain the appropriate shape and thus predict the optimal set of sources quite well. In general, when C is set to small values, the predicted error values for small amounts of data (low k) tend to be quite accurate, while predicted values for larger amounts of data overestimate the true error. As C is set to larger values, the predictions become much larger in magnitude than the true error curves, but the shape of the prediction curves become more similar to the true error. In both cases, although the bounds are loose, they can still prove useful in determining the optimal set of sources to consider.

Acknowledgments

We thank the anonymous reviewers for many valuable suggestions, especially on the simplified presentation of the application to regression.

Appendix A. Proof of Lemma 8

The proof relies on McDiarmid's inequality (McDiarmid, 1989), which is stated here for completeness.

Lemma 17 (McDiarmid's inequality) *Let $x_1,\ldots,x_n$ be independent random variables taking on values in a set A and assume that $f : A^n \to \mathbb{R}$ satisfies*

$$\sup_{x_1,\ldots,x_n,x_i' \in A} |f(x_1,\ldots,x_n) - f(x_1,\ldots,x_{i-1},x_{i'},x_{i+1},\ldots,x_n)| \leq c_i$$

for every $1 \leq i \leq n$. Then for every $t > 0$,

$$\Pr[f(x_1,\ldots,x_n) - \mathrm{E}[f(x_1,\ldots,x_n)] \geq t] \leq \exp^{-2t^2/\Sigma_{i=1}^n c_i^2} .$$

Here we show one direction of the bound, namely that with probability $1-\delta/2$, for all $h \in \mathcal{H}$,

$$e(h) \leq \hat{e}(h) + 2LR_n(\mathcal{H}) + \sqrt{\frac{2\ln(2/\delta)}{n}} .$$

The proof of the other direction is nearly identical. For $i \in \{1,\ldots,n\}$, let $\langle x_i, y_i\rangle$ be the ith training instance, distributed according to P_i, and let $\langle x_i', y_i'\rangle$ be independent random variables drawn according to P_i. Note that for all $h \in \mathcal{H}$,

$$\begin{aligned}
e(h) &= e(h) + \hat{e}(h) - \hat{e}(h) \leq \hat{e}(h) + \sup_{h' \in \mathcal{H}} \left(e(h') - \hat{e}(h')\right) \\
&= \hat{e}(h) + \sup_{h' \in \mathcal{H}} \left(\mathrm{E}_{\{\langle x_i', y_i'\rangle\}_{i=1}^n} \left[\frac{1}{n}\sum_{i=1}^n \phi(y_i', h'(x_i')) \right] - \frac{1}{n}\sum_{i=1}^n \phi(y_i, h'(x_i)) \right) \\
&= \hat{e}(h) + \sup_{h' \in \mathcal{H}} \left(\mathrm{E}_{\{\langle x_i', y_i'\rangle\}_{i=1}^n} \left[\frac{1}{n}\sum_{i=1}^n \phi'(y_i', h'(x_i')) + \phi(y_i', 0) \right] \right. \\
&\qquad \left. - \frac{1}{n}\sum_{i=1}^n \phi'(y_i, h'(x_i)) + \phi(y_i, 0) \right) .
\end{aligned}$$

When only one instance $\langle x_i, y_i\rangle$ changes, the sup term can change by at most $2/n$. Thus we can apply McDiarmid's inequality to see that with probability at least $1-\delta/2$,

$$e(h) \leq \hat{e}(h) + \mathrm{E}\left[\sup_{h' \in \mathcal{H}} \left(\mathrm{E}\left[\frac{1}{n}\sum_{i=1}^n \phi'(y_i', h'(x_i')) \right] - \frac{1}{n}\sum_{i=1}^n \phi'(y_i, h'(x_i)) \right) \right] + \sqrt{\frac{2\ln(2/\delta)}{n}} ,$$

where the outer expectation is with respect to set of training instances $\{\langle x_i, y_i\rangle\}_{i=1}^n$ and the inner expectation is with respect to the set of random variables $\{\langle x_i', y_i'\rangle\}_{i=1}^n$. Now it suffices to show that

this middle term is bounded by $2LR_n(\mathcal{H})$. Using the fact that the supremum of an expectation is less than or equal to the expectation of a supremum, we find that

$$\begin{aligned}
&\mathrm{E}_{\{\langle x_i,y_i\rangle\}_{i=1}^n}\left[\sup_{h'\in\mathcal{H}}\left(\mathrm{E}_{\{\langle x_i',y_i'\rangle\}_{i=1}^n}\left[\frac{1}{n}\sum_{i=1}^n \phi'(y_i',h'(x_i'))\right]-\frac{1}{n}\sum_{i=1}^n \phi'(y_i,h'(x_i))\right)\right]\\
&\quad\leq\quad \mathrm{E}_{\{\langle x_i,y_i\rangle\}_{i=1}^n,\{\langle x_i',y_i'\rangle\}_{i=1}^n}\left[\sup_{h'\in\mathcal{H}}\frac{1}{n}\sum_{i=1}^n\left(\phi'(y_i',h'(x_i'))-\phi'(y_i,h'(x_i))\right)\right]\\
&\quad=\quad \mathrm{E}_{\{\langle x_i,y_i\rangle\}_{i=1}^n,\{\langle x_i',y_i'\rangle\}_{i=1}^n,\{\sigma_i\}_{i=1}^n}\left[\sup_{h'\in\mathcal{H}}\frac{1}{n}\sum_{i=1}^n\sigma_i\left(\phi'(y_i',h'(x_i'))-\phi'(y_i,h'(x_i))\right)\right]\\
&\quad\leq\quad \mathrm{E}_{\{\langle x_i,y_i\rangle\}_{i=1}^n,\{\sigma_i\}_{i=1}^n}\left[\sup_{h'\in\mathcal{H}}\frac{2}{n}\sum_{i=1}^n\sigma_i\phi'(y_i,h'(x_i))\right]=R_n(\phi'\circ\mathcal{H})\ .
\end{aligned}$$

Lemma 7 implies that $R_n(\phi'\circ\mathcal{H})\leq 2LR_n(\mathcal{H})$ since ϕ is Lipschitz with parameter L. The result follows.

Abstract

Log-linear and maximum-margin models are two commonly-used methods in supervised machine learning, and are frequently used in structured prediction problems. Efficient learning of parameters in these models is therefore an important problem, and becomes a key factor when learning from very large data sets. This paper describes exponentiated gradient (EG) algorithms for training such models, where EG updates are applied to the convex dual of either the log-linear or max-margin objective function; the dual in both the log-linear and max-margin cases corresponds to minimizing a convex function with simplex constraints. We study both batch and online variants of the algorithm, and provide rates of convergence for both cases. In the max-margin case, $O(\frac{1}{\varepsilon})$ EG updates are required to reach a given accuracy ε in the dual; in contrast, for log-linear models only $O(\log(\frac{1}{\varepsilon}))$ updates are required. For both the max-margin and log-linear cases, our bounds suggest that the online EG algorithm requires a factor of n less computation to reach a desired accuracy than the batch EG algorithm, where n is the number of training examples. Our experiments confirm that the online algorithms are much faster than the batch algorithms in practice. We describe how the EG updates factor in a convenient way for structured prediction problems, allowing the algorithms to be efficiently applied to problems such as sequence learning or natural language parsing. We perform extensive evaluation of the algorithms, comparing them to L-BFGS and stochastic gradient descent for log-linear models, and to SVM-Struct for max-margin models. The algorithms are applied to a multi-class problem as well as to a more complex large-scale parsing task. In all these settings, the EG algorithms presented here outperform the other methods.

Keywords: exponentiated gradient, log-linear models, maximum-margin models, structured prediction, conditional random fields

1. Introduction

Structured prediction problems involve learning to map inputs x to labels y, where the labels have rich internal structure, and where the set of possible labels for a given input is typically exponential in size. Examples of structured prediction problems include sequence labeling and natural language parsing. Several models that implement learning in this scenario have been proposed over the last few years, including log-linear models such as conditional random fields (CRFs, Lafferty et al., 2001), and maximum-margin models such as maximum-margin Markov networks (Taskar et al., 2004a).

For both log-linear and max-margin models, learning is framed as minimization of a regularized loss function which is convex. In spite of the convexity of the objective function, finding the optimal parameters for these models can be computationally intensive, especially for very large data sets. This problem is exacerbated in structured prediction problems, where the large size of the set of possible labels adds an additional layer of complexity. The development of efficient optimization algorithms for learning in structured prediction problems is therefore an important problem.

In this paper we describe learning algorithms that exploit the structure of the dual optimization problems for log-linear and max-margin models. For both log-linear and max-margin models the dual problem corresponds to the minimization of a convex function Q subject to simplex constraints (Jaakkola and Haussler, 1999; Lebanon and Lafferty, 2002; Taskar et al., 2004a). More specifically, the goal is to find

$$\operatorname*{argmin}_{\forall i,\, \mathbf{u}_i \in \Delta} Q(\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_n) \;, \tag{1}$$

where n is the number of training examples, each $\mathbf{u}_i$ is a vector of dual variables for the i'th training example, and $Q(\mathbf{u})$ is a convex function.[1] The size of each vector $\mathbf{u}_i$ is $|\mathcal{Y}|$, where $\mathcal{Y}$ is the set of possible labels for any training example. Furthermore, $\mathbf{u}_i$ is constrained to belong to the simplex of distributions over $\mathcal{Y}$, defined as:

$$\Delta = \left\{ \mathbf{p} \in \mathbb{R}^{|\mathcal{Y}|} : p_y \geq 0 \;\;,\;\; \sum_{y \in \mathcal{Y}} p_y = 1 \right\} \;. \tag{2}$$

Thus each $\mathbf{u}_i$ is constrained to form a distribution over the set of possible labels. The max-margin and log-linear problems differ only in their definition of Q.

The algorithms in this paper make use of exponentiated gradient (EG) updates (Kivinen and Warmuth, 1997) in solving the problem in Eq. 1, in particular for the cases of log-linear or max-margin models. We focus on two classes of algorithms, which we call *batch* and *online*. In the batch case, the entire set of $\mathbf{u}_i$ variables is updated simultaneously at each iteration of the algorithm; in the online case, a single $\mathbf{u}_i$ variable is updated at each step. The "online" case essentially corresponds to coordinate-descent on the dual function Q, and is similar to the SMO algorithm (Platt, 1998) for training SVMs. The online algorithm has the advantage of updating the parameters after every sample point, rather than after making a full pass over the training examples; intuitively, this should lead to considerably faster rates of convergence when compared to the batch algorithm, and indeed our experimental and theoretical results support this intuition. A different class of online algorithms consists of stochastic gradient descent (SGD) and its variants (e.g., see LeCun et al., 1998; Vishwanathan et al., 2006). In contrast to SGD, however, the EG algorithm is guaranteed to

1. In what follows we use $\mathbf{u}$ to denote the variables $\mathbf{u}_1, \ldots, \mathbf{u}_n$.

improve the dual objective at each step, and this objective may be calculated after each example without performing a pass over the entire data set. This is particularly convenient when making a choice of learning rate in the updates.

We describe theoretical results concerning the convergence of the EG algorithms, as well as experiments. Our key results are as follows:

- For the max-margin case, we show that $O(\frac{1}{\varepsilon})$ time is required for both the online and batch algorithms to converge to within ε of the optimal value of $Q(\mathbf{u})$. This is qualitatively similar to recent results in the literature for max-margin approaches (e.g., see Shalev-Shwartz et al., 2007). For log-linear models, we show convergence rates of $O(\log(\frac{1}{\varepsilon}))$, a significant improvement over the max-margin case.

- For both the max-margin and log-linear cases, our bounds suggest that the online algorithm requires a factor of n less computation to reach a desired accuracy, where n is the number of training examples. Our experiments confirm that the online algorithms are much faster than the batch algorithms in practice.

- We describe how the EG algorithms can be efficiently applied to an important class of structured prediction problems where the set of labels $\mathcal{Y}$ is exponential in size. In this case the number of dual variables is also exponential in size, making algorithms which deal directly with the $\mathbf{u}_i$ variables intractable. Following Bartlett et al. (2005), we focus on a formulation where each label y is represented as a set of "parts", for example corresponding to labeled cliques in a max-margin network, or context-free rules in a parse tree. Under an assumption that part-based marginals can be calculated efficiently—for example using junction tree algorithms for CRFs, or the inside-outside algorithm for context-free parsing—the EG algorithms can be implemented efficiently for both max-margin and log-linear models.

- In our experiments we compare the online EG algorithm to various state-of-the-art algorithms. For log-linear models, we compare to the L-BFGS algorithm (Byrd et al., 1995) and to stochastic gradient descent. For max-margin models we compare to the SVM-Struct algorithm of Tsochantaridis et al. (2004). The methods are applied to a standard multi-class learning problem, as well as to a more complex natural language parsing problem. In both settings we show that the EG algorithm converges to the optimum much faster than the other algorithms.

- In addition to proving convergence results for the definition of $Q(\mathbf{u})$ used in max-margin and log-linear models, we give theorems which may be useful when optimizing other definitions of $Q(\mathbf{u})$ using EG updates. In particular, we give conditions for convergence which depend on bounds relating the Bregman divergence derived from $Q(\mathbf{u})$ to the Kullback-Leibler divergence. Depending on the form of these bounds for a particular $Q(\mathbf{u})$, either $O(\frac{1}{\varepsilon})$ or $O(\log(\frac{1}{\varepsilon}))$ rates of convergence can be derived.

The rest of this paper is organized as follows. In Section 2, we introduce the log-linear and max-margin learning problems, and describe their dual optimization problems. Section 3 describes the batch and online EG algorithms; in Section 4, we describe how the algorithms can be efficiently applied to structured prediction problems. Section 5 then gives convergence proofs for the batch and

online cases. Section 6 discusses related work. Sections 7 and 8 give experiments, and Section 9 discusses our results.

This work builds on previous work described by Bartlett et al. (2005) and Globerson et al. (2007). Bartlett et al. (2005) described the application of the EG algorithm to max-margin parameter estimation, and showed how the method can be applied efficiently to part-based formulations. Globerson et al. (2007) extended the approach to log-linear parameter estimation, and gave new convergence proofs for both max-margin and log-linear estimation. The work in the current paper gives several new results. We prove rates of convergence for a randomized version of the EG online algorithm; previous work on EG algorithms had not given convergence rates for the online case. We also report new experiments, including experiments with the randomized strategy. Finally, the $O(\log(\frac{1}{\varepsilon}))$ convergence rates for the log-linear case are new. The results in Globerson et al. (2007) gave $O(\frac{1}{\varepsilon})$ rates for the batch algorithm for log-linear models, and did not give any theoretical rates of convergence for the online case.

2. Primal and Dual Problems for Regularized Loss Minimization

In this section we present the log-linear and max-margin optimization problems for supervised learning. For each problem, we describe the equivalent dual optimization problem, which will form the core of our optimization approach.

2.1 The Primal Problems

Consider a supervised learning setting with objects $x \in \mathcal{X}$ and labels $y \in \mathcal{Y}$.[2] In the structured learning setting, the labels may be sequences, trees, or other high-dimensional data with internal structure. Assume we are given a function $\mathbf{f}(x,y) : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^d$ that maps (x,y) pairs to feature vectors. Our goal is to construct a linear prediction rule

$$h(x,\mathbf{w}) = \operatorname*{argmax}_{y \in \mathcal{Y}} \mathbf{w} \cdot \mathbf{f}(x,y) \ ,$$

with parameters $\mathbf{w} \in \mathbb{R}^d$, such that $h(x,\mathbf{w})$ is a good approximation of the *true* label of x. The parameters $\mathbf{w}$ are learned by minimizing a regularized loss

$$\mathcal{L}(\mathbf{w}; \{(x_i,y_i)\}_{i=1}^n, C) = \sum_{i=1}^n \ell(\mathbf{w},x_i,y_i) + \frac{C}{2}\|\mathbf{w}\|^2 \ ,$$

defined over a labeled training set $\{(x_i,y_i)\}_{i=1}^n$. Here $C > 0$ is a constant determining the amount of regularization. The function ℓ measures the loss incurred in using $\mathbf{w}$ to predict the label of x_i, given that the true label is y_i.

In this paper we will consider two definitions for $\ell(\mathbf{w},x_i,y_i)$. The first definition, originally introduced by Taskar et al. (2004a), is a variant of the hinge loss, and is defined as follows:

$$\ell_{\text{MM}}(\mathbf{w},x_i,y_i) = \max_{y \in \mathcal{Y}} \Big[e(x_i,y_i,y) - \mathbf{w} \cdot (\mathbf{f}(x_i,y_i) - \mathbf{f}(x_i,y)) \Big] \ . \tag{3}$$

2. In general the set of labels for a given example x may be a set $\mathcal{Y}(x)$ that depends on x; in fact, in our experiments on dependency parsing $\mathcal{Y}$ does depend on x. For simplicity, in this paper we use the fixed notation $\mathcal{Y}$ for all x; it is straightforward to extend our notation to the more general case.

Here $e(x_i,y_i,y)$ is some non-negative measure of the error incurred in predicting y instead of y_i as the label of x_i. We assume that $e(x_i,y_i,y_i) = 0$ for all i, so that no loss is incurred for correct prediction, and therefore $\ell_{\rm MM}(\mathbf{w},x_i,y_i)$ is always non-negative. This loss function corresponds to a maximum-margin approach, which explicitly penalizes training examples for which, for some $y \neq y_i$,

$$\mathbf{w}\cdot(\mathbf{f}(x_i,y_i)-\mathbf{f}(x_i,y)) < e(x_i,y_i,y) \ .$$

The second loss function that we will consider is based on log-linear models, and is commonly used in conditional random fields (CRFs, Lafferty et al., 2001). First define the conditional distribution

$$p(y\,|\,x;\mathbf{w}) = \frac{1}{Z_x} e^{\mathbf{w}\cdot\mathbf{f}(x,y)} \ ,$$

where $Z_x = \sum_y e^{\mathbf{w}\cdot\mathbf{f}(x,y)}$ is the partition function. The loss function is then the negative log-likelihood under the parameters $\mathbf{w}$:

$$\ell_{\rm LL}(\mathbf{w},x_i,y_i) = -\log p(y_i\,|\,x_i;\mathbf{w}) \ .$$

The function $\mathcal{L}$ is convex in $\mathbf{w}$ for both definitions $\ell_{\rm MM}$ and $\ell_{\rm LL}$. Furthermore, in both cases minimization of $\mathcal{L}$ can be re-cast as optimization of a dual convex problem. The dual problems in the two cases have a similar structure, as we describe in the next two sections.

2.2 The Log-Linear Dual

The problem of minimizing $\mathcal{L}$ with the loss function $\ell_{\rm LL}$ can be written as

$$\underline{\text{P-LL}}: \quad \mathbf{w}^* = \operatorname*{argmin}_{\mathbf{w}} \sum_i -\log p(y_i\,|\,x_i;\mathbf{w}) + \frac{C}{2}\|\mathbf{w}\|^2 \ .$$

This is a convex optimization problem, and has an equivalent convex dual which was derived by Lebanon and Lafferty (2002). Denote the dual variables by $u_{i,y}$ where $i = 1,\ldots,n$ and $y \in \mathcal{Y}$. We also use $\mathbf{u}$ to denote the set of all variables, and $\mathbf{u}_i$ the set of all variables corresponding to a given i. Thus $\mathbf{u} = [\mathbf{u}_1,\ldots,\mathbf{u}_n]$. We assume $\mathbf{u}$ is a column vector. Define the function $Q_{\rm LL}(\mathbf{u})$ as

$$Q_{\rm LL}(\mathbf{u}) = \sum_i \sum_y u_{i,y}\log u_{i,y} + \frac{1}{2C}\|\mathbf{w}(\mathbf{u})\|^2 \ ,$$

where

$$\mathbf{w}(\mathbf{u}) = \sum_i \sum_y u_{i,y}\mathbf{g}_{i,y} \ ,$$

and where $\mathbf{g}_{i,y} = \mathbf{f}(x_i,y_i) - \mathbf{f}(x_i,y)$. We shall find the following matrix notation convenient:

$$Q_{\rm LL}(\mathbf{u}) = \sum_i \sum_y u_{i,y}\log u_{i,y} + \frac{1}{2}\mathbf{u}^T A\mathbf{u} \ , \tag{4}$$

where A is a matrix of size $n|\mathcal{Y}| \times n|\mathcal{Y}|$ indexed by pairs (i,y), and $A_{(i,y),(j,z)} = \frac{1}{C}\mathbf{g}_{i,y}\cdot\mathbf{g}_{j,z}$.

In what follows we denote the set of distributions over $\mathcal{Y}$, that is, the $|\mathcal{Y}|$-dimensional probability simplex, by Δ, as in Eq. 2. The Cartesian product of n distributions over $\mathcal{Y}$ will be denoted by Δ^n. The dual optimization problem is then

$$\underline{\text{D-LL}}: \quad \mathbf{u}^* = \begin{array}{ll} \operatorname{argmin} & Q_{\rm LL}(\mathbf{u}) \\ s.t. & \mathbf{u} \in \Delta^n \ . \end{array}$$

The minimum of D-LL is equal to -1 times the minimum of P-LL. The duality between P-LL and D-LL implies that the primal and dual solutions satisfy $C\mathbf{w}^* = \mathbf{w}(\mathbf{u}^*)$.

2.3 The Max-Margin Dual

When the loss is defined using $\ell_{\text{MM}}(\mathbf{w}, x_i, y_i)$, the primal optimization problem is as follows:

$$\underline{\text{P-MM}}: \quad \mathbf{w}^* = \operatorname*{argmin}_{\mathbf{w}} \sum_i \max_y \Big[e(x_i, y_i, y) - \mathbf{w} \cdot (\mathbf{f}(x_i, y_i) - \mathbf{f}(x_i, y)) \Big] + \frac{C}{2} \|\mathbf{w}\|^2 \ .$$

The dual of this minimization problem was derived in Taskar et al. (2004a) (see also Bartlett et al., 2005). We first define the dual objective

$$Q_{\text{MM}}(\mathbf{u}) = -\mathbf{b}^T \mathbf{u} + \frac{1}{2} \mathbf{u}^T A \mathbf{u} \ . \tag{5}$$

Here, the matrix A is as defined above and $\mathbf{b} \in \mathbb{R}^{n|\mathcal{Y}|}$ is a vector defined as $b_{i,y} = e(x_i, y_i, y)$. The convex dual for the max-margin case is then given by

$$\underline{\text{D-MM}}: \quad \mathbf{u}^* = \begin{array}{ll} \operatorname{argmin} & Q_{\text{MM}}(\mathbf{u}) \\ s.t. & \mathbf{u} \in \Delta^n \ . \end{array}$$

The minimum of D-MM is equal to -1 times the minimum of P-MM. (Note that for D-MM the minimizer $\mathbf{u}^*$ may not be unique; in this case we take $\mathbf{u}^*$ to be any member of the set of minimizers of $Q_{\text{MM}}(\mathbf{u})$). The optimal primal parameters are again related to the optimal dual parameters, through $C\mathbf{w}^* = \mathbf{w}(\mathbf{u}^*)$. Here again the constraints are that $\mathbf{u}_i$ is a distribution over $\mathcal{Y}$ for all i.

It can be seen that the D-LL and D-MM problems have a similar structure, in that they both involve minimization of a convex function $Q(\mathbf{u})$ over the set Δ^n. This will allow us to describe algorithms for both problems using a common framework.

3. Exponentiated Gradient Algorithms

In this section we describe batch and online algorithms for minimizing a convex function $Q(\mathbf{u})$ subject to the constraints $\mathbf{u} \in \Delta^n$. The algorithms can be applied to both the D-LL and D-MM optimization problems that were introduced in the previous section. The algorithms we describe are based on exponentiated gradient (EG) updates, originally introduced by Kivinen and Warmuth (1997) in the context of online learning algorithms.[3]

The EG updates rely on the following operation. Given a sequence of distributions $\mathbf{u} \in \Delta^n$, a new sequence of distributions $\mathbf{u}'$ can be obtained as

$$u'_{i,y} = \frac{1}{Z_i} u_{i,y} e^{-\eta \nabla_{i,y}} \ ,$$

where $\nabla_{i,y} = \frac{\partial Q(\mathbf{u})}{\partial u_{i,y}}$, $Z_i = \sum_{\hat{y}} u_{i,\hat{y}} e^{-\eta \nabla_{i,\hat{y}}}$ is a partition function ensuring normalization of the distribution $\mathbf{u}'_i$, and the parameter $\eta > 0$ is a learning rate. We will also use the notation $u'_{i,y} \propto u_{i,y} e^{-\eta \nabla_{i,y}}$ where the partition function should be clear from the context.

3. Kivinen and Warmuth (1997) study the online setting, as opposed to a fixed data set which we study here. They are thus not interested in minimizing a fixed objective, but rather study regret type bounds. This leads to algorithms and theoretical analyses that are different from the ones considered in the current work.

Clearly $\mathbf{u}' \in \Delta^n$ by construction. For the dual function $Q_{\text{LL}}(\mathbf{u})$ the gradient is

$$\nabla_{i,y} = 1 + \log u_{i,y} + \frac{1}{C}\mathbf{w}(\mathbf{u}) \cdot \mathbf{g}_{i,y} \ ,$$

and for $Q_{\text{MM}}(\mathbf{u})$ the gradient is

$$\nabla_{i,y} = -b_{i,y} + \frac{1}{C}\mathbf{w}(\mathbf{u}) \cdot \mathbf{g}_{i,y} \ .$$

In this paper we will consider both parallel (batch), and sequential (online) applications of the EG updates, defined as follows:

- **Batch**: At every iteration the dual variables $\mathbf{u}_i$ are simultaneously updated for all $i = 1, \ldots, n$.
- **Online**: At each iteration a single example k is chosen uniformly at random from $\{1, \ldots, n\}$ and $\mathbf{u}_k$ is updated to give $\mathbf{u}'_k$. The dual variables $\mathbf{u}_i$ for $i \neq k$ are left unchanged.

Pseudo-code for the two schemes is given in Figures 1 and 2. From here on we will refer to the batch and online EG algorithms applied to the log-linear dual as LLEG-Batch, and LLEG-Online respectively. Similarly, when applied to the max-margin dual, they will be referred to as MMEG-Batch and MMEG-Online.

Note that another plausible online algorithm would be a "deterministic" algorithm that repeatedly cycles over the training examples in a fixed order. The motivation for the alternative, randomized, algorithm is two-fold. First, we are able to prove bounds on the rate of convergence of the randomized algorithm; we have not been able to prove similar bounds for the deterministic variant. Second, our experiments show that the randomized variant converges significantly faster than the deterministic algorithm.

The EG online algorithm is essentially performing coordinate descent on the dual objective, and is similar to SVM algorithms such as SMO (Platt, 1998). For binary classification, the exact minimum of the dual objective with respect to a given coordinate can be found in closed form,[4] and more complicated algorithms such as the exponentiated-gradient method may be unnecessary. However for multi-class or structured problems, the exact minimum with respect to a coordinate $\mathbf{u}_i$ (i.e., a set of $|\mathcal{Y}|$ dual variables) cannot be found in closed form: this is a key motivation for the use of EG algorithms in this paper.

In Section 5 we give convergence proofs for the batch and online algorithms. The techniques used in the convergence proofs are quite general, and could potentially be useful in deriving EG algorithms for convex functions Q other than Q_{LL} and Q_{MM}. Before giving convergence results for the algorithms, we describe in the next section how the EG algorithms can be applied to structured problems.

4. Structured Prediction with the EG Algorithms

We now describe how the EG updates can be applied to structured prediction problems, for example parameter estimation in CRFs or natural language parsing. In structured problems the label set $\mathcal{Y}$ is typically very large, but labels can have useful internal structure. As one example, in CRFs each

4. This is true for the max-margin case. For log-linear models, minimization with respect to a single coordinate is a little more involved.

Inputs: A convex function $Q : \Delta^n \to \mathbb{R}$, a learning rate $\eta > 0$.

Initialization: Set $\mathbf{u}^1$ to a point in the interior of Δ^n.

Algorithm:

- For $t = 1, \ldots, T$, repeat:
  - For all i, y, calculate $\nabla_{i,y} = \frac{\partial Q(\mathbf{u}^t)}{\partial u_{i,y}}$
  - For all i, y, update $u_{i,y}^{t+1} \propto u_{i,y}^t e^{-\eta \nabla_{i,y}}$

Output: Final parameters $\mathbf{u}^{T+1}$.

Figure 1: A general batch EG Algorithm for minimizing $Q(\mathbf{u})$ subject to $\mathbf{u} \in \Delta^n$. We use $\mathbf{u}^t$ to denote the set of parameters after t iterations.

Inputs: A convex function $Q : \Delta^n \to \mathbb{R}$, a learning rate $\eta > 0$.

Initialization: Set $\mathbf{u}^1$ to a point in the interior of Δ^n.

Algorithm:

- For $t = 1, \ldots, T$, repeat:
  - Choose k_t uniformly at random from the set $\{1, 2, \ldots, n\}$
  - For all y, calculate: $\nabla_{k_t,y} = \frac{\partial Q(\mathbf{u}^t)}{\partial u_{k_t,y}}$
  - For all y, update $u_{k_t,y}^{t+1} \propto u_{k_t,y}^t e^{-\eta \nabla_{k_t,y}}$
  - For all $i \neq k_t$, set $\mathbf{u}_i^{t+1} = \mathbf{u}_i^t$

Output: Final parameters $\mathbf{u}^{T+1}$.

Figure 2: A general randomized online EG Algorithm for minimizing $Q(\mathbf{u})$ subject to $\mathbf{u} \in \Delta^n$.

label y is an m-dimensional vector specifying the labeling of all m vertices in a graph. In parsing each label y is an entire parse tree. In both of these cases, the number of labels typically grows exponentially quickly with respect to the size of the inputs x.

We follow the framework for structured problems described by Bartlett et al. (2005). Each label y is defined to be a set of *parts*. We use R to refer to the set of all possible parts.[5] We make the assumption that the feature vector for an entire label y decomposes into a sum over feature vectors for individual parts as follows:

$$\mathbf{f}(x, y) = \sum_{r \in y} \mathbf{f}(x, r) \ .$$

5. As with the label set $\mathcal{Y}$, the set of parts R may in general be a set $R(x)$ that depends on x. For simplicity, we assume that R is fixed.

Note that we have overloaded $\mathbf{f}$ to apply to either labels y or parts r.

As one example, consider a CRF which has an underlying graph with m nodes, and a maximum clique size of 2. Assume that each node can be labeled with one of two labels, 0 or 1. In this case the labeling of an entire graph is a vector $\mathbf{y} \in \{0,1\}^m$. Each possible input x is usually a vector in $\mathcal{X}^m$ for some set $\mathcal{X}$, although this does not have to be the case. Each part corresponds to a tuple (u,v,y_u,y_v) where (u,v) is an edge in the graph, and y_u, y_v are the labels for the two vertices u and v. The feature vector $\mathbf{f}(x,r)$ can then track any properties of the input x together with the labeled clique $r = (u,v,y_u,y_v)$. In CRFs with clique size greater than 2, each part corresponds to a labeled clique in the graph. In natural language parsing, each part can correspond to a context-free rule at a particular position in the sentence x (see Bartlett et al., 2005; Taskar et al., 2004b, for more details).

The label set $\mathcal{Y}$ can be extremely large in structured prediction problems. For example, in a CRF with an underlying graph with m nodes and k possible labels at each node, there are k^m possible labelings of the entire graph. The algorithms we have presented so far require direct manipulation of dual variables $u_{i,y}$ corresponding to each possible labeling of each training example; they will therefore be intractable in cases where there are an exponential number of possible labels. However, in this section we describe an approach that does allow an efficient implementation of the algorithms in several cases. The approach is based on the method originally described in Bartlett et al. (2005).

The key idea is as follows. Instead of manipulating the dual variables $\mathbf{u}_i$ for each i directly, we will make use of alternative data structures $\mathbf{s}_i$ for all i. Each $\mathbf{s}_i$ is a vector of real values $s_{i,r}$ for all $r \in R$. In general we will assume that there are a tractable (polynomial) number of possible parts, and therefore that the number of $s_{i,r}$ variables is also polynomial. For example, for a linear chain CRF with m nodes and k labels at every node, each part takes the form $r = (u,v,y_u,y_v)$, and there are $(m-1)k^2$ possible parts.

In the max-margin case, we follow Taskar et al. (2004a) and make the additional assumption that the error function decomposes into "local" error functions over parts:

$$e(x_i,y_i,y) = \sum_{r \in y} e(x_i,y_i,r) \ .$$

For example, when $\mathcal{Y}$ is a sequence of variables, the cost could be the Hamming distance between the correct sequence y_i and the predicted sequence y; it is straightforward to decompose the Hamming distance as a sum over parts as shown above. For brevity, in what follows we use $e_{i,r}$ instead of $e(x_i,y_i,r)$.

The $\mathbf{s}_i$ variables are used to implicitly define regular dual values $\mathbf{u}_i = \mathbf{p}(\mathbf{s}_i)$ where $\mathbf{p} : \mathbb{R}^{|R|} \to \Delta$ is defined as

$$p_y(\mathbf{s}) = \frac{\exp\left\{\sum_{r \in y} s_r\right\}}{\sum_{y'} \exp\left\{\sum_{r \in y'} s_r\right\}} \ .$$

To see how the $\mathbf{s}_i$ variables can be updated, consider again the EG updates on the dual $\mathbf{u}$ variables. The EG updates in all algorithms in this paper take the form

$$u'_{i,y} = \frac{u_{i,y} \exp\{-\eta \nabla_{i,y}\}}{\sum_{\hat{y}} u_{i,\hat{y}} \exp\{-\eta \nabla_{i,\hat{y}}\}} \ ,$$

where for Q_{LL}

$$\nabla_{i,y} = 1 + \log u_{i,y} + \frac{1}{C} \mathbf{w}(\mathbf{u}) \cdot (\mathbf{f}(x_i,y_i) - \mathbf{f}(x_i,y)) \ ,$$

and for Q_{MM},

$$\nabla_{i,y} = -b_{i,y} + \frac{1}{C}\mathbf{w}(\mathbf{u}) \cdot (\mathbf{f}(x_i, y_i) - \mathbf{f}(x_i, y)) \ ,$$

where $b_{i,y} = e(x_i, y_i, y)$ as in Section 2.3.

Notice that, for both objective functions, the gradients can be expressed as a sum over parts. For the Q_{LL} objective function, this follows from the fact that $\mathbf{u}_i = \mathbf{p}(\mathbf{s}_i)$ and from the assumption that the feature vector decomposes into parts. For the Q_{MM} objective, it follows from the latter, and the assumption that the loss decomposes into parts. The following lemma describes how EG updates on the $\mathbf{u}$ variables can be restated in terms of updates to the $\mathbf{s}$ variables, provided that the gradient decomposes into parts in this way.

Lemma 1 *For a given $\mathbf{u} \in \Delta^n$, and for a given $i \in [1 \ldots n]$, take $\mathbf{u}'_i$ to be the updated value for $\mathbf{u}_i$ derived using an EG step, that is,*

$$u'_{i,y} = \frac{u_{i,y} \exp\{-\eta \nabla_{i,y}\}}{\sum_{\hat{y}} u_{i,\hat{y}} \exp\{-\eta \nabla_{i,\hat{y}}\}} \ .$$

Suppose that, for some G_i and $g_{i,r}$, we can write $\nabla_{i,y} = G_i + \sum_{r \in y} g_{i,r}$ for all y. Then if $\mathbf{u}_i = \mathbf{p}(\mathbf{s}_i)$ for some $\mathbf{s}_i \in \mathcal{R}^{|R|}$, and for all r we define

$$s'_{i,r} = s_{i,r} - \eta g_{i,r} \ ,$$

it follows that $\mathbf{u}'_i = \mathbf{p}(\mathbf{s}'_i)$.

Proof: We show that, for $\mathbf{u}_i = \mathbf{p}(\mathbf{s}_i)$, updating the $s_{i,r}$ as described leads to $\mathbf{p}(\mathbf{s}'_i) = \mathbf{u}'_i$. For suitable partition functions Z_i, Z'_i, and Z''_i, we can write

$$\begin{aligned}
p_y(\mathbf{s}'_i) &= \frac{\exp\left\{\sum_{r \in y}(s_{i,r} - \eta g_{i,r})\right\}}{Z_i} \\
&= \frac{u_{i,y} \exp\left\{-\eta \sum_{r \in y} g_{i,r}\right\}}{Z'_i} \\
&= \frac{u_{i,y} \exp\{-\eta(\nabla_{i,y} - G_i)\}}{Z'_i} \\
&= \frac{u_{i,y} \exp\{-\eta \nabla_{i,y}\}}{Z''_i} \\
&= u'_{i,y} \ .
\end{aligned}$$

□

In the case of the Q_{LL} objective, a suitable update is

$$s'_{i,r} = s_{i,r} - \eta \left(s_{i,r} - \frac{1}{C}\mathbf{w}(\mathbf{u}) \cdot \mathbf{f}(x_i, r) \right) \ .$$

In the case of the Q_{MM} objective, a suitable update is

$$s'_{i,r} = s_{i,r} - \eta \left(-e_{i,r} - \frac{1}{C}\mathbf{w}(\mathbf{u}) \cdot \mathbf{f}(x_i, r) \right) \ .$$

Inputs: Examples $\{(x_i,y_i)\}_{i=1}^n$, learning rate $\eta > 0$.

Initialization: For each $i = 1 \ldots n$, set $\mathbf{s}_i^1$ to some (possibly different) point in $\mathbb{R}^{|R|}$.

Algorithm:

- Calculate
$$\mathbf{w}^1 = \sum_i \mathbf{f}(x_i,y_i) - \sum_{i,y} p_y(\mathbf{s}_i^1)\mathbf{f}(x_i,y)$$
- For $t = 1,\ldots,T$, repeat:
  - Choose k_t uniformly at random from the set $[1,2,\ldots,n]$
  - For all $r \in R$,
$$\textbf{If optimizing } Q_{\text{LL}}\textbf{:} \quad s_{k_t,r}^{t+1} = s_{k_t,r}^t - \eta\left(s_{k_t,r}^t - \frac{1}{C}\mathbf{w}^t \cdot \mathbf{f}(x_{k_t},r)\right)$$
$$\textbf{If optimizing } Q_{\text{MM}}\textbf{:} \quad s_{k_t,r}^{t+1} = s_{k_t,r}^t - \eta\left(-e_{k_t,r} - \frac{1}{C}\mathbf{w}^t \cdot \mathbf{f}(x_{k_t},r)\right)$$
  - For all $i \neq k_t$, for all r, set $s_{i,r}^{t+1} = s_{i,r}^t$
  - Calculate
$$\begin{aligned}\mathbf{w}^{t+1} &= \sum_i \mathbf{f}(x_i,y_i) - \sum_{i,y} p_y(\mathbf{s}_i^{t+1})\mathbf{f}(x_i,y) \\ &= \mathbf{w}^t + \sum_y p_y(\mathbf{s}_{k_t}^t)\mathbf{f}(x_{k_t},y) - \sum_y p_y(\mathbf{s}_{k_t}^{t+1})\mathbf{f}(x_{k_t},y)\end{aligned}$$

Output: Final dual parameters $\mathbf{s}^{T+1}$ or primal parameters $\frac{1}{C}\mathbf{w}^{T+1}$.

Figure 3: An implementation of the algorithm in Figure 2 using a part-based representation. The algorithm uses variables $\mathbf{s}_i$ for $i = 1 \ldots n$ as a replacement for the dual variables $\mathbf{u}_i$ in Figure 2.

Because of this result, all of the EG algorithms that we have presented can be restated in terms of the **s** variables: instead of maintaining a sequence $\mathbf{u}^t = \{\mathbf{u}_1^t, \mathbf{u}_2^t, \ldots, \mathbf{u}_n^t\}$ of dual variables, a sequence $\mathbf{s}^t = \{\mathbf{s}_1^t, \mathbf{s}_2^t, \ldots, \mathbf{s}_n^t\}$ is maintained and updated using the method described in the above lemmas.[6] To illustrate this, Figure 3 gives a version of the randomized algorithm in Figure 2 that makes use of **s** variables. The batch algorithm can be implemented in a similar way.

6. Note that in the max-margin case, the optimal **u** values may have zero probabilities which correspond to infinite **s** values. This does not pose a problem, since the algorithm will indeed converge to infinite **s** values at the limit, but $\mathbf{s}^t$ will not be infinite for any finite t. For the log-linear case, the optimal **u** will never have zero values, as shown in Globerson et al. (2007).

The main computational challenge in the new algorithms comes in computing the parameter vector $\mathbf{w}(\mathbf{p}(\mathbf{s}^t))$. The value for $\mathbf{w}(\mathbf{p}(\mathbf{s}^t))$ can be expressed as a function of the *marginal probabilities* of the part variables, as follows:

$$\begin{aligned}
\mathbf{w}(\mathbf{p}(\mathbf{s}^t)) &= \sum_i \sum_y u_{i,y} \left(\mathbf{f}(x_i, y_i) - \mathbf{f}(x_i, y)\right) \\
&= \sum_i \mathbf{f}(x_i, y_i) - \sum_{i,y} p_y(\mathbf{s}_i^t) \mathbf{f}(x_i, y) \\
&= \sum_i \mathbf{f}(x_i, y_i) - \sum_{i,y} \sum_{r \in y} p_y(\mathbf{s}_i^t) \mathbf{f}(x_i, r) \\
&= \sum_i \mathbf{f}(x_i, y_i) - \sum_i \sum_{r \in R} \mu_{i,r}(\mathbf{s}_i^t) \mathbf{f}(x_i, r) \ .
\end{aligned}$$

Here the $\mu_{i,r}$ terms correspond to marginals, defined as

$$\mu_{i,r}(\mathbf{s}_i^t) = \sum_{y : r \in y} p_y(\mathbf{s}_i^t) \ .$$

The mapping from parameters $\mathbf{s}_i^t$ to marginals $\mu_{i,r}(\mathbf{s}_i^t)$ can be computed efficiently in several important cases of structured models. For example, in CRFs belief propagation can be used to efficiently calculate the marginal values, assuming that the tree-width of the underlying graph is small. In weighted context-free grammars the inside-outside algorithm can be used to calculate marginals, assuming that the set of parts R corresponds to context-free rule productions. Once marginals are computed, it is straightforward to compute $\mathbf{w}(\mathbf{p}(\mathbf{s}^t))$ and thereby implement the part-based EG algorithms.

5. Convergence Results

In this section, we provide convergence results for the EG batch and online algorithms presented in Section 3. Section 5.1 provides the key results, and the following sections give the proofs and the technical details.

5.1 Main Convergence Results

Our convergence results give bounds on how quickly the error $|Q(\mathbf{u}) - Q(\mathbf{u}^*)|$ decreases with respect to the number of iterations, T, of the algorithms. In all cases we have $|Q(\mathbf{u}) - Q(\mathbf{u}^*)| \to 0$ as $T \to \infty$.

In what follows we use $D[\mathbf{p} \| \mathbf{q}]$ to denote the KL divergence between $\mathbf{p}, \mathbf{q} \in \Delta^n$ (see Section 5.2). We also use $|A|_\infty$ to denote the maximum magnitude element of A (i.e., $|A|_\infty = \max_{(i,y),(j,z)} |A_{(i,y),(j,z)}|$). The first theorem provides results for the EG-batch algorithms, and the second for the randomized online algorithms.

Theorem 1 *For the batch algorithm in Figure 1, for Q_{LL} and Q_{MM},*

$$Q(\mathbf{u}^*) \leq Q(\mathbf{u}^{T+1}) \leq Q(\mathbf{u}^*) + \frac{1}{\eta T} D[\mathbf{u}^* \| \mathbf{u}^1] \ , \tag{6}$$

assuming that the learning rate η satisfies $0 < \eta \leq \frac{1}{1+n|A|_\infty}$ for Q_{LL}, and $0 < \eta \leq \frac{1}{n|A|_\infty}$ for Q_{MM}. Furthermore, for Q_{LL},

$$Q(\mathbf{u}^*) \leq Q(\mathbf{u}^{T+1}) \leq Q(\mathbf{u}^*) + \frac{e^{-\eta T}}{\eta} D[\mathbf{u}^* \| \mathbf{u}^1] \ ,$$

	Batch Algorithm	Online Algorithm
Q_{MM}	$\frac{n^2}{\varepsilon}\|A\|_\infty D[\mathbf{u}^*\|\mathbf{u}^1]$	$\frac{n}{\varepsilon}\left(\|A\|_\infty D[\mathbf{u}^*\|\mathbf{u}^1] + Q(\mathbf{u}^1) - Q(\mathbf{u}^*)\right)$
Q_{LL}	$n(1+n\|A\|_\infty)\log(\frac{c_1}{\varepsilon})$	$n(1+\|A\|_\infty)\log(\frac{c_2}{\varepsilon})$

Table 1: Each entry shows the amount of computation (measured in terms of the number of training sample processed using the EG updates) required to obtain $|Q(\mathbf{u}) - Q(\mathbf{u}^*)| \leq \varepsilon$ for the batch algorithm, or $\mathbf{E}\left[|Q(\mathbf{u}) - Q(\mathbf{u}^*)|\right] \leq \varepsilon$ for the online algorithm, for a given $\varepsilon > 0$. The constants are $c_1 = (1+n|A|_\infty)D[\mathbf{u}^*\|\mathbf{u}^1]$, and $c_2 = \left[(1+|A|_\infty)D[\mathbf{u}^*\|\mathbf{u}^1] + Q(\mathbf{u}^1) - Q(\mathbf{u}^*))\right]$.

assuming again that $0 < \eta \leq \frac{1}{1+n|A|_\infty}$.

The randomized online algorithm will produce different results at every run, since different points will be processed on different runs. Our main result for this algorithm characterizes the mean value of the objective $Q(\mathbf{u}^{T+1})$ when averaged over all possible random orderings of points. The result implies that this mean will converge to the optimal value $Q(\mathbf{u}^*)$.

Theorem 2 *For the randomized algorithm in Figure 2, for* Q_{LL} *and* Q_{MM}*,*

$$Q(\mathbf{u}^*) \leq \mathbf{E}\left[Q(\mathbf{u}^{T+1})\right] \leq Q(\mathbf{u}^*) + \frac{n}{\eta T} D[\mathbf{u}^*\|\mathbf{u}^1] + \frac{n}{T}\left[Q(\mathbf{u}^1) - Q(\mathbf{u}^*)\right] , \tag{7}$$

assuming that the learning rate η *satisfies* $0 < \eta \leq \frac{1}{1+|A|_\infty}$ *for* Q_{LL}*, and* $0 < \eta \leq \frac{1}{|A|_\infty}$ *for* Q_{MM}*. Furthermore, for* Q_{LL}*, for the algorithm in Figure 2,*

$$Q(\mathbf{u}^*) \leq \mathbf{E}\left[Q(\mathbf{u}^{T+1})\right] \leq Q(\mathbf{u}^*) + e^{-\frac{\eta T}{n}}\left[\frac{1}{\eta} D[\mathbf{u}^*\|\mathbf{u}^1] + Q(\mathbf{u}^1) - Q(\mathbf{u}^*)\right] ,$$

assuming again that $0 < \eta \leq \frac{1}{1+|A|_\infty}$.

The above result characterizes the average behavior of the randomized algorithm, but does not provide guarantees for any specific run of the algorithm. However, by applying the standard approach of repeated sampling (see, for example, Mitzenmacher and Upfal, 2005; Shalev-Shwartz et al., 2007), one can obtain a solution that, with high probability, does not deviate by much from the average behavior. In what follows, we briefly outline this derivation.

Note that the random variable $Q(\mathbf{u}^{T+1}) - Q(\mathbf{u}^*)$ is nonnegative, and so by Markov's inequality, it satisfies

$$\Pr\left\{Q(\mathbf{u}^{T+1}) - Q(\mathbf{u}^*) \geq 2\left(\mathbf{E}\left[Q(\mathbf{u}^{T+1})\right] - Q(\mathbf{u}^*)\right)\right\} \leq \frac{1}{2} .$$

Given some $\delta > 0$, if we run the algorithm $k = \log_2(\frac{1}{\delta})$ times,[7] each time with T iterations, and choose the best $\hat{\mathbf{u}}$ of these k results, we see that

$$\Pr\left\{Q(\hat{\mathbf{u}}) - Q(\mathbf{u}^*) \geq 2\left(\mathbf{E}\left[Q(\mathbf{u}^{T+1})\right] - Q(\mathbf{u}^*)\right)\right\} \leq \delta .$$

7. Assume for simplicity that $\log_2(\frac{1}{\delta})$ is integral.

Thus, for any desired confidence $1-\delta$, we can obtain a solution that is within a factor of 2 of the bound for T iterations in Theorem 2 by using $T\log_2(\frac{1}{\delta})$ iterations. In our experiments, we found that repeated trials of the randomized algorithm did not yield significantly different results.

The first consequence of the two theorems above is that the batch and randomized online algorithms converge to a $\mathbf{u}$ with the optimal value $Q(\mathbf{u}^*)$. This follows since Equations 6 and 7 imply that as $T \to \infty$ the value of $Q(\mathbf{u}^{T+1})$ approaches $Q(\mathbf{u}^*)$.

The second consequence is that for a given $\varepsilon > 0$ we can find the number of iterations needed to reach a $\mathbf{u}$ such that $|Q(\mathbf{u}) - Q(\mathbf{u}^*)| \leq \varepsilon$ for the batch algorithm or $\mathbf{E}\left[|Q(\mathbf{u}) - Q(\mathbf{u}^*)|\right] \leq \varepsilon$ for the online algorithm. Table 1 shows the computation required by the different algorithms, where the computation is measured by the number of training examples that need to be processed using the EG updates.[8] The entries in the table assume that the maximum possible learning rates are used for each of the algorithms—that is, $\frac{1}{1+n|A|_\infty}$ for LLEG-Batch, $\frac{1}{1+|A|_\infty}$ for LLEG-Online, $\frac{1}{n|A|_\infty}$ for MMEG-batch, and $\frac{1}{|A|_\infty}$ for MMEG-Online.

Crucially, note that these rates suggest that the online algorithms are significantly more efficient than the batch algorithms; specifically, the bounds suggest that the online algorithms require a factor of n less computation in both the Q_{LL} and Q_{MM} cases. Thus these results suggest that the randomized online algorithm should converge much faster than the batch algorithm. Roughly speaking, this is a direct consequence of the learning rate η being a factor of n larger in the online case (see also Section 9). This prediction is confirmed in our empirical evaluations, which show that the online algorithm is far more efficient than the batch algorithm.

A second important point is that the rates for Q_{LL} lead to an $O(\log(\frac{1}{\varepsilon}))$ dependence on the desired accuracy ε, which is a significant improvement over Q_{MM}, which has an $O(\frac{1}{\varepsilon})$ dependence. Note that the $O(\frac{1}{\varepsilon})$ dependence for Q_{MM} is similar to several other max-margin algorithms in the literature (see Section 6 for more discussion).

To gain further intuition into the order of magnitude of iterations required, note that the factor $D[\mathbf{u}^*\|\mathbf{u}^1]$ which appears in the above expressions is at most $n\log|\mathcal{Y}|$, which can be achieved by setting $\mathbf{u}_i^1$ to be the uniform distribution over $\mathcal{Y}$ for all i. Also, the value of $|A|_\infty$ can easily be seen to be $\frac{1}{C}\max_{i,y}\|\mathbf{g}_{i,y}\|^2$.

In the remainder of this section we give proofs of the results in Theorems 1 and 2. In doing so, we also give theorems that apply to the optimization of general convex functions $Q : \Delta^n \to \mathbb{R}$.

5.2 Divergence Measures

Before providing convergence proofs, we define several divergence measures between distributions. Define the KL divergence between two distributions $\mathbf{u}_i, \mathbf{v}_i \in \Delta$ to be

$$D[\mathbf{u}_i\|\mathbf{v}_i] = \sum_y u_{i,y}\log\frac{u_{i,y}}{v_{i,y}} \ .$$

Given two sets of n distributions $\mathbf{u}, \mathbf{v} \in \Delta^n$ define their KL divergence as

$$D[\mathbf{u}\|\mathbf{v}] = \sum_i D[\mathbf{u}_i\|\mathbf{v}_i] \ .$$

8. Note that if we run the batch algorithm for T iterations (as in the figure), nT training examples are processed. In contrast, running the online algorithm for T iterations (again, as shown in the figure) only requires T training examples to be processed. It is important to take this into account when comparing the rates in Theorems 1 and 2; this is the motivation for measuring computation in terms of the number of examples that are processed.

Next, we consider a more general class of divergence measures, Bregman divergences (e.g., see Bregman, 1967; Censor and Zenios, 1997; Kivinen and Warmuth, 1997). Given a convex function $Q(\mathbf{u})$, the Bregman divergence between $\mathbf{u}$ and $\mathbf{v}$ is defined as

$$B_Q[\mathbf{u}\|\mathbf{v}] = Q(\mathbf{u}) - Q(\mathbf{v}) - \nabla Q(\mathbf{v}) \cdot (\mathbf{u} - \mathbf{v}) \ .$$

Convexity of Q implies $B_Q[\mathbf{u}\|\mathbf{v}] \geq 0$ for all $\mathbf{u}, \mathbf{v} \in \Delta^n$.

Note that the Bregman divergence with $Q(\mathbf{u}) = \sum_{i,y} u_{i,y} \log u_{i,y}$ is the KL divergence. We shall also be interested in the Mahalanobis distance

$$M_A[\mathbf{u}\|\mathbf{v}] = \frac{1}{2}(\mathbf{u} - \mathbf{v})^T A (\mathbf{u} - \mathbf{v}) \ ,$$

which is the Bregman divergence for $Q(\mathbf{u}) = \frac{1}{2}\mathbf{u}^T A \mathbf{u}$.

In what follows, we also use the L_p norm defined for $\mathbf{x} \in \mathbb{R}^m$ as $\|\mathbf{x}\|_p = \sqrt[p]{\sum_i |x_i|^p}$.

5.3 Dual Improvement and Bregman Divergence

In this section we provide a useful lemma that determines when the EG updates in the batch algorithm will result in monotone improvement of $Q(\mathbf{u})$. The lemma requires a condition on the relation between the Bregman and KL divergences which we define as follows (the second part of the definition will be used in the next section):

Definition 5.1 : A convex function $Q : \Delta^n \to \mathbb{R}$ is τ-upper-bounded for some $\tau > 0$ if for any $\mathbf{p}, \mathbf{q} \in \Delta^n$,

$$B_Q[\mathbf{p}\|\mathbf{q}] \leq \tau D[\mathbf{p}\|\mathbf{q}] \ .$$

In addition, we say $Q(\mathbf{u})$ is (μ, τ)-bounded for constants $0 < \mu < \tau$ if for any $\mathbf{p}, \mathbf{q} \in \Delta^n$,

$$\mu D[\mathbf{p}\|\mathbf{q}] \leq B_Q[\mathbf{p}\|\mathbf{q}] \leq \tau D[\mathbf{p}\|\mathbf{q}] \ .$$

The next lemma states that if $Q(\mathbf{u})$ is τ-upper-bounded, then the change in the objective as a result of an EG update can be related to the KL divergence between consecutive values of the dual variables.

Lemma 2 *If $Q(\mathbf{u})$ is τ-upper-bounded, then if η is chosen such that $0 < \eta \leq \frac{1}{\tau}$, it holds that for all t in the batch algorithm (Figure 1):*

$$Q(\mathbf{u}^t) - Q(\mathbf{u}^{t+1}) \geq \frac{1}{\eta} D[\mathbf{u}^t \| \mathbf{u}^{t+1}] \ .$$

Proof: Given a $\mathbf{u}^t$, the EG update is

$$u^{t+1}_{i,y} = \frac{1}{Z^t_i} u^t_{i,y} e^{-\eta \nabla^t_{i,y}} \ ,$$

where

$$\nabla^t_{i,y} = \frac{\partial Q(\mathbf{u}^t)}{\partial u_{i,y}} \ , \qquad Z^t_i = \sum_{\hat{y}} u^t_{i,\hat{y}} e^{-\eta \nabla^t_{i,y}} \ .$$

Simple algebra yields

$$\sum_i \left(D[\mathbf{u}_i^t \| \mathbf{u}_i^{t+1}] + D[\mathbf{u}_i^{t+1} \| \mathbf{u}_i^t] \right) = \eta \sum_{i,y} (u_{i,y}^t - u_{i,y}^{t+1}) \nabla_{i,y}^t \ .$$

Equivalently, using the notation for KL divergence between multiple distributions:

$$D[\mathbf{u}^t \| \mathbf{u}^{t+1}] + D[\mathbf{u}^{t+1} \| \mathbf{u}^t] = \eta (\mathbf{u}^t - \mathbf{u}^{t+1}) \cdot \nabla Q(\mathbf{u}^t) \ .$$

The definition of the Bregman divergence B_Q then implies

$$-\eta B_Q[\mathbf{u}^{t+1} \| \mathbf{u}^t] + D[\mathbf{u}^t \| \mathbf{u}^{t+1}] + D[\mathbf{u}^{t+1} \| \mathbf{u}^t] = \eta (Q(\mathbf{u}^t) - Q(\mathbf{u}^{t+1})) \ . \tag{8}$$

Since $Q(\mathbf{u})$ is τ-upper-bounded and $\eta \leq \frac{1}{\tau}$ it follows that $D[\mathbf{u}^{t+1} \| \mathbf{u}^t] \geq \eta B_Q[\mathbf{u}^{t+1} \| \mathbf{u}^t]$, and together with Eq. 8 we obtain the desired result $\eta(Q(\mathbf{u}^t) - Q(\mathbf{u}^{t+1})) \geq D[\mathbf{u}^t \| \mathbf{u}^{t+1}]$. □

Note that the condition in the lemma may be weakened to requiring that $\tau D[\mathbf{u}^t \| \mathbf{u}^{t+1}] \geq B_Q[\mathbf{u}^t \| \mathbf{u}^{t+1}]$ for all t. For simplicity, we require the condition for all $\mathbf{p}, \mathbf{q} \in \Delta^n$. Note also that $D[\mathbf{p} \| \mathbf{q}] \geq 0$ for all $\mathbf{p}, \mathbf{q} \in \Delta^n$, so the lemma implies that for an appropriately chosen η, the EG updates always decrease the objective $Q(\mathbf{u})$. We next show that the log-linear dual $Q_{\text{LL}}(\mathbf{u})$ is in fact τ-upper-bounded.

Lemma 3 *Define $|A|_\infty$ to be the maximum magnitude of any element of A, that is, $|A|_\infty = \max_{(i,y),(j,z)} |A_{(i,y),(j,z)}|$. Then $Q_{\text{LL}}(\mathbf{u})$ is τ_{LL}-upper-bounded with $\tau_{\text{LL}} = 1 + n|A|_\infty$.*

Proof: First notice that the Bregman divergence B_Q is linear in Q. Thus, for any $\mathbf{p}, \mathbf{q} \in \Delta^n$ we can write $B_{Q_{\text{LL}}}$ as a sum of two terms (see Eq. 4).

$$B_{Q_{\text{LL}}}[\mathbf{p} \| \mathbf{q}] = D[\mathbf{p} \| \mathbf{q}] + M_A[\mathbf{p} \| \mathbf{q}] \ .$$

We first bound $M_A[\mathbf{p} \| \mathbf{q}]$ in terms of squared L_1 distance between $\mathbf{p}$ and $\mathbf{q}$. Denote $\mathbf{r} = \mathbf{p} - \mathbf{q}$. Then:

$$M_A[\mathbf{p} \| \mathbf{q}] = \frac{1}{2} \sum_{i,y,j,z} r_{i,y} r_{j,z} A_{(i,y),(j,z)} \leq \frac{|A|_\infty}{2} \sum_{i,y,j,z} |r_{i,y}| |r_{j,z}| = \frac{|A|_\infty}{2} \|\mathbf{p} - \mathbf{q}\|_1^2 \ .$$

Next, we use the inequality $D[p_1 \| p_2] \geq \frac{1}{2} \|p_1 - p_2\|_1^2$ (also known as Pinsker's inequality, see Cover and Thomas, 1991, p. 300), which holds for any two distributions p_1 and p_2. Consider the two distributions $\hat{\mathbf{p}} = \frac{1}{n}\mathbf{p}$ and $\hat{\mathbf{q}} = \frac{1}{n}\mathbf{q}$, each defined over an alphabet of size $n|\mathcal{Y}|$. Then it follows that:[9]

$$\frac{|A|_\infty}{2} \|\mathbf{p} - \mathbf{q}\|_1^2 = \frac{n^2 |A|_\infty}{2} \|\hat{\mathbf{p}} - \hat{\mathbf{q}}\|_1^2 \leq n^2 |A|_\infty D[\hat{\mathbf{p}} \| \hat{\mathbf{q}}] = n|A|_\infty D[\mathbf{p} \| \mathbf{q}] \ ,$$

and thus $M_A[\mathbf{p} \| \mathbf{q}] \leq n|A|_\infty D[\mathbf{p} \| \mathbf{q}]$. So for the Bregman divergence of $Q_{\text{LL}}(\mathbf{u})$ we obtain

$$B_{Q_{\text{LL}}}[\mathbf{p} \| \mathbf{q}] \leq (1 + n|A|_\infty) D[\mathbf{p} \| \mathbf{q}] \ ,$$

yielding the desired result. □

The next lemma shows that a similar result can be obtained for the Q_{MM} objective.

9. Note that $D[\hat{\mathbf{p}} \| \hat{\mathbf{q}}]$ is a divergence between two distributions over $|\mathcal{Y}|n$ symbols and $D[\mathbf{p} \| \mathbf{q}]$ is a divergence between two sets of n distributions over $|\mathcal{Y}|$ symbols.

Lemma 4 *The function $Q_{\text{MM}}(\mathbf{u})$ is τ_{MM}-upper-bounded with $\tau_{\text{MM}} = n|A|_\infty$.*

Proof: For Q_{MM} defined in Eq. 5, we have

$$B_{Q_{\text{MM}}}[\mathbf{p}\|\mathbf{q}] = M_A[\mathbf{p}\|\mathbf{q}] \ .$$

We can then use a similar derivation to that of Lemma 3 to obtain the result. □

We thus have that the condition in Lemma 2 is satisfied for both the $Q_{\text{LL}}(\mathbf{u})$ and $Q_{\text{MM}}(\mathbf{u})$ objectives, implying that their EG updates result in monotone improvement of the objective, for a suitably chosen η:

Corollary 1 *The LLEG-Batch algorithm with $0 < \eta \leq \frac{1}{\tau_{\text{LL}}}$ satisfies for all t*

$$Q_{\text{LL}}(\mathbf{u}^t) - Q_{\text{LL}}(\mathbf{u}^{t+1}) \geq \frac{1}{\eta} D[\mathbf{u}^t \| \mathbf{u}^{t+1}] \ ,$$

and the MMEG-Batch algorithm with $0 < \eta \leq \frac{1}{\tau_{\text{MM}}}$ satisfies for all t

$$Q_{\text{MM}}(\mathbf{u}^t) - Q_{\text{MM}}(\mathbf{u}^{t+1}) \geq \frac{1}{\eta} D[\mathbf{u}^t \| \mathbf{u}^{t+1}] \ .$$

5.4 Convergence Rates for the EG Batch Algorithms

The previous section showed that for appropriate choices of the learning rate η, the batch EG updates are guaranteed to improve the Q_{LL} and Q_{MM} loss functions at each iteration. In this section we build directly on these results, and address the following question: how many iterations does the batch EG algorithm require so that the $|Q(\mathbf{u}^t) - Q(\mathbf{u})| \leq \varepsilon$ for a given $\varepsilon > 0$? We show that as long as $Q(\mathbf{u})$ is τ-upper-bounded, the number of iterations required is $O(\frac{1}{\varepsilon})$. This bound thus holds for both the log-linear and max-margin batch algorithms. Next, we show that if $Q(\mathbf{u})$ is (μ, τ)-bounded, the rate can be significantly improved to requiring $O(\log(\frac{1}{\varepsilon}))$ iterations. We conclude by showing that $Q_{\text{LL}}(\mathbf{u})$ is (μ, τ)-bounded, implying that the $O(\log(\frac{1}{\varepsilon}))$ rate holds for LLEG-Batch.

The following result gives an $O(\frac{1}{\varepsilon})$ rate for Q_{LL} and Q_{MM}:

Lemma 5 *If $Q(\mathbf{u})$ is τ-upper-bounded and $0 \leq \eta \leq \frac{1}{\tau}$, then after T iterations of the EG-Batch algorithm, for any $\mathbf{z} \in \Delta^n$ including $\mathbf{z} = \mathbf{u}^*$,*

$$Q(\mathbf{u}^{T+1}) - Q(\mathbf{z}) \leq \frac{1}{\eta T} D[\mathbf{z}\|\mathbf{u}^1] \ .$$

Proof: See Appendix A. □

The lemma implies that to get ε-close to the optimal objective value, $O(\frac{1}{\varepsilon})$ iterations are required—more precisely, if a choice of $\eta = \frac{1}{\tau}$ is made, then at most $\frac{\tau}{\varepsilon} D[\mathbf{z}\|\mathbf{u}^1]$ iterations are required. Since its conditions are satisfied by both $Q_{\text{LL}}(\mathbf{u})$ and $Q_{\text{MM}}(\mathbf{u})$ (given an appropriate choice of η) the result holds for both the LLEG-Batch and MMEG-Batch algorithms.

A much improved rate may be obtained if $Q(\mathbf{u})$ is not only τ-upper-bounded, but also (μ, τ)-bounded (see Definition 5.1).

Lemma 6 *If $Q(\mathbf{u})$ is (μ,τ)-bounded and $0 < \eta \leq \frac{1}{\tau}$ then after T iterations of the EG-Batch algorithm, for any $\mathbf{z} \in \Delta^n$ including $\mathbf{z} = \mathbf{u}^*$,*

$$Q(\mathbf{u}^{T+1}) - Q(\mathbf{z}) \leq \frac{e^{-\eta\mu T}}{\eta} D[\mathbf{z}||\mathbf{u}^1] \ .$$

Proof: See Appendix B. □

The lemma implies that an accuracy of ε may be achieved by using $O(\log(\frac{1}{\varepsilon}))$ iterations.

To see why $Q_{\text{LL}}(\mathbf{u})$ is (μ,τ)-bounded note that for any $\mathbf{p},\mathbf{q} \in \Delta^n$,

$$B_{Q_{\text{LL}}}[\mathbf{p}\|\mathbf{q}] = D[\mathbf{p}\|\mathbf{q}] + M_A[\mathbf{p}\|\mathbf{q}] \geq D[\mathbf{p}\|\mathbf{q}] \ ,$$

implying (together with Lemma 3) that $Q_{\text{LL}}(\mathbf{u})$ is $(1,\tau_{\text{LL}})$-bounded.

Finally, note that Lemmas 5 and 6, together with the facts that Q_{LL} is $(1,\tau_{\text{LL}})$-bounded and Q_{MM} is τ_{MM}-upper-bounded, imply Theorem 1 of Section 5.1.

5.5 Convergence Results for the Randomized Online Algorithm

This section analyzes the rate of convergence of the randomized online algorithm in Figure 2. Before stating the results, we need some definitions. We will use $Q_{\mathbf{u},i} : \Delta \rightarrow \mathbb{R}$ to be the function defined as

$$Q_{\mathbf{u},i}(\mathbf{v}) = Q(\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_{i-1}, \mathbf{v}, \mathbf{u}_{i+1}, \ldots, \mathbf{u}_n) \ ,$$

for any $\mathbf{v} \in \Delta$. We denote the Bregman divergence associated with $Q_{\mathbf{u},i}$ as $B_{Q_{\mathbf{u},i}}[\mathbf{x}\|\mathbf{y}]$. We then introduce the following definitions:

Definition 5.2: *A convex function $Q : \Delta^n \rightarrow \mathbb{R}$ is τ-online-upper-bounded for some $\tau > 0$ if for any $i \in 1 \ldots n$ and for any $\mathbf{p},\mathbf{q} \in \Delta$,*

$$B_{Q_{\mathbf{u},i}}[\mathbf{p}\|\mathbf{q}] \leq \tau D[\mathbf{p}\|\mathbf{q}] \ .$$

In addition, Q is (μ,τ)-online-bounded for $0 < \mu < \tau$ if Q is τ-online-upper-bounded, and in addition, for any $\mathbf{p},\mathbf{q} \in \Delta^n$,

$$\mu D[\mathbf{p}\|\mathbf{q}] \leq B_Q[\mathbf{p}\|\mathbf{q}] \ .$$

Note that the lower bound in the above definition refers to B_Q and not to $B_{Q_{\mathbf{u},i}}$. Also, note that if a function is (μ,τ)-online-bounded then it must also be τ-online-upper-bounded.

The following lemma then gives results for the Q_{LL} and Q_{MM} functions:

Lemma 7 *The log-linear dual $Q_{\text{LL}}(\mathbf{u})$ is (μ,τ)-online-bounded for $\mu = 1$ and $\tau = 1 + |A|_\infty$. The max-margin dual $Q_{\text{MM}}(\mathbf{u})$ is τ-online-upper-bounded for $\tau = |A|_\infty$.*

Proof: See Appendix C. □

For any τ-online-upper-bounded Q, the online EG algorithm converges at an $O(\frac{1}{\varepsilon})$ rate, as shown by the following lemma.

Lemma 8 *Consider the algorithm in Figure 2 applied to a convex function $Q(\mathbf{u})$ that is τ-online-upper-bounded. If $\eta > 0$ is chosen such that $\eta \leq \frac{1}{\tau}$, then it follows that for all $\mathbf{z} \in \Delta^n$*

$$\mathbf{E}\left[Q(\mathbf{u}^{T+1})\right] \leq Q(\mathbf{z}) + \frac{n}{\eta T} D[\mathbf{z}\|\mathbf{u}^1] + \frac{n}{T}\left[Q(\mathbf{u}^1) - Q(\mathbf{u}^*)\right] ,$$

where $\mathbf{E}\left[Q(\mathbf{u}^{T+1})\right]$ is the expected value of $Q(\mathbf{u}^{T+1})$, and $\mathbf{u}^* = \operatorname{argmin}_{\mathbf{u}\in\Delta^n} Q(\mathbf{u})$.

Proof: See Appendix D. □

The previous lemma shows, in particular, that the online EG algorithm converges at an $O(\frac{1}{\varepsilon})$ rate for the function Q_{MM}. However, we can prove a faster rate of convergence for Q_{LL}, which is (μ,τ)-online-bounded. The following lemma shows that such functions exhibit an $O(\log(\frac{1}{\varepsilon}))$ rate of convergence.

Lemma 9 *Consider the algorithm in Figure 2 applied to a convex function $Q(\mathbf{u})$ that is (μ,τ)-online-bounded. If $\eta > 0$ is chosen such that $\eta \leq \frac{1}{\tau}$, then it follows that for all $\mathbf{z} \in \Delta^n$*

$$\mathbf{E}\left[Q(\mathbf{u}^{T+1})\right] \leq Q(\mathbf{z}) + e^{-\frac{\eta\mu T}{n}}\left[\frac{1}{\eta} D[\mathbf{z}\|\mathbf{u}^1] + Q(\mathbf{u}^1) - Q(\mathbf{u}^*)\right] ,$$

where $\mathbf{u}^* = \operatorname{argmin}_{\mathbf{u}\in\Delta^n} Q(\mathbf{u})$.

Proof: See Appendix E. □

Note that Lemmas 7, 9 and 8 complete the proof of Theorem 2 in Section 5.1.

6. Related Work

The idea of solving regularized loss-minimization problems via their convex duals has been addressed in several previous papers. Here we review those, specifically focusing on the log-linear and max-margin problems.

Zhang (2002) presented a study of convex duals of general regularized loss functions, and provided a methodology for deriving such duals. He also considered a general procedure for solving such duals by optimizing one coordinate at a time. However, it is not clear how to implement this procedure in the structured learning case (i.e., when $|\mathcal{Y}|$ is large), and convergence rates are not given.

In the specific context of log-linear models, several papers have addressed dual optimization. Earlier work (Jaakkola and Haussler, 1999; Keerthi et al., 2005; Zhu and Hastie, 2001) treated the logistic regression model, a simpler version of a CRF. In the binary logistic regression case, there is essentially one parameter u_i per example with the constraint $0 \leq u_i \leq 1$, and therefore simple line-search methods can be used for optimization. Minka (2003) presents empirical results which show that this approach performs similarly to conjugate gradient. The problem becomes much harder when $\mathbf{u}_i$ is constrained to be a distribution over many labels, as in the case discussed here. Recently, Memisevic (2006) addressed this setting, and suggests optimizing $\mathbf{u}_i$ by transferring probability mass between two labels y_1, y_2 while keeping the distribution normalized. This requires a strategy for choosing these two labels, and the author suggests one which seems to perform well.

While some previous work on log-linear models proved convergence of dual methods (e.g., Keerthi et al., 2005), we are not aware of rates of convergence that have been reported in this context. Convergence rates for related algorithms, in particular a generalization of EG, known as the Mirror-Descent algorithm, have been studied in a more general context in the optimization literature. For instance, Beck and Teboulle (2003) describe convergence results which apply to quite general definitions of $Q(\mathbf{u})$, but which have only $O(\frac{1}{\varepsilon^2})$ convergence rates, as compared to our results of $O(\frac{1}{\varepsilon})$ and $O(\log(\frac{1}{\varepsilon}))$ for the max-margin and log-linear cases respectively. Also, their work considers optimization over a single simplex, and does not consider online-like algorithms such as the one we have presented.

For max-margin models, numerous dual methods have been suggested, an earlier example being the SMO algorithm of Platt (1998). Such methods optimize subsets of the $\mathbf{u}$ parameters in the dual SVM formulation (see also Crammer and Singer, 2002). Analysis of a similar algorithm (Hush et al., 2006) results in an $O(\frac{1}{\varepsilon})$ rate, similar to the one we have here. Another algorithm for solving SVMs via the dual is the multiplicative update method of Sha et al. (2007). These updates are shown to converge to the optimum of the SVM dual, but convergence rate has not been analyzed, and extension to the structured case seems non-trivial. An application of EG to binary SVMs was previously studied by Cristianini et al. (1998). They show convergence rates of $O(\frac{1}{\varepsilon^2})$, that are slower than our $O(\frac{1}{\varepsilon})$, and no extension to structured learning (or multi-class) is discussed.

Recently, several new algorithms have been presented, along with a rate of convergence analysis (Joachims, 2006; Shalev-Shwartz et al., 2007; Teo et al., 2007; Tsochantaridis et al., 2004; Taskar et al., 2006). All of these algorithms are similar to ours in having a relatively low dependence on n in terms of memory and computation. Among these, Shalev-Shwartz et al. (2007), Teo et al. (2007) and Taskar et al. (2006) present an $O(\frac{1}{\varepsilon})$ rate, but where accuracy is measured in the primal or via the duality gap, and not in the dual as in our analysis. Thus, it seems that a rate of $O(\frac{1}{\varepsilon})$ is currently the best known result for algorithms that have a relatively low dependence on n (general QP solvers, which may have $O(\log(\frac{1}{\varepsilon}))$ behavior, generally have a larger dependence on n, both in time and space). Note that, as in our analysis, all these convergence rates depend on $|A|_\infty$.

Finally, we emphasize again that the EG algorithm is substantially different from stochastic gradient and stochastic subgradient approaches (LeCun et al., 1998; Nedic and Bertsekas, 2001; Shalev-Shwartz et al., 2007; Vishwanathan et al., 2006). EG and stochastic gradient methods are similar in that they both process a single training example at a time. However, EG corresponds to block-coordinate descent in the dual, and uses the *exact* gradient with respect to the block being updated. In contrast, stochastic gradient methods directly optimize the primal problem, and at each update use a single example to *approximate* the gradient (or subgradient) of the primal objective function.

7. Experiments on Regularized Log-Likelihood

In this section we analyze the performance of the EG algorithms for optimization of regularized log-likelihood. We describe experiments on two tasks: first, the MNIST digit classification task, which is a multiclass classification task; second, a log-linear model for a structured natural-language dependency-parsing task. In each case we first give results for the EG method, and then compare

its performance to L-BFGS (Byrd et al., 1995), which is a batch gradient descent method, and to stochastic gradient descent.[10]

We do not report results on LLEG-Batch, since we found it to converge much more slowly than the online algorithm. This is expected from our theoretical results, which anticipate a factor of n speed-up for the online algorithm. We also report experiments comparing the randomized online algorithm to a deterministic online EG algorithm, where samples are drawn in a fixed order (e.g., the algorithm first visits the first example, then the second, etc.).

Although EG is guaranteed to converge for an appropriately chosen η, it turns out to be beneficial to use an adaptive learning rate. Here we use the following simple strategy: we first consider only 10% of the data-set, and find a value of η that results in monotone improvement for at least 95% of the samples. Denote this value by η^{ini} (for the experiments in Section 7.1 we simply use $\eta^{\text{ini}} = 0.5$). For learning over the entire data-set, we keep a learning rate η_i for each sample i (where $i = 1,\ldots,n$), and initialize this rate to η^{ini} for all points. When sample i is visited, we halve η_i until an improvement in the objective is obtained. Finally, after the update, we multiply η_i by 1.05, so that it does not decrease monotonically.

It is important that when updating a single example using the online algorithms, the improvement (or decrease) in the dual can be easily evaluated, allowing the halving strategy described in the previous paragraph to be implemented efficiently. If the current dual parameters are $\mathbf{u}$, the i'th coordinate is selected, and the EG updates then map $\mathbf{u}_i$ to $\mathbf{u}'_i$, the change in the dual objective is

$$\sum_y u'_{i,y} \log u'_{i,y} + \frac{1}{2C} \left\| \mathbf{w}(\mathbf{u}) + \sum_y \left(u'_{i,y} - u_{i,y}\right) \mathbf{g}_{i,y} \right\|^2 - \sum_y u_{i,y} \log u_{i,y} - \frac{1}{2C} \|\mathbf{w}(\mathbf{u})\|^2 \ .$$

The primal parameters $\mathbf{w}(\mathbf{u})$ are maintained throughout the algorithm (see Figure 3), so that this change in the dual objective can be calculated efficiently. A similar method can be used to calculate the change in the dual objective in the max-margin case.

We measure the performance of each training algorithm (the EG algorithms, as well as the batch gradient and stochastic gradient methods) as a function of the amount of computation spent. Specifically, we measure computation in terms of the number of times each training example is visited. For EG, an example is considered to be visited for every value of η that is tested on it. For L-BFGS, all examples are visited for every evaluation performed by the line-search routine. We define the measure of *effective iterations* to be the number of examples visited, divided by n. In the following sections we compare the algorithms in terms of their performance as a function of the effective number of iterations. A comparison in terms of running time is provided in Appendix F; there is little difference between the timed comparisons and the results presented in this section.

7.1 Multi-class Classification

We first conducted multi-class classification experiments on the MNIST classification task. Examples in this data set are images of handwritten digits represented as 784-dimensional vectors. We used a training set of 59k examples, and a validation set of 10k examples.[11] Note that since we

10. We also experimented with conjugate gradient algorithms, but since these resulted in worse performance than L-BFGS, we do not report these results here.

11. In reporting results, we consider only *validation* error; that is, error computed during the training process on a validation set. This measure is often used in early-stopping of algorithms, and is therefore of interest in the current context. We do not report test error since our main focus is algorithmic.

only use a linear kernel, accuracy results are not competitive with state of the art classifiers which use non-linear kernels (e.g., see Cortes and Vapnik, 1995). We define a ten-class logistic-regression model where

$$p(y|x) \propto e^{\mathbf{x}\cdot\mathbf{w}_y} ,$$

and $\mathbf{x}, \mathbf{w}_y \in \mathbb{R}^{784}, y \in \{1, \ldots, 10\}$.

Models were trained for various values of the regularization parameter C: specifically, we tried values of C equal to 1000, 100, 10, 1, 0.1, and 0.01. Convergence of the EG algorithm for low values of C (i.e., 0.1 and 0.01) was found to be slow; we discuss this issue more in Section 7.1.1, arguing that it is not a serious problem.

Figure 4 shows plots of the validation error versus computation for C equal to 1000, 100, 10, and 1, when using the EG algorithm. For C equal to 10 or more, convergence is fast. For $C = 1$ convergence is somewhat slower. Note that there is little to choose between $C = 10$ and $C = 1$ in terms of validation error.

Figure 5 shows plots of the primal and dual objective functions for different values of C. To obtain the primal objective values, we used the EG weight vector $\frac{1}{C}\mathbf{w}(\mathbf{u}^t)$. Note that EG does not explicitly minimize the primal objective function, so the EG primal will not necessarily decrease at every iteration. Nevertheless, our experiments show that the EG primal decreases quite quickly. Figure 6 shows how the duality gap decreases with the amount of computation spent (the duality gap is the difference between the primal and dual values at each iteration). The log of the duality gap decreases more-or-less linearly with the amount of computation spent, as predicted by the $O(\log(\frac{1}{\varepsilon}))$ bounds on the rate of convergence.[12]

Finally, we compare the deterministic and randomized versions of the EG algorithm. Figure 7 shows the primal and dual objectives for both algorithms. It can be seen that the randomized algorithm is clearly much faster to converge. This is even more evident when plotting the duality gap, which converges much faster to zero in the case of the randomized algorithm. These results give empirical evidence that the randomized strategy is to be preferred over a fixed ordering of the training examples (note that we have been able to prove bounds on convergence rate for the randomized algorithm, but have not been able to prove similar bounds for the deterministic case).

7.1.1 CONVERGENCE FOR LOW VALUES OF C

As mentioned in the previous section, convergence of the EG algorithm for low values of C can be very slow. This is to be expected from the bounds on convergence, which predict that convergence time should scale linearly with $\frac{1}{C}$ (other algorithms, e.g., see Shalev-Shwartz et al., 2007, also require $O(\frac{1}{C})$ time for convergence). This is however, not a serious problem on the MNIST data, where validation error has reached a minimum point for around $C = 10$ or $C = 1$.

If convergence for small values of C is required, one strategy we have found effective is to start C at a higher value, then "anneal" it towards the target value. For example, see Figure 8 for results for $C = 1$ using one such annealing scheme. For this experiment, if we take t to be the number of iterations over the training set, where for any t we have processed $t \times n$ training examples, we set $C = 10$ for $t \leq 5$, and set $C = 1 + 9 \times 0.7^{t-5}$ for $t > 5$. Thus C starts at 10, then decays exponentially quickly towards the target value of 1. It can be seen that convergence is significantly faster for the annealed method. The intuition behind this method is that the solution to the dual problem for

12. The rate results presented in this paper are for dual accuracy, but it is straightforward to obtain an $O(\log(\frac{1}{\varepsilon}))$ for the duality gap in the log-linear case.

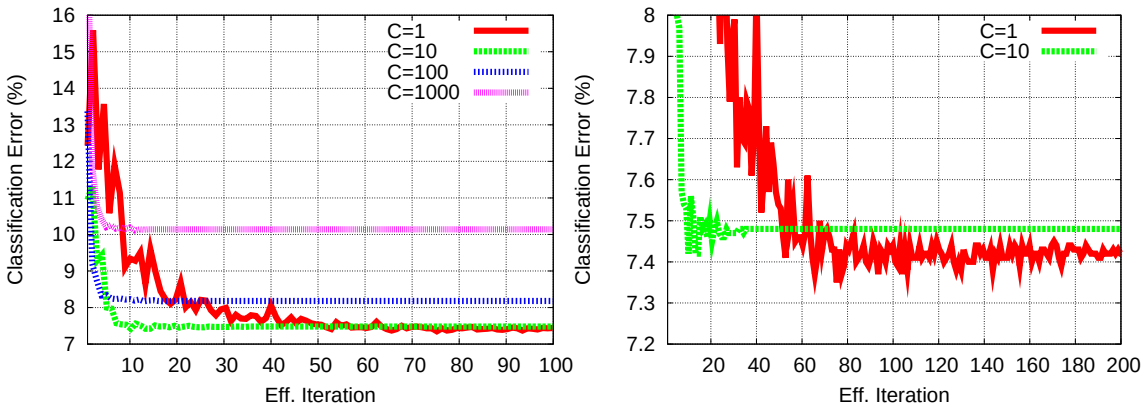

Figure 4: Validation error results on the MNIST learning task for log-linear models trained using the EG randomized online algorithm. The X axis shows the number of effective iterations over the entire data set. The Y axis shows validation error percentages. The left figure shows plots for values of C equal to 1, 10, 100, and 1000. The right figure shows plots for C equal to 1 and 10 at a larger scale.

$C = 10$ is a reasonable approximation to the solution for $C = 1$, and is considerably easier to solve; in the annealing strategy we start with an easier problem and then gradually move towards the harder problem of $C = 1$.

7.1.2 AN EFFICIENT METHOD FOR OPTIMIZING A RANGE OF C VALUES

In practice, when estimating parameters using either regularized log-likelihood or hinge-loss, a range of values for C are tested, with cross-validation or validation on a held-out set being used to choose the optimal value of C. In the previously described experiments, we independently optimized log-likelihood-based models for different values of C. In this section we describe a highly efficient method for training a sequence of models for a range of values of C.

The method is as follows. We pick some maximum value for C; as in our previous experiments, we will choose a maximum value of $C = 1000$. We also pick a tolerance value ε, and a parameter $0 < \nu < 1$. We then optimize C using the randomized online algorithm, until the duality gap is less than $\varepsilon \times p$, where p is the primal value. Once the duality gap has converged to within this ε tolerance, we reduce C by a factor of ν, and again optimize to within an ε tolerance. We continue this strategy—for each value of C optimizing to within a factor of ε, then reducing C by a factor of ν—until C has reached a low enough value. At the end of the sequence, this method recovers a series of models for different values of C, each optimized to within a tolerance of ε.

It is crucial that each time we decrease C, we take our initial dual values to be the final dual values resulting from optimization for the previous value of C. In practice, if C does not decrease too quickly, the previous dual values are a very good starting point for the new value of C; this corresponds to a "warm start" in optimizing values of C that are less than the maximum value. A

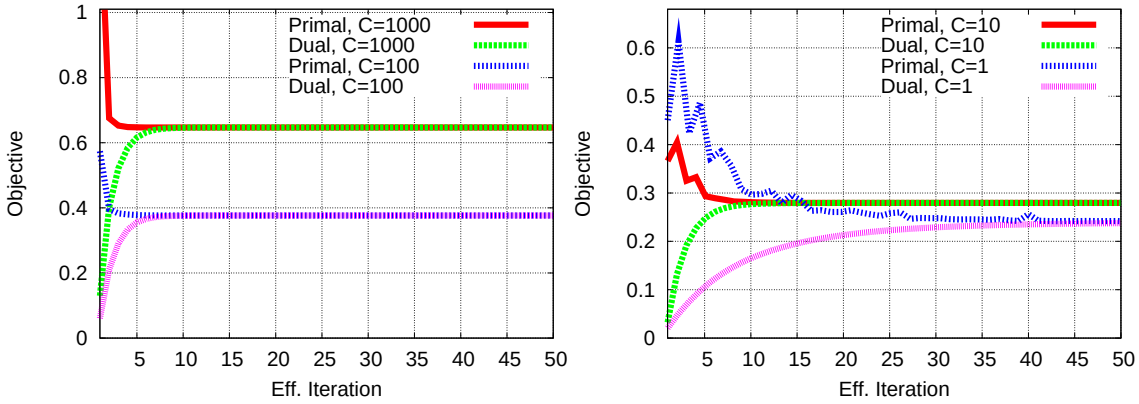

Figure 5: Primal and dual objective values on the MNIST learning task for log-linear models trained using the EG randomized online algorithm. The dual values have been negated so that the primal and dual problems have the same optimal value. The X axis shows the number of effective iterations over the entire data set. The Y axis shows the value of the primal or dual objective functions. The left figure shows plots for values of C equal to 1000 and 100; the right figure shows plots for C equal to 10, and 1. In all cases the primal and dual objectives converge to the same value, with faster convergence for larger values of C.

similar initialization method is used in Koh et al. (2007) in the context of ℓ_1 regularized logistic regression.

As one example of this approach, we trained models in this way with the starting (maximum) value of C set to 1000, ε set to 0.001 (i.e., 0.1%), and v set to 0.7. Table 2 shows the number of iterations of training required for each value of C. The benefits of using the previous dual values at each new value of C are clear: for $13.84 \leq C \leq 700$ at most 5 iterations are required for convergence; even for $C = 0.798$ only 15.24 iterations are required; a range of 25 different values of C between 1000 and 0.274 can be optimized with 211.17 effective iterations over the training set.

7.1.3 COMPARISONS TO STOCHASTIC GRADIENT DESCENT

This section compares performance of the EG algorithms to stochastic gradient descent (SGD) on the primal objective. In SGD the parameters $\mathbf{w}$ are initially set to be 0. At each step an example index i is chosen at random, and the following update is performed:

$$\mathbf{w} = \mathbf{w} - \eta \frac{\partial}{\partial \mathbf{w}} \left(-\log p(y_i \,|\, x_i; \mathbf{w}) + \frac{C}{2n} \|\mathbf{w}\|^2 \right) ,$$

where $\eta > 0$ is a learning rate. The term

$$\frac{\partial}{\partial \mathbf{w}} \left(-\log p(y_i \,|\, x_i; \mathbf{w}) + \frac{C}{2n} \|\mathbf{w}\|^2 \right) ,$$

C	Iterations	Total Iterations	Error
1000	11	11	0.1011

Table 2: Table showing number of effective iterations required to optimize a sequence of values for C for the MNIST task, using the method described in Section 7.1.2. The column C shows the sequence of decreasing regularizer constants. *Iterations* shows the number of effective iterations over the training set required to optimized each value of C. *Total iterations* shows the cumulative value of *Iterations*, and *Error* shows the validation error obtained for every C value. It can be seen that the optimal error is reached at $C = 1.62841$.

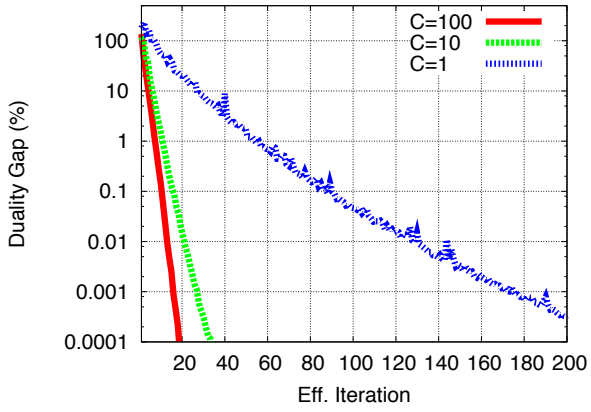

Figure 6: Graph showing the duality gap on the MNIST learning task for log-linear models trained using the EG randomized online algorithm. The X axis shows the number of effective iterations over the entire data set. The Y axis (with a log scale) shows the value of the duality gap, as a percentage of the final optimal value.

can be thought of as an estimate of the gradient of the primal objective function for the entire training set.

In our experiments, we chose the learning rate η to be

$$\eta = \frac{\eta_0}{1 + k/n} ,$$

where $\eta_0 > 0$ is a constant, n is the number of training examples, and k is the number of updates that have been performed up to this point. Thus the learning rate decays to 0 with the number of examples that are updated. This follows the approach described in LeCun et al. (1998); we have consistently found that it performs better than using a single, fixed learning rate.

We tested SGD for C values of 1000, 100, 10, 1, 0.1 and 0.01. In each case we chose the value of η_0 as follows. For each value of C we first tested values of η_0 equal to 1, 0.1, 0.01, 0.001, and 0.0001, and then chose the value of η_0 which led to the best validation error after a single iteration of SGD. This strategy resulted in a choice of $\eta_0 = 0.01$ for all values of C except $C = 1000$, where $\eta_0 = 0.001$ was chosen. We have found this strategy to be a robust method for choosing η_0 (note that we do not want to run SGD for more than one iteration with all (C, η_0) combinations, since each iteration is costly).

Figure 9 compares validation error rates for SGD and the randomized EG algorithm. For the initial (roughly 5) iterations of training, SGD has better validation error scores, but beyond this the EG algorithm is very competitive on this task. Note that the amount of computation for SGD does not include the iterations required to find the optimal value of η_0; if this computation was included the SGD curves would be shifted 5 iterations to the right.

Figure 10 shows graphs comparing the primal objective value for EG and SGD. For C equal to 1000, 100, and 10, the results are similar: SGD is initially better than EG, but after around 5

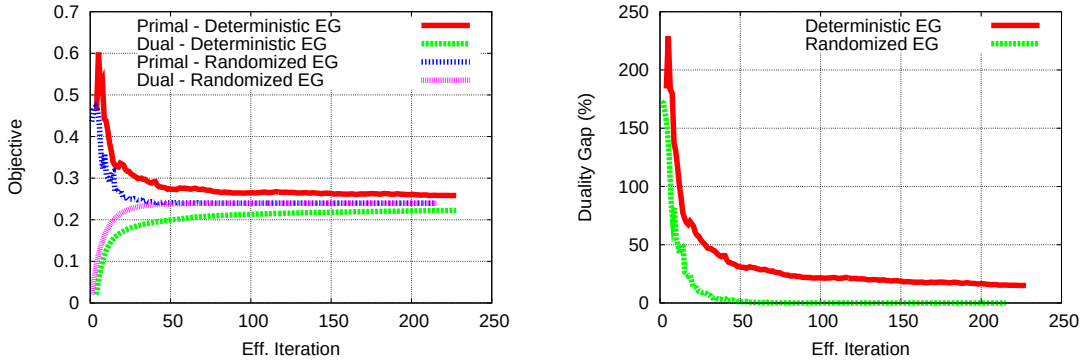

Figure 7: Results on the MNIST learning task, comparing the randomized and deterministic online EG algorithms, for $C = 1$. The left figure shows primal and dual objective values for both algorithms. The right figure shows the normalized value of the duality gap: $(\text{primal(t)} - \text{dual(t)})/\text{opt}$, where opt is the value of the joint optimum of the primal and dual problems, and t is the iteration number. The X axis counts the number of effective iterations over the entire data set.

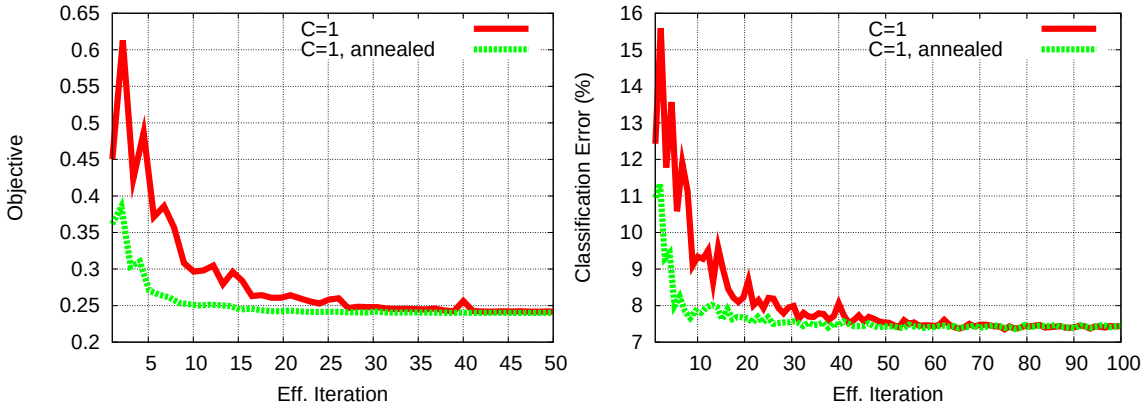

Figure 8: Results on the MNIST learning task, for $C = 1$, comparing the regular EG randomized algorithm with an annealed version of the algorithm (see Section 7.1.1). The left figure shows primal objective values calculated for $C = 1$; the right figure shows validation error. The annealed strategy gives significantly faster convergence.

iterations EG overtakes SGD, and converges much more quickly to the optimal point. The difference between EG and SGD appears to become more pronounced as C becomes smaller. For $C = 1$ our

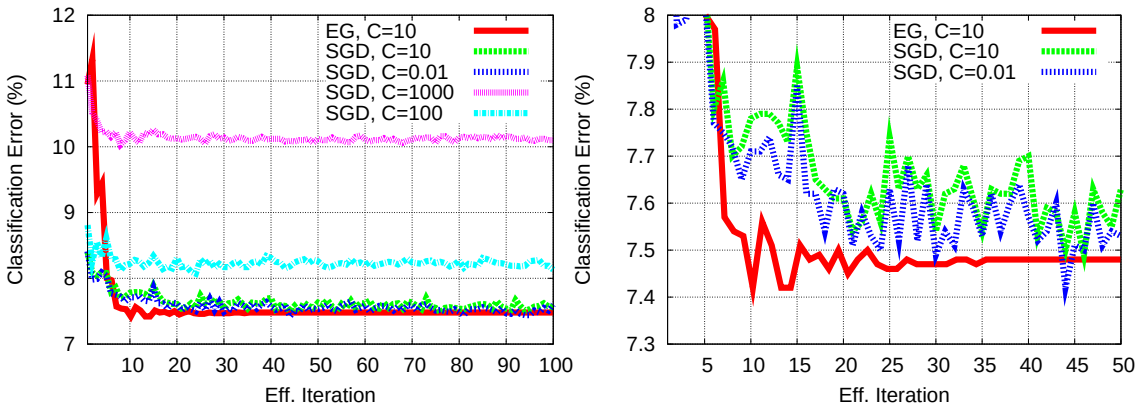

Figure 9: Graphs showing validation error results on the MNIST learning task, comparing the EG randomized algorithm to stochastic gradient descent (SGD). The X axis shows number of effective training iterations, the Y axis shows validation error in percent. The EG results are shown for $C = 10$; SGD results are shown for several values of C. For SGD for $C = 1$, $C = 0.1$, and $C = 0.01$ the curves were nearly identical, hence we omit the curves for $C = 1$ and $C = 0.1$. Note that the amount of computation for SGD does not include the iterations required to find the optimal value for the learning rate η_0.

strategy for choosing η_0 does not pick the optimal value for η_0 at least when evaluating the primal objective; see the caption to the figure for more discussion. EG again appears to out-perform SGD after the initial few iterations.

7.1.4 COMPARISONS TO L-BFGS

One of the standard approaches to training log-linear models is using the L-BFGS gradient-based algorithm (Sha and Pereira, 2003). L-BFGS is a batch algorithm, in the sense that its updates require evaluating the primal objective and gradient, which involves iterating over the entire data-set. To compare L-BFGS to EG, we used the implementation based on Byrd et al. (1995).[13]

For L-BFGS, a total of n training examples must be processed every time the gradient or objective function is evaluated; note that because L-BFGS uses a line search, each iteration may involve several such evaluations.[14]

13. Specifically, we used the code by Zhu, Byrd, Lu, and Nocedal (www.ece.northwestern.edu/∼nocedal/) with L. Stewart's wrapper (www.cs.toronto.edu/∼liam/). In all the experiments, we used 10 pairs of saved gradient vectors (see also Sha and Pereira, 2003).

14. The implementation of L-BFGS that we use requires both the gradient and objective when performing the line-search. In some line-search variants, it is possible to use only objective evaluations. In this case, the EG line search will be somewhat more costly, since the dual objective requires evaluations of both marginals and partition function, whereas the primal objective only requires the partition function. This will have an effect on running times only if the EG line search evaluates more than one point, which happened for less than 10%.

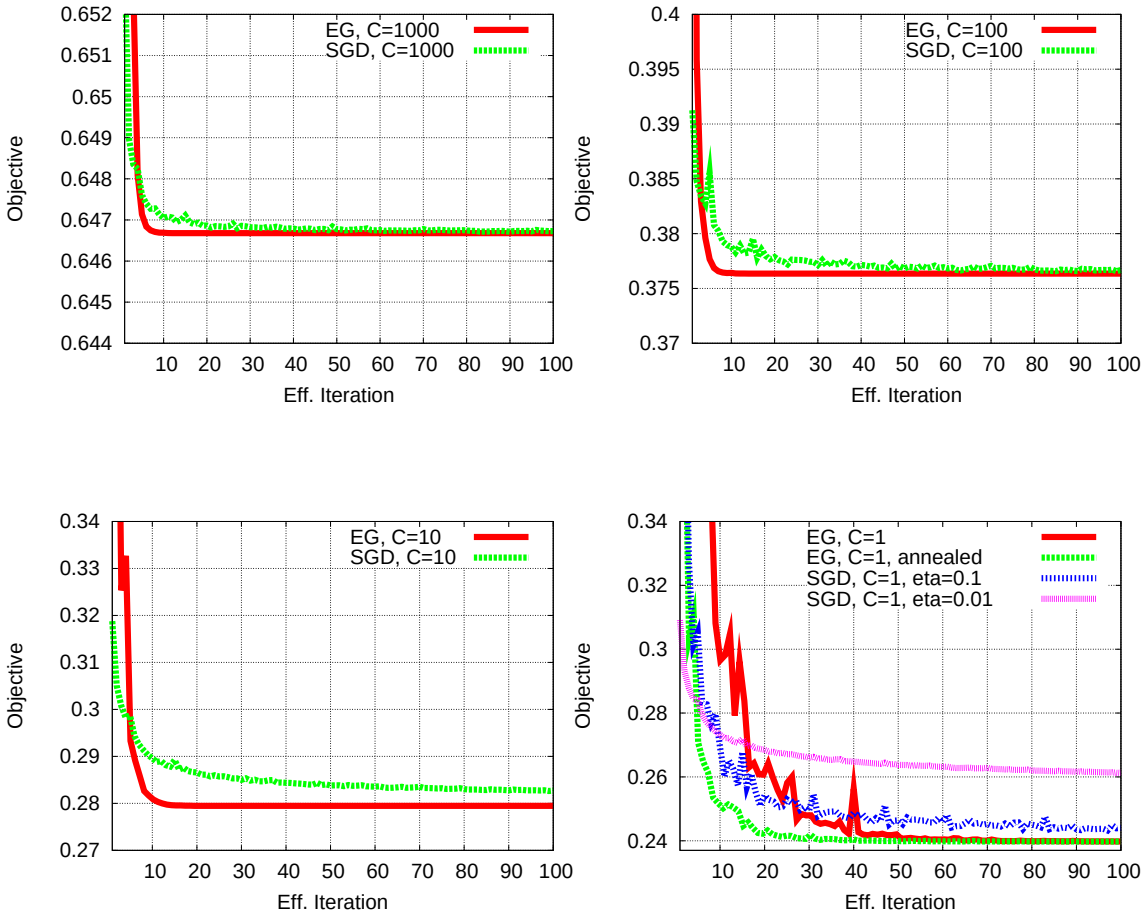

Figure 10: Graphs showing primal objective values on the MNIST learning task, comparing the EG randomized algorithm to stochastic gradient descent (SGD). The X axis shows number of effective training iterations, the Y axis shows primal objective. The graphs are for C equal to 1000, 100, 10, and 1. For $C = 1$ we show EG results with and without the annealed strategy described in Section 7.1.1. For $C = 1$ we also show two SGD curves, for learning rates 0.01 and 0.1: in this case $\eta_0 = 0.01$ was the best-performing learning rate after one iteration for both validation error and primal objective, however a post-hoc analysis shows that $\eta_0 = 0.1$ converges to a better value in the limit. Thus our strategy for choosing η_0 was not optimal in this case, although it is difficult to know how $\eta_0 = 0.1$ could be chosen without post-hoc analysis of the convergence for the different values of η_0. For other values of C our strategy for picking η_0 was more robust.

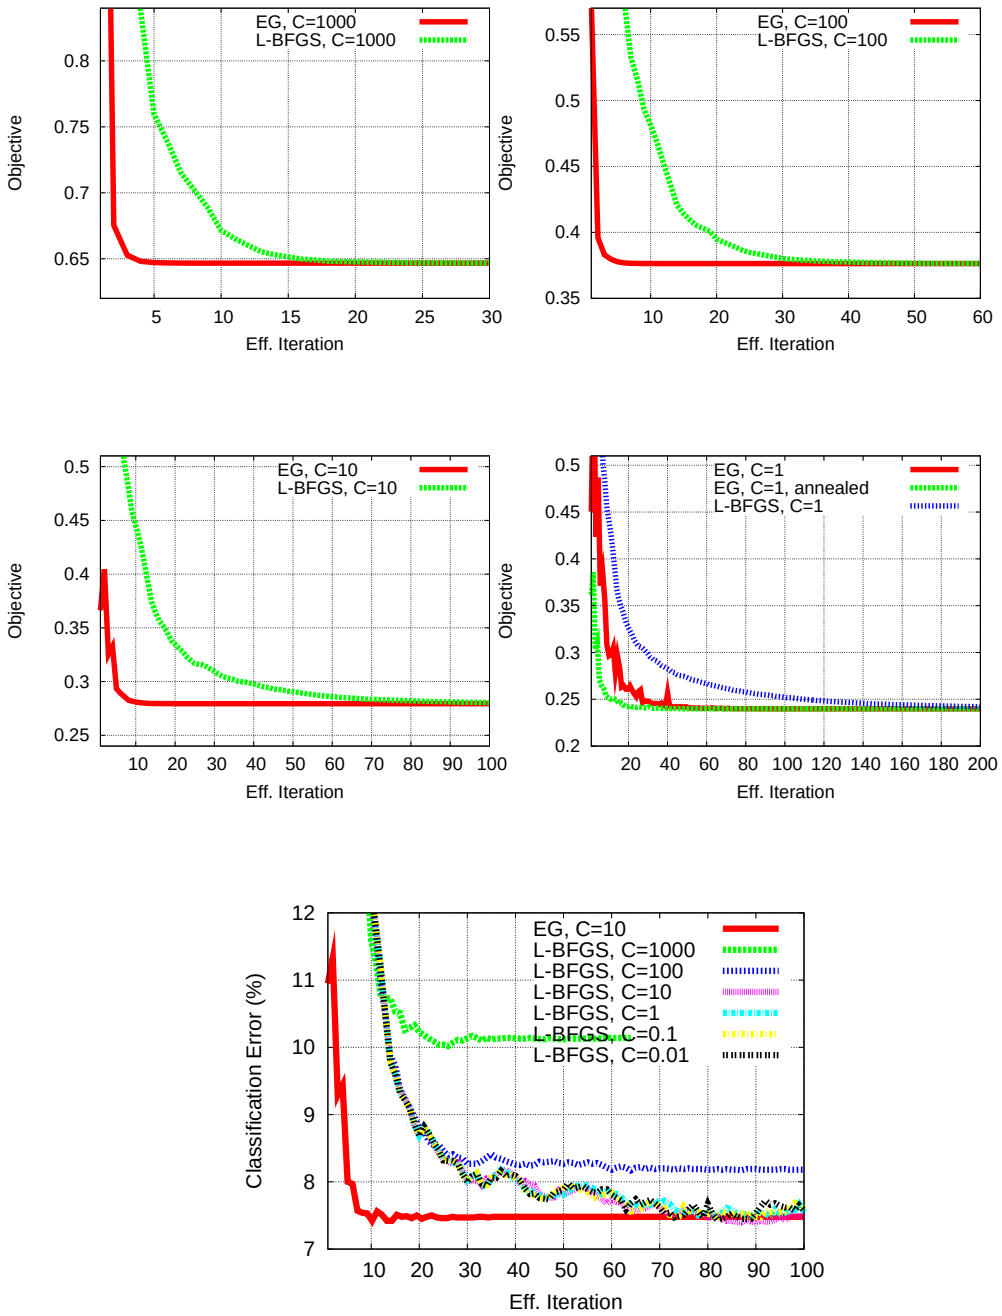

Figure 11: Results on the MNIST learning task, comparing the EG algorithm to L-BFGS. The figures on the first and second row show the primal objective for both algorithms, for various values of C. The bottom curve shows validation error for L-BFGS for various values of C and for EG with $C = 10$.

As in Section 7.1.3, we calculated primal values for EG. Figure 11 shows the primal objective for EG, and L-BFGS. It can be seen that the primal value for EG converges considerably faster than the L-BFGS one. Also shown is a curve of validation error for both algorithms. Here we show the results for EG with $C = 10$ and L-BFGS with various C values. It can be seen that L-BFGS does not outperform the EG curve for any value of C.

7.2 Structured learning - Dependency Parsing

Parsing of natural language sentences is a challenging structured learning task. Dependency parsing (McDonald et al., 2005) is a simplified form of parsing where the goal is to map sentences x into projective directed spanning trees over the set of words in x. Each label y is a set of directed arcs (dependencies) between pairs of words in the sentence. Each dependency is a pair (h,m) where h is the index of the head word of the dependency, and m is the index of the modifier word. Assuming we have a function $\mathbf{f}(x,h,m)$ that assigns a feature vector to dependencies (h,m), we can use a weight vector $\mathbf{w}$ to score a given tree y by $\mathbf{w}\cdot\sum_{(h,m)\in y}\mathbf{f}(x,h,m)$. Dependency parsing corresponds to a structured problem where the parts r are dependencies (h,m); the approach described in Section 4 can be applied efficiently to dependency structures. For projective dependency trees (e.g., see Koo et al., 2007), the required marginals can be computed efficiently using a variant of the inside-outside algorithm (Baker, 1979).

In the experiments below we use a feature set $\mathbf{f}(x,h,m)$ similar to that in McDonald et al. (2005) and Koo et al. (2007), resulting in $2,500,554$ features. We report results on the Spanish data-set which is part of the CoNLL-X Shared Task on multilingual dependency parsing (Buchholz and Marsi, 2006). The training data consists of $2,306$ sentences ($58,771$ tokens). To evaluate validation error, we use $1,000$ sentences ($30,563$ tokens) and report accuracy (rate of correct edges in a predicted parse tree) on these sentences.[15] Since we used only sentences from the training set, results are not directly comparable to the CoNLL-X shared task results. However, our previous work on this data set (Koo et al., 2007) shows that regularized max-margin and log-linear models typically outperform the averaged perceptron, which is not explicitly regularized.

As in the multi-class experiments, we compare to SGD and L-BFGS. The implementation of the algorithms is similar to that described in Section 7.1. The gradients for SGD and L-BFGS were obtained by calculating the relevant marginals of the model, using the inside-outside algorithm that was also used for EG. The learning rate for SGD was chosen as in the previous section; that is, we tested several learning rates ($\eta_0 = 1, 0.1, 0.001, 0.0001$) and chose the one that yielded the minimum validation error after one iteration.

Figure 12 shows results for EG and L-BFGS on the parsing task. We experiment with values of C in the set $\{0.1, 1, 10, 100, 1000\}$. Of these, the value that results in optimal validation error was $C = 10$. The performance of L-BFGS, SGD and EG is demonstrated in terms of the primal objective for a subset of the C values. L-BFGS and EG both converge to the optimal value, and EG is significantly faster. On the other hand, SGD does not converge to the optimum for all C values (e.g., for $C = 1, 10$), and when it does converge to the optimum, it is slower than EG.

Figure 12 also shows the validation error for EG at the optimal C value, compared to validation error for L-BFGS and SGD at various C values. Again, it can be seen that EG significantly outperforms L-BFGS. For SGD, performance is comparable to EG. However, as mentioned earlier, SGD

15. All $3,306$ sentences were obtained from the training data section of the CoNLL-X Spanish data-set (Civit and Martí, 2002).

C	Iterations	Total Iterations	Accuracy
1000	8	8	72.44
700	3.01	11.01	73.42

Table 3: Table showing number of effective iterations required to optimize a sequence of values for C for the parsing task, using the method described in Section 7.1.2. The column C shows the sequence of decreasing regularizer constants. *Iterations* shows the number of effective iterations over the training set required to optimize each value of C. *Total iterations* shows the cumulative value of *Iterations*, and *Accuracy* shows the validation accuracy obtained for every C value. It can be seen that the optimal accuracy is reached at $C = 13.841$.

in fact does not successfully optimize the primal objective for low values of C, and for higher values of C the SGD primal objective is slower to converge.

As in the multi-class experiments (see Figure 10), it is possible to find learning rates for SGD such that it converges to the primal optimum for $C = 1, 10$. However, the optimality of these rates only becomes evident after 10 iterations or more (results not shown). Thus, to find a learning rate for SGD that actually solves the optimization problem would typically require an additional few tens of iterations, making it significantly slower than EG.

Finally, it is possible to use EG to efficiently optimize over a set of regularization constants, as in Section 7.1.2. Table 3 shows results for a sequence of regularization constants.

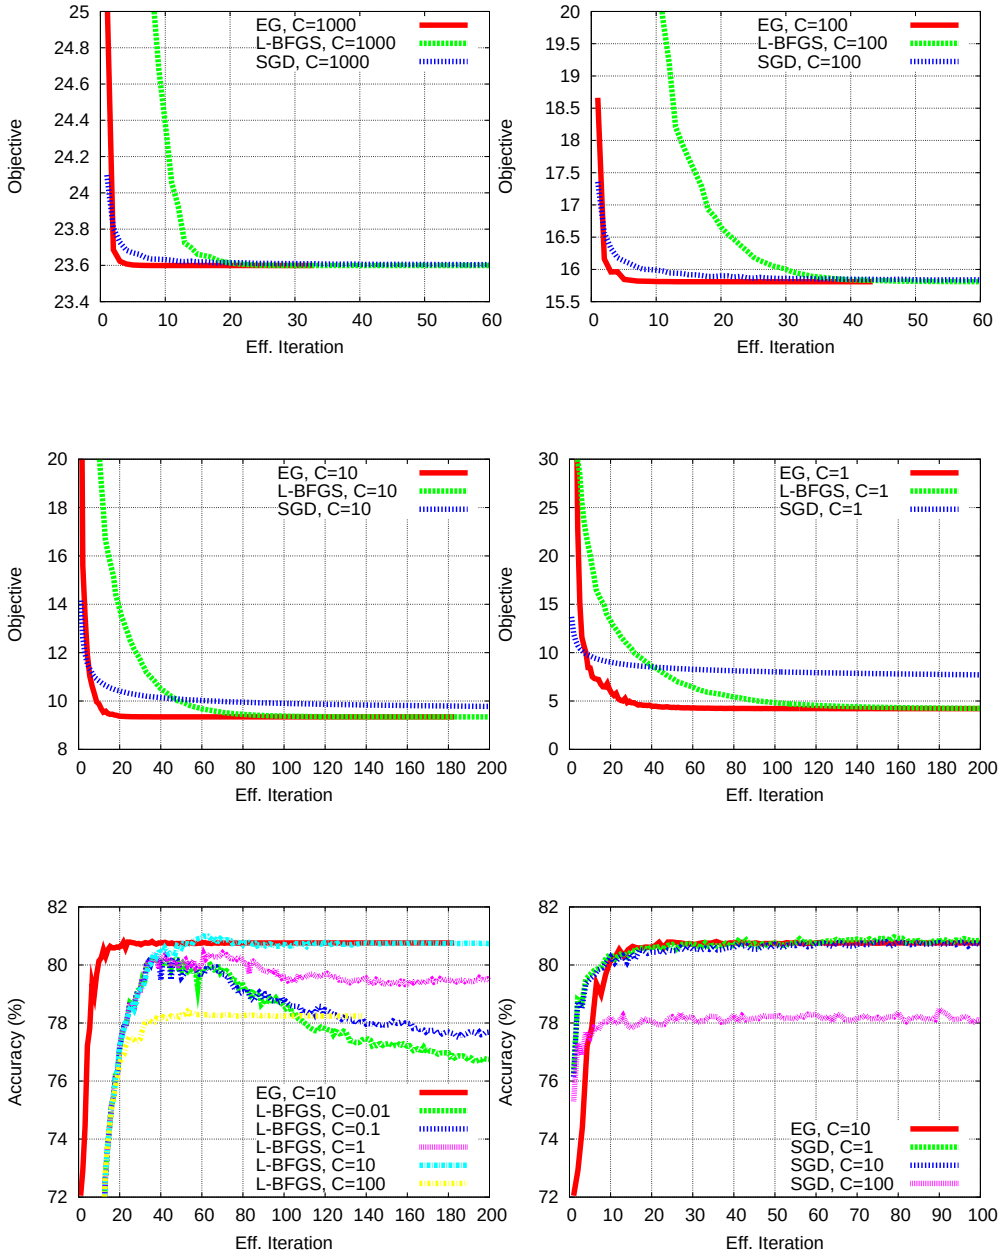

Figure 12: Results on the dependency-parsing task, comparing the EG algorithm to L-BFGS and SGD. All algorithms are trained on the log-linear objective function. The figures on the first and second rows show the primal objective for the three algorithms, for various values of C. The left bottom plot shows validation accuracy (measured as the fraction of correctly predicted edges) for L-BFGS for various values of C and for EG with $C = 10$. The right bottom plot show validation accuracy for EG (with $C = 10$) and SGD.

8. Experiments on Max-Margin Models

The max-margin loss (Eq. 3) has a discontinuity in its derivative. This makes optimization of max-margin models somewhat more involved than log-linear ones, since gradient algorithms such as L-BFGS cannot be used. This difficulty is exacerbated in the case of structured prediction models, since maximization in Eq. 3 is potentially over an exponentially large set.

In this section, we apply the EG algorithm to the max-margin problem, and compare its performance to the SVM-Struct algorithm presented in Tsochantaridis et al. (2004).[16] SVM-Struct is based on a cutting-plane algorithm that operates on the dual max-margin problem (D-MM) and results in monotone improvement in this dual. In this sense, it is similar to our EG algorithm. In order to facilitate a fair comparison, we report the performance of the two algorithms as a function of time. We do not report results by iteration since EG and SVM-struct involve different computation per iteration (e.g., SVM-Struct solves a QP per iteration).

We applied SVM-Struct and EG to the dependency parsing problem described in Section 7.2. To apply SVM-Struct to this problem, we supply it with a routine that finds the $y \in \mathcal{Y}$ which attains the maximum of the hinge-loss in Eq. 3. This maximum can be found using a Viterbi-style algorithm. For the value of C we experimented with $C \in \{1, 10, 100, 1000, 10000\}$. The optimal value in terms of validation error was $C = 100$.

Figure 13 shows results in terms of primal and dual objective and in terms of accuracy. It can be seen that EG is considerably faster than SVM-Struct for most C values. The performance is comparable only for $C = 1$, where convergence is slow for both algorithms.

9. Conclusion

We have presented novel algorithms for large-scale learning of log-linear and max-margin models, which provably converge to the optimal value of the respective loss functions. Although the algorithms have both batch and online variants, the online version turns out to be much more effective, both in theory and in practice. Our theoretical results (see Section 5.1) suggest that the online algorithm requires a factor of n less iterations to achieve a desired accuracy ε in the dual objective. This factor results from the fact that the online algorithm can use a learning rate η that is n times larger than the batch case to obtain updates that decrease the dual objective. Intuitively, this difference is associated with the fact that the batch algorithm updates all $\mathbf{u}$ values simultaneously. The dual objective has a term $\mathbf{u}^T A\mathbf{u}$ which involves all the $\mathbf{u}_i$ variables and second order interactions between them. It turns out that for batch updates only a relatively small change in the $\mathbf{u}_i$ is allowed, if one still requires an improvement in the dual objective after the update. It is possible that our bounds for the batch convergence rate are more conservative than those for the online case. However, we have observed in practice that the batch algorithm is much slower to converge. Furthermore, we also observed that other batch-based algorithms such as L-BFGS and conjugate gradient converge more slowly than the online EG algorithm.

Our results provide an $O(\log(\frac{1}{\varepsilon}))$ rate for the log-linear model, as opposed to $O(\frac{1}{\varepsilon})$ for max-margin. If these bounds are tight, they would imply that log-linear models have an advantage over max-margin ones in terms of training efficiency. However, it is possible that the analysis is not tight, and that improved rates may also be obtained for the max-margin model. In any case, this raises

16. The code is available from svmlight.joachims.org/svm_struct.html.

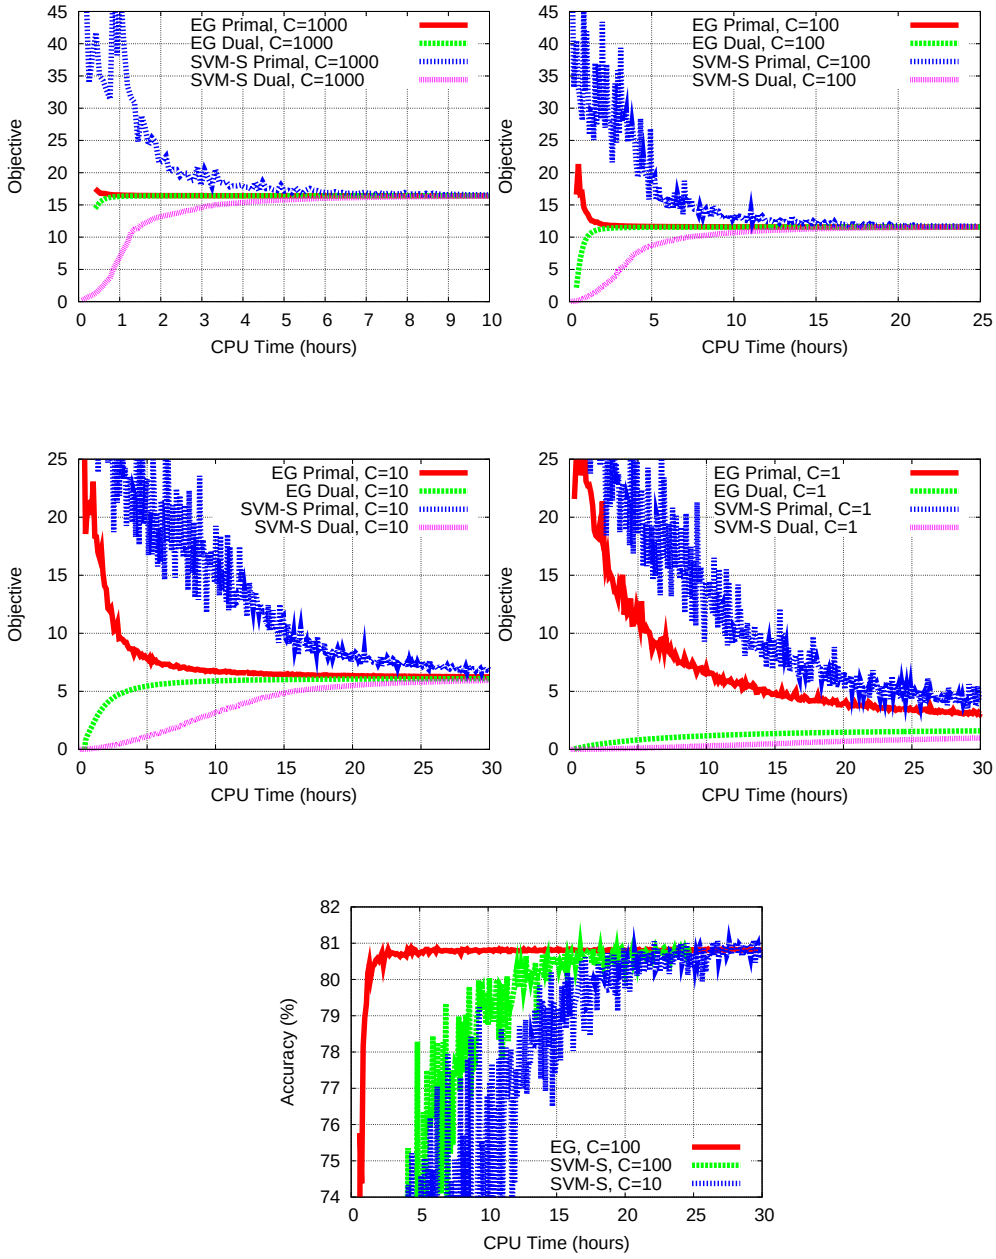

Figure 13: Results on the dependency-parsing task, comparing the EG algorithm to SVM-Struct. Both algorithms are trained on a max-margin model. The figures on the first and second rows show the primal objective for both algorithms, for various values of C. The bottom curve shows validation accuracy (measured as the fraction of correctly predicted edges) for SVM-Struct for various values of C and for EG with $C = 100$ (the value that yielded the highest validation accuracy). The X axis on all curves is running time in hours.

the interesting question of comparing classification models not only in terms of accuracy but also in terms of optimization efficiency.

Our convergence rates are with respect to accuracy in the dual objective. Some previous work (e.g., Shalev-Shwartz et al., 2007) has considered the accuracy with respect to the primal objective. It is relatively easy to show that in order to obtain ε accuracy in the primal, the EG algorithms require $O(\log(\frac{1}{\varepsilon}))$ updates for the log-linear problem and $O(\frac{1}{\varepsilon^2})$ for the max-margin case. It is possible that a more refined analysis of the max-margin case will result in $O(\frac{1}{\varepsilon})$ (e.g., see List et al., 2007), but we leave this for further study.

Most of our proofs rely on a relation between B_Q and the KL divergence. This relation holds for max-margin learning as well, a fact that simplifies previous results in this setting (Bartlett et al., 2005). We expect a similar analysis to hold for other functions Q.

An interesting extension of our method is to using second order derivative information, or its approximations, as in L-BFGS (Byrd et al., 1995). Such information may be used to obtain more accurate minimization for each $\mathbf{u}_i$ and may speed up convergence. Another possible improvement is to the line search method. In the experiments reported here we use a crude mechanism for adapting the learning rate, and it is possible that a more careful procedure will improve convergence rates in practice.

Parallelization is becoming increasingly relevant as multi-core CPUs become available. For the batch EG algorithm, it is straightforward to distribute the computation among k processors. One method for distributing the online EG algorithm would be to update k examples in parallel on k different processors. It should be possible to analyze this setting in a similar way to our proofs for the online case, but we leave this to future work.

Finally, our results show that the EG algorithms are highly competitive with state-of-the-art methods for training log-linear and max-margin models. We thus expect them to become useful as learning algorithms, particularly in the structured prediction setting.

Appendix A. $O(\frac{1}{\varepsilon})$ Rate for Batch Algorithms - Proof of Lemma 5

We use a similar proof technique to that of Kivinen and Warmuth (2001). In particular, we need the following Lemma, which is very similar to results used by Kivinen and Warmuth (2001):

Lemma 10 *(See Kivinen and Warmuth (2001), Proof of Lemma 4) For any convex function $Q(\mathbf{u})$ over Δ^n, for any $\mathbf{z} \in \Delta^n$, and any $\mathbf{u}^t$ in the interior of Δ^n, if $\mathbf{u}^{t+1}$ is derived from $\mathbf{u}^t$ using the EG updates with a learning rate η, then*

$$\eta Q(\mathbf{u}^t) - \eta Q(\mathbf{z}) = D[\mathbf{z}\|\mathbf{u}^t] - D[\mathbf{z}\|\mathbf{u}^{t+1}] + D[\mathbf{u}^t\|\mathbf{u}^{t+1}] - \eta B_Q[\mathbf{z}\|\mathbf{u}^t] \; . \tag{9}$$

Proof: By the definition of Bregman divergence, we have

$$\eta Q(\mathbf{u}^t) - \eta Q(\mathbf{z}) = -\eta \nabla Q(\mathbf{u}^t) \cdot (\mathbf{z} - \mathbf{u}^t) - \eta B_Q[\mathbf{z} \| \mathbf{u}^t] \ . \tag{10}$$

Given that $\mathbf{u}^{t+1}$ is derived from $\mathbf{u}^t$ using EG updates,

$$u_{i,y}^{t+1} = \frac{u_{i,y}^t e^{-\eta \nabla_{i,y}}}{Z_i^t} \ ,$$

where Z_i^t is a normalization constant, and $\nabla_{i,y} = \frac{\partial Q(\mathbf{u}^t)}{\partial u_{i,y}}$. Simple algebra then shows that:

$$\begin{aligned} D[\mathbf{z}\|\mathbf{u}^t] - D[\mathbf{z}\|\mathbf{u}^{t+1}] + D[\mathbf{u}^t\|\mathbf{u}^{t+1}] &= \sum_{i,y} \left(z_{i,y} \log \frac{z_{i,y}}{u_{i,y}^t} - z_{i,y} \log \frac{z_{i,y}}{u_{i,y}^{t+1}} + u_{i,y}^t \log \frac{u_{i,y}^t}{u_{i,y}^{t+1}} \right) \\ &= \sum_{i,y} (z_{i,y} - u_{i,y}^t) \log \frac{u_{i,y}^{t+1}}{u_{i,y}^t} \\ &= \sum_{i,y} (z_{i,y} - u_{i,y}^t)(-\eta \nabla_{i,y} - \log Z_i^t) \\ &= \sum_{i,y} (z_{i,y} - u_{i,y}^t)(-\eta \nabla_{i,y}) \\ &= -\eta \nabla Q(\mathbf{u}^t) \cdot (\mathbf{z} - \mathbf{u}^t) \ . \end{aligned} \tag{11}$$

Note that we have used $\sum_{i,y}(z_{i,y} - u_{i,y}^t) \log Z_i^t = 0$, which follows because $\sum_{i,y} z_{i,y} \log Z_i^t = \sum_{i,y} u_{i,y}^t \log Z_i^t$ $= \sum_i \log Z_i^t$.

Combining Eq. 10 and Eq. 11 gives Eq. 9, thus proving the lemma. □

We can now prove Lemma 5:

Proof of Lemma 5: Using $-\eta B_Q[\mathbf{z}\|\mathbf{u}^t] \leq 0$, Lemma 10 implies that for all t

$$\eta Q(\mathbf{u}^t) - \eta Q(\mathbf{z}) \leq D[\mathbf{z}\|\mathbf{u}^t] - D[\mathbf{z}\|\mathbf{u}^{t+1}] + D[\mathbf{u}^t\|\mathbf{u}^{t+1}] \ . \tag{12}$$

By the assumptions of Lemma 5, $Q(\mathbf{u})$ is τ-upper-bounded, and $0 \leq \eta \leq \frac{1}{\tau}$, hence by Lemma 3 we have

$$Q(\mathbf{u}^t) - Q(\mathbf{u}^{t+1}) \geq \frac{1}{\eta} D[\mathbf{u}^t\|\mathbf{u}^{t+1}] \ . \tag{13}$$

Combining Eqs. 12 and 13 gives for all t

$$\eta Q(\mathbf{u}^{t+1}) - \eta Q(\mathbf{z}) \leq D[\mathbf{z}\|\mathbf{u}^t] - D[\mathbf{z}\|\mathbf{u}^{t+1}] \ .$$

Summing this over $t = 1, \ldots, T$ gives (the sum on the RHS telescopes)

$$\eta \sum_{t=1}^{T} Q(\mathbf{u}^{t+1}) - \eta T Q(\mathbf{z}) \leq D[\mathbf{z}\|\mathbf{u}^1] - D[\mathbf{z}\|\mathbf{u}^{T+1}] \ .$$

Because $Q(\mathbf{u}^t)$ is monotone decreasing (by Eq. 13), we have $T Q(\mathbf{u}^{T+1}) \leq \sum_{t=1}^{T} Q(\mathbf{u}^{t+1})$ and simple algebra gives

$$Q(\mathbf{u}^{T+1}) \leq Q(\mathbf{z}) + \frac{D[\mathbf{z}\|\mathbf{u}^1] - D[\mathbf{z}\|\mathbf{u}^{T+1}]}{\eta T} \ .$$

Dropping the term $D[\mathbf{z}\|\mathbf{u}^{T+1}]$ (because $-D[\mathbf{z}\|\mathbf{u}^{T+1}] \leq 0$) we obtain

$$Q(\mathbf{u}^{T+1}) \leq Q(\mathbf{z}) + \frac{D[\mathbf{z}\|\mathbf{u}^1]}{\eta T} ,$$

as required.

Appendix B. $O(\log(\frac{1}{\varepsilon}))$ Rate for Batch Algorithms - Proof of Lemma 6

By the assumptions of Lemma 6, $Q(\mathbf{u})$ is τ-upper-bounded, and $0 \leq \eta \leq \frac{1}{\tau}$, hence by Lemma 3 we have for all t

$$Q(\mathbf{u}^t) - Q(\mathbf{u}^{t+1}) \geq \frac{1}{\eta} D[\mathbf{u}^t\|\mathbf{u}^{t+1}] .$$

Combining this result with Lemma 10 gives

$$\eta Q(\mathbf{u}^{t+1}) - \eta Q(\mathbf{z}) \leq D[\mathbf{z}\|\mathbf{u}^t] - D[\mathbf{z}\|\mathbf{u}^{t+1}] - \eta B_Q[\mathbf{z}\|\mathbf{u}^t] .$$

We can now make use of the assumption that $Q(\mathbf{u})$ is (μ,τ)-bounded, and hence $\eta B_Q[\mathbf{z}\|\mathbf{u}^t] \geq \eta\mu D[\mathbf{z}\|\mathbf{u}^t]$, to obtain

$$\begin{aligned} \eta Q(\mathbf{u}^{t+1}) - \eta Q(\mathbf{z}) &\leq D[\mathbf{z}\|\mathbf{u}^t] - D[\mathbf{z}\|\mathbf{u}^{t+1}] - \eta\mu D[\mathbf{z}\|\mathbf{u}^t] \\ &= (1-\eta\mu) D[\mathbf{z}\|\mathbf{u}^t] - D[\mathbf{z}\|\mathbf{u}^{t+1}] \\ &\leq (1-\eta\mu) D[\mathbf{z}\|\mathbf{u}^t] . \end{aligned} \tag{14}$$

If there exists a $t \leq T$ such that $Q(\mathbf{u}^{t+1}) - Q(\mathbf{z}) \leq 0$ then because $Q(\mathbf{u}^t)$ decreases monotonically with t we have $Q(\mathbf{u}^{T+1}) \leq Q(\mathbf{u}^{t+1}) \leq Q(\mathbf{z})$ and the lemma trivially holds. Otherwise, it must be the case that $Q(\mathbf{u}^{t+1}) - Q(\mathbf{z}) \geq 0$ for all $t \leq T$, and thus for all $t \leq T$

$$D[\mathbf{z}\|\mathbf{u}^{t+1}] \leq (1-\eta\mu) D[\mathbf{z}\|\mathbf{u}^t] .$$

Using this inequality recursively for $t = 1,\ldots,T$ we get

$$D[\mathbf{z}\|\mathbf{u}^{T+1}] \leq (1-\eta\mu)^T D[\mathbf{z}\|\mathbf{u}^1] .$$

Substituting back into Eq. 14 we obtain

$$Q(\mathbf{u}^{T+1}) - Q(\mathbf{z}) \leq \frac{(1-\eta\mu)^T}{\eta} D[\mathbf{z}\|\mathbf{u}^1] \leq \frac{e^{-\eta\mu T}}{\eta} D[\mathbf{z}\|\mathbf{u}^1] ,$$

where we have used $\log(1-x) \leq -x$.

Appendix C. Proof of Lemma 7

For the regularized log-likelihood dual, for any $\mathbf{v} \in \Delta$

$$Q_{\mathbf{u},i}(\mathbf{v}) = \sum_y v_y \log v_y + \frac{1}{2}\mathbf{v}^T A(i,i)\mathbf{v} + \sum_{j\neq i}\sum_y u_{j,y}\log u_{j,y} + \frac{1}{2}\sum_{j\neq i}\sum_{k\neq i}\mathbf{u}_j^T A(j,k)\mathbf{u}_k + \sum_{j\neq i}\mathbf{u}_j^T A(j,i)\mathbf{v} ,$$

where $A(j,k)$ is the $|\mathcal{Y}| \times |\mathcal{Y}|$ sub-matrix of A defined as $A_{y,z}(j,k) = A_{(j,y),(k,z)}$. To obtain the Bregman divergence $B_{Q_{\mathbf{u},i}}[\mathbf{p}\|\mathbf{q}]$, note that the last three terms in $Q_{\mathbf{u},i}(\mathbf{v})$ are either constant or linear in $\mathbf{v}$ and thus do not contribute to $B_{Q_{\mathbf{u},i}}[\mathbf{p}\|\mathbf{q}]$. It follows that

$$B_{Q_{\mathbf{u},i}}[\mathbf{p}\|\mathbf{q}] = D[\mathbf{p}\|\mathbf{q}] + M_{A(i,i)}[\mathbf{p}\|\mathbf{q}] \ .$$

By a similar argument to the proof of Lemma 3, it follows that $B_{Q_{\mathbf{u},i}}[\mathbf{p}\|\mathbf{q}] \leq (1+|A(i,i)|_\infty)D[\mathbf{p}\|\mathbf{q}]$. Because $A(i,i)$ is a sub-matrix of A we have $|A(i,i)|_\infty \leq |A|_\infty$, and the first part of the lemma follows. For the max-margin dual, a similar argument shows that

$$B_{Q_{\mathbf{u},i}}[\mathbf{p}\|\mathbf{q}] = M_{A(i,i)}[\mathbf{p}\|\mathbf{q}] \ ,$$

so we have $B_{Q_{\mathbf{u},i}}[\mathbf{p}\|\mathbf{q}] \leq |A(i,i)|_\infty D[\mathbf{p}\|\mathbf{q}] \leq |A|_\infty D[\mathbf{p}\|\mathbf{q}]$. □

Appendix D. Proof of Lemma 8

For the proof we will need some additional notation, which makes explicit the relationship between the sequence of dual variables $\mathbf{u}^1, \mathbf{u}^2, \ldots, \mathbf{u}^{T+1}$ and the sequence of indices $k_1, k_2, \ldots, k_T$ used in the algorithm in Figure 2. We will use the following definitions:

- We use k_1^t to denote a sequence of indices $k_1, k_2, \ldots, k_t$. We take k_1^0 to be the empty sequence.
- We write $\mathbf{r} : \Delta^n \times [1 \ldots n] \to \Delta^n$ to denote the function that corresponds to an EG update on a single example. More specifically, we have

$$\begin{aligned} \mathbf{r}_i(\mathbf{u},k) &= \mathbf{u}_i \ \text{ for } i \neq k \\ r_{i,y}(\mathbf{u},k) &\propto u_{i,y} \exp\{-\eta \nabla_{i,y}\} \ \text{ where } \nabla_{i,y} = \tfrac{\partial Q(\mathbf{u})}{\partial u_{i,y}} \text{ for } i = k, \text{ for all } y \ . \end{aligned}$$

- Finally, for any choice of index sequence k_1^T we will define a sequence of dual variables using the following iterative definition:

$$\begin{aligned} \mathbf{u}(k_1^0) &= \mathbf{u}^1 \\ \mathbf{u}(k_1^t) &= \mathbf{r}(\mathbf{u}(k_1^{t-1}), k_t) \ \text{ for } t \geq 1 \ . \end{aligned}$$

  Here $\mathbf{u}^1$ is the initial setting of the dual variables, as shown in the algorithm in Figure 2.

From these definitions it follows that if k_1^T is the sequence of indices chosen during a run of the algorithm in Figure 2, then the sequence of dual variables $\mathbf{u}^1, \mathbf{u}^2, \ldots, \mathbf{u}^{T+1}$ is such that $\mathbf{u}^{t+1} = \mathbf{u}(k_1^t)$ for $t = 0 \ldots T$. We can now give the proof.

Proof of Lemma 8. First, we have for any $\mathbf{u}, \mathbf{z} \in \Delta^n$

$$\begin{aligned} Q(\mathbf{u}) &\leq Q(\mathbf{z}) + (\mathbf{u}-\mathbf{z}) \cdot \nabla Q(\mathbf{u}) \\ &= Q(\mathbf{z}) + \frac{1}{\eta} \sum_{i=1}^n \Big[D[\mathbf{z}_i \| \mathbf{u}_i] - D[\mathbf{z}_i \| \mathbf{r}_i(\mathbf{u},i)] + D[\mathbf{u}_i \| \mathbf{r}_i(\mathbf{u},i)] \Big] \ . \end{aligned} \tag{15}$$

The second line follows by similar arguments to those in the proof of Lemma 10.

Next consider the terms on the right-hand-side of the inequality. For any i, we have

$$\begin{aligned} & D[\mathbf{z}_i \| \mathbf{u}_i] - D[\mathbf{z}_i \| \mathbf{r}_i(\mathbf{u}, i)] \\ &= D[\mathbf{z}_i \| \mathbf{u}_i] - D[\mathbf{z}_i \| \mathbf{r}_i(\mathbf{u}, i)] + \sum_{j=1\ldots n, j\neq i} D[\mathbf{z}_j \| \mathbf{u}_j] - \sum_{j=1\ldots n, j\neq i} D[\mathbf{z}_j \| \mathbf{u}_j] \quad (16) \\ &= D[\mathbf{z}_i \| \mathbf{u}_i] - D[\mathbf{z}_i \| \mathbf{r}_i(\mathbf{u}, i)] + \sum_{j=1\ldots n, j\neq i} D[\mathbf{z}_j \| \mathbf{u}_j] - \sum_{j=1\ldots n, j\neq i} D[\mathbf{z}_j \| \mathbf{r}_j(\mathbf{u}, i)] \quad (17) \\ &= D[\mathbf{z} \| \mathbf{u}] - D[\mathbf{z} \| \mathbf{r}(\mathbf{u}, i)] \ . \quad (18) \end{aligned}$$

Here Eq. 17 follows from Eq. 16 because $\mathbf{r}_j(\mathbf{u}, i) = \mathbf{u}_j$ for $j \neq i$. In addition, for any i we have

$$\frac{1}{\eta} D[\mathbf{u}_i \| \mathbf{r}_i(\mathbf{u}, i)] \leq Q(\mathbf{u}) - Q(\mathbf{r}(\mathbf{u}, i)) \ . \quad (19)$$

This follows because by the assumption in the lemma, $Q(\mathbf{u})$ is τ-online-upper-bounded, so we have $B_{Q_{\mathbf{u},i}}[\mathbf{r}_i(\mathbf{u}, i) \| \mathbf{u}_i] \leq \tau D[\mathbf{r}_i(\mathbf{u}, i) \| \mathbf{u}_i]$. By an application of Lemma 2 to the convex function $Q_{\mathbf{u},i}$, noting that by assumption $\eta \leq 1/\tau$, it follows that

$$\frac{1}{\eta} D[\mathbf{u}_i \| \mathbf{r}_i(\mathbf{u}, i)] \leq Q_{\mathbf{u},i}(\mathbf{u}_i) - Q_{\mathbf{u},i}(\mathbf{r}_i(\mathbf{u}, i)) \ .$$

Finally, note that $Q_{\mathbf{u},i}(\mathbf{u}_i) = Q(\mathbf{u})$, and $Q_{\mathbf{u},i}(\mathbf{r}_i(\mathbf{u}, i)) = Q(\mathbf{r}(\mathbf{u}, i))$, giving the result in Eq. 19.

Combining Equations 15, 18 and 19 gives for any $\mathbf{u}$,

$$Q(\mathbf{u}) \leq Q(\mathbf{z}) + \frac{1}{\eta} \sum_{i=1}^{n} \Big[D[\mathbf{z} \| \mathbf{u}] - D[\mathbf{z} \| \mathbf{r}(\mathbf{u}, i)] \Big] + \sum_{i=1}^{n} \Big[Q(\mathbf{u}) - Q(\mathbf{r}(\mathbf{u}, i)) \Big] \ . \quad (20)$$

Because Eq. 20 holds for any value of $\mathbf{u}$, we have for all $t = 1 \ldots T$, for all $k_1^{t-1} \in [1 \ldots n]^{t-1}$,

$$\begin{aligned} Q(\mathbf{u}(k_1^{t-1})) \leq Q(\mathbf{z}) &+ \frac{1}{\eta} \sum_{i=1}^{n} \Big[D[\mathbf{z} \| \mathbf{u}(k_1^{t-1})] - D[\mathbf{z} \| \mathbf{r}(\mathbf{u}(k_1^{t-1}), i)] \Big] \\ &+ \sum_{i=1}^{n} \Big[Q(\mathbf{u}(k_1^{t-1})) - Q(\mathbf{r}(\mathbf{u}(k_1^{t-1}), i)) \Big] \ . \quad (21) \end{aligned}$$

We can now take an expectation of both sides of the inequality in Eq. 21. For any function $f(k_1^t)$, we use the notation $\mathbf{E}_t[f(k_1^t)]$ to denote the expected value of $f(k_1^t)$ when k_1^t is drawn uniformly at random from $[1, 2, \ldots, n]^t$; more precisely

$$\mathbf{E}_t[f(k_1^t)] = \frac{1}{n^t} \sum_{k_1^t \in [1,2,\ldots,n]^t} f(k_1^t) \ .$$

We apply the operator $\mathbf{E}_{t-1}$ to both sides of Eq. 21. We consider the different terms in turn. First,

$$\mathbf{E}_{t-1}[Q(\mathbf{u}(k_1^{t-1}))] = \mathbf{E}_T[Q(\mathbf{u}(k_1^{t-1}))] \ .$$

This follows because $Q(\mathbf{u}(k_1^{t-1}))$ does not depend on the values for $k_t, \ldots, k_T$. Clearly, $\mathbf{E}_{t-1}[Q(\mathbf{z})] = Q(\mathbf{z})$. Next,

$$\mathbf{E}_{t-1} \left[\frac{1}{\eta} \sum_{i=1}^{n} D[\mathbf{z} \| \mathbf{u}(k_1^{t-1})] - D[\mathbf{z} \| \mathbf{r}(\mathbf{u}(k_1^{t-1}), i)] \right]$$

$$
\begin{aligned}
&= \mathbf{E}_{t-1}\left[\frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}(k_1^{t-1})]\right] - \mathbf{E}_{t-1}\left[\frac{n}{\eta}\sum_{i=1}^{n}\frac{1}{n}D[\mathbf{z}\|\mathbf{r}(\mathbf{u}(k_1^{t-1}),i)]\right] \\
&= \mathbf{E}_{t-1}\left[\frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}(k_1^{t-1})]\right] - \mathbf{E}_{t}\left[\frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}(k_1^{t})]\right] \\
&= \mathbf{E}_{T}\left[\frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}(k_1^{t-1})]\right] - \mathbf{E}_{T}\left[\frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}(k_1^{t})]\right] .
\end{aligned}
$$

Finally, we consider the last term:

$$
\begin{aligned}
&\mathbf{E}_{t-1}\left[\sum_{i=1}^{n} Q(\mathbf{u}(k_1^{t-1})) - Q(\mathbf{r}(\mathbf{u}(k_1^{t-1}),i))\right] \\
&\quad= \mathbf{E}_{t-1}\left[nQ(\mathbf{u}(k_1^{t-1})) - n\sum_{i=1}^{n}\frac{1}{n}Q(\mathbf{r}(\mathbf{u}(k_1^{t-1}),i))\right] \\
&\quad= \mathbf{E}_{t-1}\left[nQ(\mathbf{u}(k_1^{t-1}))\right] - \mathbf{E}_{t}\left[nQ(\mathbf{u}(k_1^{t}))\right] \\
&\quad= \mathbf{E}_{T}\left[nQ(\mathbf{u}(k_1^{t-1}))\right] - \mathbf{E}_{T}\left[nQ(\mathbf{u}(k_1^{t}))\right] .
\end{aligned}
$$

Combining these results with Eq. 21 gives

$$
\begin{aligned}
\mathbf{E}_T[Q(\mathbf{u}(k_1^{t-1}))] \;\leq\; & Q(\mathbf{z}) + \mathbf{E}_T\left[\frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}(k_1^{t-1})]\right] - \mathbf{E}_T\left[\frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}(k_1^{t})]\right] \\
& + \mathbf{E}_T\left[nQ(\mathbf{u}(k_1^{t-1}))\right] - \mathbf{E}_T\left[nQ(\mathbf{u}(k_1^{t}))\right] . \qquad (22)
\end{aligned}
$$

Summing Eq. 22 over $t = 1 \ldots T$ gives

$$
\begin{aligned}
\sum_{t=1}^{T}\mathbf{E}_T[Q(\mathbf{u}(k_1^{t-1}))] \;\leq\; & TQ(\mathbf{z}) + \mathbf{E}_T\left[\frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}(k_1^{0})]\right] - \mathbf{E}_T\left[\frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}(k_1^{T})]\right] \\
& + \mathbf{E}_T\left[nQ(\mathbf{u}(k_1^{0}))\right] - \mathbf{E}_T\left[nQ(\mathbf{u}(k_1^{T}))\right] \\
\leq\; & TQ(\mathbf{z}) + \frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}(k_1^{0})] + n\left[Q(\mathbf{u}(k_1^{0})) - Q(\mathbf{u}^*)\right] \\
=\; & TQ(\mathbf{z}) + \frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}^1] + n\left[Q(\mathbf{u}^1) - Q(\mathbf{u}^*)\right] , \qquad (23)
\end{aligned}
$$

where $\mathbf{u}^* = \operatorname{argmin}_{\mathbf{u}\in\Delta^n} Q(\mathbf{u})$. Finally, note that for any value of k_1^T we have $Q(\mathbf{u}(k_1^t)) \leq Q(\mathbf{u}(k_1^{t-1}))$ for $t = 1 \ldots T$. Thus

$$
\mathbf{E}_T[Q(\mathbf{u}(k_1^t))] \leq \mathbf{E}_T[Q(\mathbf{u}(k_1^{t-1}))] ,
$$

and

$$
T\mathbf{E}_T[Q(\mathbf{u}(k_1^T)] \leq \sum_{t=1}^{T}\mathbf{E}_T[Q(\mathbf{u}(k_1^{t-1}))] .
$$

Combining this with Eq. 23 gives

$$
T\mathbf{E}_T[Q(\mathbf{u}(k_1^T)] \leq TQ(\mathbf{z}) + \frac{n}{\eta}D[\mathbf{z}\|\mathbf{u}^1] + n\left[Q(\mathbf{u}^1) - Q(\mathbf{u}^*)\right] ,
$$

thus proving the lemma. □

Appendix E. Proof of Lemma 9

(Note: this proof builds on notation and techniques given in the proof of Lemma 8, see Appendix D.)

We begin with the following identity

$$B_Q[\mathbf{z}||\mathbf{u}] \;=\; Q(\mathbf{z}) - Q(\mathbf{u}) - \nabla Q(\mathbf{u}) \cdot (\mathbf{z} - \mathbf{u}) \;.$$

Rearranging yields for any $\mathbf{z}, \mathbf{u} \in \Delta^n$,

$$\begin{aligned} Q(\mathbf{u}) - Q(\mathbf{z}) &= \nabla Q(\mathbf{u}) \cdot (\mathbf{u} - \mathbf{z}) - B_Q[\mathbf{z}||\mathbf{u}] \\ &= \frac{1}{\eta} \sum_{i=1}^{n} \Big[D[\mathbf{z}_i||\mathbf{u}_i] - D[\mathbf{z}_i||\mathbf{r}_i(\mathbf{u},i)] + D[\mathbf{u}_i||\mathbf{r}_i(\mathbf{u},i)] \Big] - B_Q[\mathbf{z}||\mathbf{u}] \;, \end{aligned}$$

where the second line follows by a similar argument to the proof of Lemma 10.

By applying similar arguments to those leading to Eq. 20 in Appendix D, we get for any $\mathbf{z}, \mathbf{u} \in \Delta^n$,

$$\begin{aligned} Q(\mathbf{u}) - Q(\mathbf{z}) &\leq \frac{1}{\eta} \sum_{i=1}^{n} \Big[D[\mathbf{z}\|\mathbf{u}] - D[\mathbf{z}\|\mathbf{r}(\mathbf{u},i)] \Big] + \sum_{i=1}^{n} \Big[Q(\mathbf{u}) - Q(\mathbf{r}(\mathbf{u},i)) \Big] - B_Q[\mathbf{z}||\mathbf{u}] \\ &= \frac{n}{\eta} D[\mathbf{z}\|\mathbf{u}] - \frac{n}{\eta} \sum_{i=1}^{n} \frac{1}{n} D[\mathbf{z}\|\mathbf{r}(\mathbf{u},i)] + \sum_{i=1}^{n} \Big[Q(\mathbf{u}) - Q(\mathbf{r}(\mathbf{u},i)) \Big] - B_Q[\mathbf{z}||\mathbf{u}] \\ &\leq \left(\frac{n}{\eta} - \mu \right) D[\mathbf{z}\|\mathbf{u}] - \frac{n}{\eta} \sum_{i=1}^{n} \frac{1}{n} D[\mathbf{z}\|\mathbf{r}(\mathbf{u},i)] + \sum_{i=1}^{n} \Big[Q(\mathbf{u}) - Q(\mathbf{r}(\mathbf{u},i)) \Big] \;, \end{aligned}$$

where in the third line, we have used the assumption from the lemma that $Q(\mathbf{u})$ is (μ, τ)-online-bounded, and hence $B_Q[\mathbf{z}||\mathbf{u}] \geq \mu D[\mathbf{z}\|\mathbf{u}]$. The inequality above holds for all $\mathbf{u}, \mathbf{z} \in \Delta^n$, so we can take $\mathbf{u} = \mathbf{u}(k_1^{t-1})$ for any sequence k_1^{t-1}. Taking expectations of both sides, and using similar arguments to those leading to Eq. 22 in Appendix D, we get

$$\begin{aligned} \mathbf{E}_T \Big[Q(\mathbf{u}(k_1^{t-1})) \Big] - Q(\mathbf{z}) \;\leq\; & \left(\frac{n}{\eta} - \mu \right) \mathbf{E}_T \Big[D[\mathbf{z}\|\mathbf{u}(k_1^{t-1})] \Big] - \frac{n}{\eta} \mathbf{E}_T \Big[D[\mathbf{z}\|\mathbf{u}(k_1^{t})] \Big] \\ & + n \mathbf{E}_T \Big[Q(\mathbf{u}(k_1^{t-1})) \Big] - n \mathbf{E}_T \Big[Q(\mathbf{u}(k_1^{t})) \Big] \;, \end{aligned} \tag{24}$$

where $\mathbf{E}_T$ is again an expectation with respect to the sequence k_1^T being drawn from the uniform distribution over $[1 \ldots n]^T$. For convenience, define

$$\tilde{\mathcal{Q}}^t \equiv \mathbf{E}_T \Big[Q(\mathbf{u}(k_1^t)) \Big] - Q(\mathbf{z}) \qquad \text{and} \qquad \tilde{\mathcal{D}}^t \equiv \frac{1}{\eta} \mathbf{E}_T \Big[D[\mathbf{z}||\mathbf{u}(k_1^t)] \Big] \;.$$

We may assume that $\tilde{\mathcal{Q}}^t \geq 0$ for all $t \leq T$ since if this is not true the lemma trivially holds.[17] Eq. 24 can be rearranged to give

$$\begin{aligned} \tilde{\mathcal{Q}}^{t-1} &\leq (n - \eta\mu) \tilde{\mathcal{D}}^{t-1} - n \tilde{\mathcal{D}}^t + n \tilde{\mathcal{Q}}^{t-1} - n \tilde{\mathcal{Q}}^t \\ n \tilde{\mathcal{Q}}^t + n \tilde{\mathcal{D}}^t &\leq (n-1) \tilde{\mathcal{Q}}^{t-1} + (n - \eta\mu) \tilde{\mathcal{D}}^{t-1} \;\leq\; (n - \eta\mu) \left(\tilde{\mathcal{Q}}^{t-1} + \tilde{\mathcal{D}}^{t-1} \right) \\ \tilde{\mathcal{Q}}^t + \tilde{\mathcal{D}}^t &\leq \left(1 - \frac{\eta\mu}{n} \right) \left(\tilde{\mathcal{Q}}^{t-1} + \tilde{\mathcal{D}}^{t-1} \right) \;, \end{aligned} \tag{25}$$

17. Note that $\mathbf{E}_T \left[Q(\mathbf{u}(k_1^t)) \right]$ is monotone decreasing since every random sequence of updates results in monotone improvement. The lemma then holds by an argument similar to Appendix B.

where Eq. 25 uses the observation that $n-\eta\mu \geq n-1$ because $\eta\mu \leq 1$ (this follows because $\eta \leq 1/\tau$ and $\mu < \tau$ for some $\tau > 0$). By iterating this result, it follows that

$$\begin{aligned}
\tilde{\mathcal{Q}}^T + \tilde{\mathcal{D}}^T &\leq \left(1-\frac{\eta\mu}{n}\right)^T \left(\tilde{\mathcal{Q}}^0 + \tilde{\mathcal{D}}^0\right) \\
\mathbf{E}_T\left[Q(\mathbf{u}(k_1^T))\right] &\leq Q(\mathbf{z}) + \left(1-\frac{\eta\mu}{n}\right)^T \left(Q(\mathbf{u}^1) - Q(\mathbf{z}) + \frac{1}{\eta} D[\mathbf{z}||\mathbf{u}^1]\right) \\
&\leq Q(\mathbf{z}) + e^{-\eta\mu T/n} \left(Q(\mathbf{u}^1) - Q(\mathbf{z}) + \frac{1}{\eta} D[\mathbf{z}||\mathbf{u}^1]\right) ,
\end{aligned}$$

thus proving the lemma. □

Appendix F. Empirical Comparisons in Terms of Running Time

In this section we compare EG to SGD and L-BFGS in terms of running time. The experiments in the main text provide comparison in terms of "effective" iterations, which do not take into account the computational cost of processing a single example. Here we show that EG maintains its advantages over the other learning algorithms when running time is used as a performance measure, with similar relative improvements to those reported in the main text.

Clearly, any timed comparison depends on the quality of the implementations being compared. Data processing and gradient and objective calculations were performed using the same C++ code for all three algorithms: EG, SGD, and L-BFGS. For L-BFGS, we used the implementation based on Byrd et al. (1995).[18] This code is available online and is written in Fortran. The SGD update is straightforward and we implemented it ourselves in our C++ package. All the timing experiments were performed on a 1.8GHz AMD Opteron™ CPU.

We focus on the log-linear case here, since timing results for the max-margin case were provided in Section 8.

Figures 14 and 15 show results for the MNIST multi-class (see Section 7.1), and the parsing tasks (see Section 7.2) respectively. As in the results in the main text, it can be seen that the EG objective converges faster than the two other algorithms. Also, as in the main text, SGD converges quickly in terms of accuracy, but its objective converges very slowly to the optimum.

Note that the timing of the EG experiments includes the time required to convert the dual parameters to the primal representation. We have found that the EG algorithm is quite fast in practice; in the MNIST task, for example, the EG algorithm requires on average only 10% more time per iteration (including the step-size search) than SGD and L-BFGS. To help explain why EG is able to run almost as fast as SGD, Figure 16 presents pseudocode for the SGD and online EG algorithms. Both SGD and EG share the following operations: (a) inner products between the feature vectors and the primal vector, (b) computation of part-wise marginals, and (c) addition of scaled feature vectors to the primal vector. In the EG algorithm, we require two additional loops over $R(x_i)$ in order to update the dual variables and compute the dual entropy term. In practice, however, the cost of the two additional loops is dominated by the three shared operations mentioned above. Thus, processing a single example takes roughly the same time for EG and SGD. Similar arguments can be used to explain why EG can run almost as fast as L-BFGS.

18. Specifically, we used the code by Zhu, Byrd, Lu, and Nocedal (www.ece.northwestern.edu/∼nocedal/).

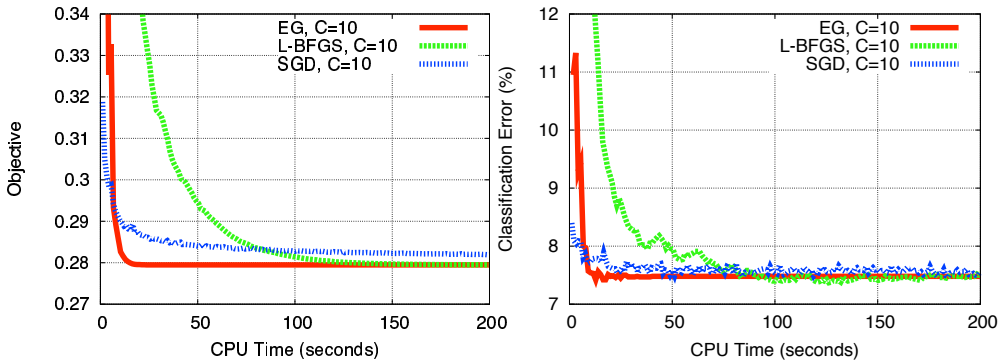

Figure 14: Timing results on the MNIST task, comparing the EG algorithm to L-BFGS and SGD. All algorithms are trained on the log-linear objective function with $C = 10$. The left figure shows objective values and the right figure shows classification error (see Figure 12). The results roughly correspond to 200 effective iterations.

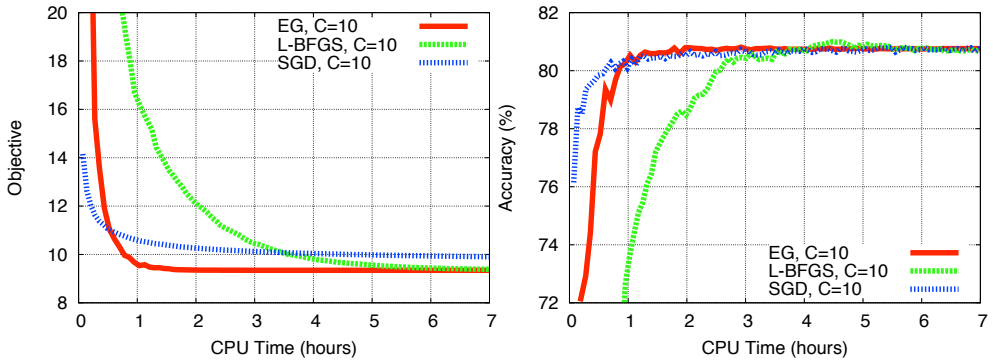

Figure 15: Timing results on the dependency-parsing task, comparing the EG algorithm to L-BFGS and SGD. All algorithms are trained on the log-linear objective function with $C = 10$. The left figure shows objective values and the right figure shows accuracy (see Figure 12). The results roughly correspond to 100 effective iterations.

SGD Update:

◁ *compute part-wise inner products*
1. $\mathbf{q} = \mathbf{0}$
2. **for** $r \in R(x_i)$
3. $\quad q_r = \mathbf{w}^t \cdot \mathbf{f}(x_i, r)$
4. **endfor**

◁ *compute marginals*
5. $\mathbf{m} = \text{MARGINALS}(\mathbf{q})$

◁ *apply gradient of regularizer*
6. $\mathbf{w}^{t+1} = (1 - \eta C)\mathbf{w}^t$

◁ *apply gradient of log-loss*
7. **for** $r \in R(x_i)$
8. $\quad$ **if** $r \in y_i$

◁ *empirical contribution*
9. $\quad\quad \mathbf{w}^{t+1} = \mathbf{w}^{t+1} + \eta \mathbf{f}(x_i, r)$
10. $\quad$ **endif**

◁ *expected contribution*
11. $\quad \mathbf{w}^{t+1} = \mathbf{w}^{t+1} - \eta m_r \mathbf{f}(x_i, r)$
12. **endfor**

Online EG Update:

◁ *compute part-wise inner products*
1. $\mathbf{q} = \mathbf{0}$
2. **for** $r \in R(x_i)$
3. $\quad q_r = \frac{1}{C}\mathbf{w}^t \cdot \mathbf{f}(x_i, r)$
4. **endfor**

◁ *update part-wise duals*
5. **for** $r \in R(x_i)$
6. $\quad s_{i,r}^{t+1} = (1 - \eta) s_{i,r}^t + \eta q_r$
7. **endfor**

◁ *compute marginals and partition function*
8. $(\mu_i^{t+1}, Z) = \text{MARGINALS}(\mathbf{s}_i^{t+1})$

◁ *compute new dual entropy*
9. $H_i^{t+1} = \log Z$
10. **for** $r \in R(x_i)$
11. $\quad H_i^{t+1} = H_i^{t+1} - \mu_{i,r}^{t+1} s_{i,r}^{t+1}$
12. **endfor**

◁ *update primals*
13. $\mathbf{w}^{t+1} = \mathbf{w}^t$
14. **for** $r \in R(x_i)$
15. $\quad \mathbf{w}^{t+1} = \mathbf{w}^{t+1} + (\mu_{i,r}^t - \mu_{i,r}^{t+1}) \mathbf{f}(x_i, r)$
16. **endfor**

◁ *compute change in dual objective*
17. $\delta = \frac{1}{2C}\|\mathbf{w}^{t+1}\|^2 - H_i^{t+1} - (\frac{1}{2C}\|\mathbf{w}^t\|^2 - H_i^t)$

Figure 16: Pseudocode for the updates performed in SGD and online EG for structured log-linear models (note that ◁ denotes a comment). In EG, we maintain dual vectors $\mathbf{s}_i^t$, marginals μ_i^t, entropy values H_i^t, and a vector $\mathbf{w}^t = \mathbf{w}(\mathbf{u}^t)$. Note that line-search techniques can be implemented based on the δ value computed in line 17 of the EG update. A vector scaling operation is required in line 6 of SGD, and vector norm operations are required in line 17 of EG; these can be performed in $O(1)$ time using an appropriate representation (e.g., see Shalev-Shwartz et al., 2007).

Abstract

We consider the problem of binary classification where the classifier can, for a particular cost, choose not to classify an observation. Just as in the conventional classification problem, minimization of the sample average of the cost is a difficult optimization problem. As an alternative, we propose the optimization of a certain convex loss function ϕ, analogous to the hinge loss used in support vector machines (SVMs). Its convexity ensures that the sample average of this surrogate loss can be efficiently minimized. We study its statistical properties. We show that minimizing the expected surrogate loss—the ϕ-risk—also minimizes the risk. We also study the rate at which the ϕ-risk approaches its minimum value. We show that fast rates are possible when the conditional probability $\mathbb{P}(Y=1|X)$ is unlikely to be close to certain critical values.

Keywords: Bayes classifiers, classification, convex surrogate loss, empirical risk minimization, hinge loss, large margin classifiers, margin condition, reject option, support vector machines

1. Introduction

The aim of binary classification is to classify observations that take values in an arbitrary feature space $\mathcal{X}$ into one of two classes, labeled -1 or $+1$. A *discriminant function* $f : \mathcal{X} \to \mathbb{R}$ yields a classifier $\mathrm{sgn}(f(x)) \in \{-1,+1\}$ that represents our guess of the label Y of a future observation X and we err if the margin $y \cdot f(x) < 0$. The Bayes discriminant function

$$\mathbb{P}\{Y=1|X=x\} - \mathbb{P}\{Y=-1|X=x\}$$

minimizes the probability of misclassification $\mathbb{P}\{Y f(X) < 0\}$. Observations x for which the conditional probability

$$\eta(x) = \mathbb{P}\{Y=+1|X=x\}$$

is close to $1/2$, are the most difficult to classify. In the extreme case where $\eta(x) = 1/2$, we may just as well toss a coin to make a decision. While it is our aim to classify the majority of future observations in an automatic way, it is often appropriate to instead report a warning for those observations that are hard to classify (the ones having conditional probability $\eta(x)$ near the value $1/2$). This motivates the introduction of a *reject option* for classifiers, by allowing for a third decision, ® (*reject*),

expressing doubt. For instance, in clinical trials it is important to be able to reject a tumor diagnostic classification since the consequences of misdiagnosis are severe and scientific expertise is required to make reliable determination. Although such classifiers are valuable in practice, few theoretical results are available in the statistical literature (Herbei and Wegkamp, 2006; Ripley, 1996). In the engineering community on the other hand this option is more common and empirically shown to effectively reduce the misclassification rate (Chow, 1970; Fumera and Roli, 2002, 2004; Fumera et al., 2000; Golfarelli et al., 1997; Györfi et al., 1978; Hansen et al., 1997; Landgrebe et al., 2006).

We propose to incorporate the reject option into our classification scheme by using a threshold value $0 \le \delta < 1$ as follows. Given a discriminant function $f : \mathcal{X} \to \mathbb{R}$, we report $\mathrm{sgn}(f(x))) \in \{-1,1\}$ if $|f(x)| > \delta$, but we withhold decision if $|f(x)| \le \delta$ and report ®. In this note, we assume that the cost of making a wrong decision is 1 and the cost of using the reject option is $d > 0$. The appropriate risk function is then

$$L_{d,\delta}(f) = \mathbb{E}\ell_d(Yf(X)) = \mathbb{P}\{Yf(X) < -\delta\} + d\mathbb{P}\{|Yf(X)| \le \delta\} \tag{1}$$

for the discontinuous loss

$$\ell_{d,\delta}(z) = \begin{cases} 1 & \text{if } z < -\delta, \\ d & \text{if } |z| \le \delta, \\ 0 & \text{otherwise.} \end{cases}$$

The classifier associated with the discriminant function $f_d^*(x)$ that minimizes the risk $L_{d,\delta}(f)$ assigns $-1, 1$ or ® depending on which of $\eta(x)$, $1-\eta(x)$ or d is smallest. Since we never reject if $d > 1/2$, we restrict ourselves to the cases $0 \le d \le 1/2$. The generalized Bayes discriminant function $f_d^*(x)$ is then

$$f_d^*(x) = \begin{cases} -1 & \text{if } \eta(x) < d \\ 0 & \text{if } d \le \eta(x) \le 1-d \\ +1 & \text{if } \eta(x) > 1-d \end{cases} \tag{2}$$

with risk

$$L_d^* = L_{d,\delta}(f_d^*) = \mathbb{E}\min\{\eta(X), 1-\eta(X), d\}.$$

The case $(\delta, d) = (0, 1/2)$ reduces to the classical situation without the reject option. We emphasize that the rejection cost d should be known a priori. In a medical setting when determining whether a disease is present or absent, the reject option often leads to quantifiable costs for additional tests and perhaps in delays of treatment. The exact value of d will be dictated by such considerations. From the above we can also view d as an upper bound on the conditional probability of misclassification (given X) that is considered tolerable.

We postpone the discussion on the choice of the threshold δ until after Theorem 2.

Plug-in classification rules replace the regression function $\eta(x)$ by an estimate $\widehat{\eta}(x)$ in the formula for $f_d^*(x)$ above. It is shown by Herbei and Wegkamp (2006) that the rate of convergence of the risk (1) to the Bayes risk L_d^* of a general plug-in rule with reject option depends on how well $\widehat{\eta}(X)$ estimates $\eta(X)$ and on the behavior of $\eta(X)$ near the values d and $1-d$. This condition on $\eta(X)$ nicely generalizes the margin condition of Tsybakov (2004) from the classical setting ($d = 1/2$) to our more general framework ($0 \le d \le 1/2$). The same paper derives oracle inequalities for the excess risk $L_{d,\delta}(\widehat{f}) - L_d^*$ of the (naive) empirical risk minimizer $\widehat{f}$ of $\sum_{i=1}^n \ell_{d,\delta}(Y_i f(X_i))$ based on n

independent observations (X_i, Y_i), over a class of discriminant functions $\mathcal{F}$. The results are in line with recent theoretical developments (Boucheron et al., 2006, 2005; Massart, 2007) of standard binary classification ($d = 1/2$). Despite its attractive theoretical properties, the naive empirical risk minimization method is often hard to implement. This paper addresses this pitfall by considering a convex surrogate for the loss function akin to the hinge loss that is used in SVMs. In the engineering literature, there are recently encouraging empirical results on SVMs with a reject option (Bounsiar et al., 2006; Fumera et al., 2003; Fumera and Roli, 2002; Tortorella, 2004).

The next section introduces a piecewise linear loss function $\phi_d(x)$ that generalizes the hinge loss function $\max\{0, 1-x\}$ in that it allows for the reject option and $\phi_d(x) = \max\{0, 1-x\}$ for $d = 1/2$. We prove that f_d^* in (2) also minimizes the risk associated with this new loss and that the excess risk $L_{d,\delta} - L_d^*$ can be bounded by $2d$ times the excess risk based on the piecewise linear loss ϕ_d if $\delta = 1/2$. Thus classifiers with small excess ϕ_d-risk automatically have small excess classification risk, providing theoretical justification of the more computationally appealing method.

In Section 3, we illustrate the computational convenience of the new loss, showing that the SVM classifier with reject option can be obtained by solving a standard convex optimization problem.

Finally, in Section 4, we show that fast rates (for instance, faster than $n^{-1/2}$) of the SVM classifier with reject option are possible under the same noise conditions on $\eta(X)$ used by Herbei and Wegkamp (2006). As a side effect, for the standard SVM (the special case of $d = 1/2$), our results imply fast rates without an assumption that $\eta(X)$ is unlikely to be near 0 and 1, a technical condition that has been imposed in the literature for that case (Blanchard et al., 2008; Tarigan and van de Geer, 2006).

2. Generalized Hinge Loss

Instead of the discontinuous loss $\ell_{d,\delta}$, we consider the convex surrogate loss

$$\phi_d(z) = \begin{cases} 1 - az & \text{if } z < 0, \\ 1 - z & \text{if } 0 \le z < 1, \\ 0 & \text{otherwise} \end{cases}$$

where $a = (1-d)/d \ge 1$. The next result states that the minimizer of the expectation of the discrete loss $\ell_{d,\delta}(z)$ and the convex loss $\phi_d(z)$ remains the same.

Proposition 1 *The Bayes discriminant function (2) minimizes the risk*

$$L_{\phi_d}(f) = \mathbb{E}\phi_d(Y f(X))$$

over all measurable $f : \mathcal{X} \to \mathbb{R}$. *Furthermore,*

$$dL_{\phi_d}(f_d^*) = L_{d,\delta}(f_d^*).$$

Proof Observe that

$$L_{\phi_d}(f) = \mathbb{E}\eta(X)\phi_d(f(X)) + \mathbb{E}(1-\eta(X))\phi_d(-f(X)).$$

Hence, for

$$r_{\eta,\phi_d}(z) = \eta\phi_d(z) + (1-\eta)\phi_d(-z) \tag{3}$$

it suffices to show that

$$z^* = \begin{cases} -1 & \text{if } \eta < 1/(1+a), \\ 0 & \text{if } 1/(1+a) \le \eta \le a/(1+a), \\ 1 & \text{if } \eta > a/(1+a) \end{cases}$$

minimizes $r_{\eta,\phi_d}(z)$. The function $r_{\eta,\phi_d}(z)$ can be written as

$$r_{\eta,\phi_d}(z) = \begin{cases} \eta - a\eta z & \text{if } z \le -1, \\ 1 + z(1-(1+a)\eta) & \text{if } -1 \le z \le 0, \\ 1 + z(-\eta + a(1-\eta)) & \text{if } 0 \le z \le 1, \\ z(a(1-\eta)) + (1-\eta) & \text{if } z \ge 1 \end{cases}$$

and it is now a simple exercise to verify that z^* indeed minimizes $r_{\eta,\phi_d}(z)$. Finally, since $L_{\phi_d}(f) = \mathbb{E} r_{\eta,\phi_d}(f(X))$ and

$$\begin{aligned} & \inf_z \eta\phi_d(z) + (1-\eta)\phi_d(-z) \\ = \;& \eta\phi_d(z^*) + (1-\eta)\phi_d(z^*) \\ = \;& \frac{\eta}{d}\mathbf{1}[\eta < d] + \mathbf{1}[d \le \eta \le 1-d] + \frac{1-\eta}{d}\mathbf{1}[\eta > 1-d], \end{aligned}$$

where $\mathbf{1}[A]$ denotes the indicator function of a set A, we find that

$$d L_{\phi_d}(f_d^*) = \mathbb{E}[\min(\eta(X), 1-\eta(X), d)] = L_d^*.$$

and the second claim follows as well. ■

We see that $\phi_d(z) \ge \ell_{d,\delta}(z)$ for all $z \in \mathbb{R}$ as long as $0 \le \delta \le 1-d$. Since this pointwise relation remains preserved under taking expected values, we immediately obtain $L_{d,\delta}(f) \le L_{\phi_d}(f)$. The following comparison theorem shows that a relation like this holds not only for the risks, but for the excess risks as well.

Theorem 2 *Let $0 \le d < 1/2$ and a measurable function f be fixed. For all $0 < \delta \le 1/2$, we have*

$$L_{d,\delta}(f) - L_d^* \le \frac{d}{\delta}\left(L_{\phi_d}(f) - L_{\phi_d}^*\right),$$

where $L_{\phi_d}^* = L_{\phi_d}(f_d^*)$. For $1/2 \le \delta \le 1-d$, we have

$$L_{d,\delta}(f) - L_d^* \le L_{\phi_d}(f) - L_{\phi_d}^*.$$

Finally, for $(\delta, d) = (0, 1/2)$, we have

$$L(f) - L^* \le L_\phi(f) - L_\phi^*, \tag{4}$$

where $L(f) := \mathbb{P}\{Y f(X) < 0\}$, $L^* := \mathbb{E}\min(\eta(X), 1-\eta(X))$ and $\phi(x) = \max\{0, 1-x\}$.

Remark 3 *The optimal multiplicative constant (d/δ or 1 depending on the value of δ) in front of the ϕ_d-excess risk is achieved at $\delta = 1/2$. For this choice, Theorem 2 states that*

$$L_{d,1/2}(f) - L_d^* \leq 2d\left(L_{\phi_d}(f) - L_{\phi_d}^*\right).$$

For all $d \leq \delta \leq 1-d$, the multiplicative constant in front of the ϕ_d-excess risk does not exceed 1. The choice $\delta = 1/2$ with the smallest constant $2d < 1$ is right in the middle of the interval $[d, 1-d]$. The choice $\delta = 1-d$ corresponds to the largest value of δ for which the piecewise constant function $\ell_{d,\delta}(z)$ is still majorized by the convex surrogate $\phi_d(z)$. For $\delta = d$ we will reject less frequently than for $\delta = 1-d$ and $\delta = 1/2$ can be seen as a compromise among these two extreme cases.

Inequality (4) is due to Zhang (2004).

Before we prove the theorem, we need an intermediate result. We define the functions

$$\xi(\eta) = \eta \mathbf{1}[\eta < d] + d\mathbf{1}[d \leq \eta \leq 1-d] + (1-\eta)\mathbf{1}[\eta > 1-d]$$

and

$$\begin{aligned} H(\eta) &= \inf_z \eta\phi_d(z) + (1-\eta)\phi_d(-z) \\ &= \frac{\eta}{d}\mathbf{1}[\eta < d] + \mathbf{1}[d \leq \eta \leq 1-d] + \frac{1-\eta}{d}\mathbf{1}[\eta > 1-d]. \end{aligned}$$

(We suppress their dependence on d in our notation.) Their expectations are $L_d^* = \mathbb{E}\xi(\eta(X))$ and $L_{\phi_d}^* = \mathbb{E}H(\eta(X))$, respectively. Furthermore, we define

$$\begin{aligned} H_{-1}(\eta) &= \inf_{z<-\delta}(\eta\phi_d(z) + (1-\eta)\phi_d(-z)), \\ H_{\textcircled{R}}(\eta) &= \inf_{|z|\leq\delta}(\eta\phi_d(z) + (1-\eta)\phi_d(-z)), \\ H_1(\eta) &= \inf_{z>\delta}(\eta\phi_d(z) + (1-\eta)\phi_d(-z)); \\ \xi_{-1}(\eta) &= \eta - \xi(\eta), \\ \xi_{\textcircled{R}}(\eta) &= d - \xi(\eta), \\ \xi_1(\eta) &= 1 - \eta - \xi(\eta). \end{aligned}$$

Proposition 4 *Let $0 \leq d < 1/2$.*

If $0 < \delta \leq 1/2$, then, for $b \in \{-1, 1, \textcircled{R}\}$,

$$\xi_b(\eta) \leq \frac{\delta}{d}\{H_b(\eta) - H(\eta)\}.$$

If $d \leq \delta \leq 1-d$, then, for $b \in \{-1, 1, \textcircled{R}\}$,

$$\xi_b(\eta) \leq H_b(\eta) - H(\eta).$$

If $(\delta, d) = (0, 1/2)$, then, for $b \in \{-1, 1, \textcircled{R}\}$,

$$\xi_b(\eta) \leq H_b(\eta) - H(\eta).$$

The proof is in the appendix.

Proof [Proof of Theorem 2] Recall that $L_{d,\delta}(f) = \mathrm{P}(\eta \mathbf{1}[f < -\delta] + d\mathbf{1}[-\delta \le f \le \delta] + (1-\eta)\mathbf{1}[f > \delta])$ and $L_{\phi_d}(f) = \mathrm{P}r_{\eta,\phi_d}(f)$ with r_{η,ϕ_d} defined in the proof of Proposition 1. Here P is the probability measure of X and $\mathrm{P}g = \int g d\mathrm{P}$ for any P-integrable g. Assume $0 < \delta \le 1/2$ and $0 \le d < 1/2$. Define $\psi(x) = x\delta/d$. By linearity of ψ, we have for any measurable function f,

$$\begin{aligned}\psi(L_{d,\delta}(f) - L_d^*) &= \mathrm{P}\left(\mathbf{1}[f < -\delta]\,\psi(\xi_{-1}(\eta)) + \mathbf{1}[-\delta \le f \le \delta]\,\psi(\xi_{\circledR}(\eta))\right. \\ &\qquad \left. + \mathbf{1}[f > \delta]\,\psi(\xi_1(\eta))\right).\end{aligned}$$

Invoke now Proposition 4 to deduce

$$\begin{aligned}\psi(L_{d,\delta}(f) - L_d^*) &\le \mathrm{P}\left(\mathbf{1}[f < -\delta]\,[H_{-1}(\eta) - H(\eta)] + \mathbf{1}[-\delta \le f \le \delta]\,[H_{\circledR}(\eta) - H(\eta)]\right. \\ &\qquad \left. + \mathbf{1}[f > \delta]\,[H_1(\eta) - H(\eta)]\right) \\ &\le \mathrm{P}\left\{r_{\eta,\phi_d}(f) - H(\eta)\right\}\end{aligned}$$

and conclude the proof by observing that the term on the right of the previous inequality equals $L_{\phi_d}(f) - L_{\phi_d}^*$.

For the case $(\delta, d) = (0, 1/2)$ and the case (δ, d) with $d \le \delta \le 1 - d$ and $0 \le d < 1/2$, take $\psi(x) = x$. ■

3. SVM Classifiers with Reject Option

In this section, we consider an SVM-like classifier for classification with a reject option, and show that it can be obtained by solving a quadratically constrained quadratic program (QCQP).

Let $K : \mathcal{X}^2 \to \mathbb{R}$ be the kernel of a reproducing kernel Hilbert space (RKHS) $\mathcal{H}$, and let $\|f\|$ be the norm of f in $\mathcal{H}$. The SVM classifier with reject option is the minimizer of the empirical ϕ_d-risk subject to a constraint on the RKHS norm.[1] The following theorem shows that this classifier is the solution to a QCQP, that is, it is the minimizer of a convex quadratic criterion on a convex subset of Euclidean space defined by quadratic inequalities. Thus, the classifier can be found efficiently using general-purpose algorithms.

Theorem 5 *For any $x_1, \ldots, x_n \in \mathcal{X}$ and $y_1, \ldots, y_n \in \{-1, 1\}$, let $\widehat{f} \in \mathcal{H}$ be the solution to*

$$\begin{aligned}&\textit{minimize} && f \mapsto \sum_{i=1}^n \phi_d(y_i f(x_i)) \\ &\textit{such that} && \|f\|^2 \le r^2,\end{aligned}$$

where $r > 0$. Then we can represent $\widehat{f}$ as the finite sum

$$\widehat{f}(x) = \sum_{i=1}^n \widehat{\alpha}_i K(x_i, x),$$

1. Notice that we parameterize the optimization problem in terms of the constraint on the RKHS norm, rather than in terms of its Lagrange multiplier, which is more standard. The regularization path—the set of solutions to these problems as the parameter of the optimization problem varies—is identical.

where $\widehat{\alpha}_1, \ldots, \widehat{\alpha}_n$ is the solution to the following QCQP.

$$\begin{aligned}
\min_{\alpha_i, \xi_i, \gamma_i} \quad & \frac{1}{n} \sum_{i=1}^{n} \left(\xi_i + \frac{1-2d}{d} \gamma_i \right) \\
\textit{such that} \quad & \sum_{i,j} \alpha_i \alpha_j K(x_i, x_j) \leq r^2 \\
& \xi_i \geq 0, \qquad \gamma_i \geq 0, \\
& \xi_i \geq 1 - y_i \sum_{j=1}^{n} \alpha_j K(x_i, x_j), \\
& \gamma_i \geq -y_i \sum_{j=1}^{n} \alpha_j K(x_i, x_j) \qquad\qquad \textit{for } i = 1, \ldots, n.
\end{aligned}$$

Proof The fact that $\widehat{f}$ can be represented as a finite sum over the kernel basis functions is a standard argument (Kimeldorf and Wahba, 1971; Cox and O'Sullivan, 1990). It follows from Pythagoras' theorem in Hilbert space: the squared RKHS norm can be split into the squared norm of the component in the space spanned by the kernel basis functions $x \mapsto K(x_i, x)$ and that of the component in the orthogonal subspace. Since the cost function depends on f only at the points x_i, and the reproducing property $f(x_i) = \langle K(x_i, \cdot), f \rangle$ shows that these values depend only on the component of f in the space spanned by the kernel basis functions, the orthogonal subspace only makes the constraint harder to satisfy, but does not affect the cost function. Thus, a minimizing $\widehat{f}$ can be represented in terms of the solution $\widehat{\alpha}$ to the minimization

$$\begin{aligned}
\min_{\alpha_1, \ldots, \alpha_n} \quad & \frac{1}{n} \sum_{i=1}^{n} \phi_d \left(y_i \sum_{j=1}^{n} \alpha_j K(x_i, x_j) \right) \\
\text{such that} \quad & \sum_{1 \leq i,j \leq n} \sum \alpha_i \alpha_j K(x_i, x_j) \leq r^2.
\end{aligned}$$

But then it is easy to see that we can decompose ϕ_d as

$$\phi_d(\beta) = \max\{0, 1-\beta\} + \frac{1-2d}{d} \max\{0, -\beta\}.$$

Parameterizing ϕ_d using the slack variables

$$\xi_i = \max\{0, 1 - y_i f(x_i)\}, \qquad \gamma_i = \max\{0, -y_i f(x_i)\}$$

gives the QCQP. ■

4. Tsybakov's Margin Condition, Bernstein Classes, and Fast Rates

In this section, we consider methods that choose the function $\widehat{f}$ from some class $\mathcal{F}$ so as to minimize the empirical ϕ_d-risk

$$\widehat{L}_{\phi_d}(f) = \frac{1}{n} \sum_{i=1}^{n} \phi_d(Y_i f(X_i)).$$

For instance, to analyze the SVM classifier with reject option, we could consider classes $\mathcal{F}_n = \{f \in \mathcal{H} : \|f\| \leq c_n\}$ for some sequence of constants c_n. We are interested in bounds on the excess ϕ_d-risk, that is, the difference between the ϕ_d-risk of $\widehat{f}$ and the minimal ϕ_d-risk over all measurable functions, of the form

$$\mathbb{E}L_{\phi_d}(\widehat{f}) - L^*_{\phi_d} \leq 2 \inf_{f \in \mathcal{F}} \left(L_{\phi_d}(f) - L^*_{\phi_d}\right) + \varepsilon_n.$$

Such bounds can be combined with an assumption on the rate of decrease of the approximation error $\inf_{f \in \mathcal{F}_n} \left(L_{\phi_d}(f) - L^*_{\phi_d}\right)$ for a sequence of classes $\mathcal{F}_n$ used by a method of sieves, and thus provide bounds on the rate of convergence of risk $L_{d,\delta}(\widehat{f})$ to the optimal Bayes risk L^*_d.

For many binary classification methods (including empirical risk minimization, plug-in estimates, and minimization of the sample average of a suitable convex loss), the estimation error term ε_n approaches zero at a faster rate when the conditional probability $\eta(X)$ is unlikely to be close to the critical value of $1/2$ (Audibert and Tsybakov, 2007; Bartlett et al., 2006; Blanchard et al., 2008; Steinwart and Scovel, 2007; Tarigan and van de Geer, 2006; Tsybakov, 2004). For plug-in rules, Herbei and Wegkamp (2006) showed an analogous result for classification with a reject option, where the corresponding condition concerns the probability that $\eta(X)$ is close to the critical values of d and $1-d$. In this section, we prove a bound on the excess ϕ_d-risk of $\widehat{f}$ that converges rapidly when a condition of this kind applies. We begin with a precise statement of the condition. For $d = 1/2$, it is equivalent to the margin condition of Tsybakov (2004).

Definition 6 *We say that η satisfies the margin condition at d with exponent $\alpha > 0$ if there is a $c \geq 1$ such that for all $t > 0$,*

$$\mathbb{P}\{|\eta(X) - d| \leq t\} \leq ct^\alpha \text{ and } \mathbb{P}\{|\eta(X) - (1-d)| \leq t\} \leq ct^\alpha.$$

The reason that conditions of this kind allow fast rates is related to the variance of the excess ϕ_d-loss,

$$g_f(x,y) = \phi_d(yf(x)) - \phi_d(yf^*_d(x)),$$

where f^*_d minimizes the ϕ_d-risk. Notice that the expectation of g_f is precisely the excess risk of f, $\mathbb{E}g_f(X,Y) = L_{\phi_d}(f) - L^*_{\phi_d}$. We will show that when η satisfies the margin condition at d with exponent α, the variance of each g_f is bounded in terms of its expectation, and thus approaches zero as the ϕ-risk of f approaches the minimal value. Classes for which this occurs are called Bernstein classes.

Definition 7 *We say that $\mathcal{G} \subset L_2(\mathrm{P})$ is a (β, B)-Bernstein class with respect to the probability measure P $(0 < \beta \leq 1, B \geq 1)$ if every $g \in \mathcal{G}$ satisfies*

$$\mathrm{P}g^2 \leq B(\mathrm{P}g)^\beta.$$

We say that $\mathcal{G}$ has a Bernstein exponent β with respect to P if there exists a constant B for which $\mathcal{G}$ is a (β, B)-Bernstein class.

Lemma 8 *If η satisfies the margin condition at d with exponent α, then for any class $\mathcal{F}$ of measurable uniformly bounded functions, the class $\mathcal{G} = \{g_f : f \in \mathcal{F}\}$ has a Bernstein exponent $\beta = \alpha/(1+\alpha)$.*

The result relies on the following two lemmas. The first shows that the excess ϕ_d-risk is at least linear in a certain pseudo-norm of the difference between f and f_d^*. It is similar to the $L_1(\mathrm{P})$ norm, but it penalizes f less for large excursions that have little impact on the ϕ_d-risk. For example, if $\eta(x) = 1$, then the conditional ϕ_d-risk is zero even if $f(x)$ takes a large positive value. For $\eta \in [0,1]$, define

$$\rho_\eta(f, f_d^*) = \begin{cases} \eta|f - f_d^*| & \text{if } \eta < d \text{ and } f < -1, \\ (1-\eta)|f - f_d^*| & \text{if } \eta > 1-d \text{ and } f > 1, \\ |f - f_d^*| & \text{otherwise,} \end{cases}$$

and recall the definition of the conditional ϕ_d-risk in (3).

Lemma 9 *For* $\eta \in [0,1]$,

$$d\left(r_{\eta,\phi_d}(f) - r_{\eta,\phi_d}(f_d^*)\right) \geq (|\eta - d| \wedge |\eta - (1-d)|)\,\rho_\eta(f, f_d^*).$$

Proof Since r_{η,ϕ_d} is convex,

$$r_{\eta,\phi_d}(f) \geq r_{\eta,\phi_d}(f_d^*) + g(f - f_d^*)$$

for any g in the subgradient of $r_{\eta,\phi_d}(f)$ at f_d^*. In our case, r_{η,ϕ_d} is piecewise linear, with four pieces, and the subgradients include

$$\begin{array}{ll} \eta\frac{1-d}{d} & \text{at } f_d^* = -1, \\ |\eta - d|\frac{1}{d} & \text{at } f_d^* = -1, 0, \\ |1 - \eta - d|\frac{1}{d} & \text{at } f_d^* = 0, 1, \\ (1-\eta)\frac{1-d}{d} & \text{at } f_d^* = 1. \end{array}$$

Thus, we have

$$\begin{aligned} & d(r_{\eta,\phi_d}(f) - r_{\eta,\phi_d}(f_d^*)) \\ & \geq \begin{cases} \eta(1-d)|f - f_d^*| & \text{if } \eta < d \text{ and } f < -1, \\ |\eta - d||f - f_d^*| & \text{if } \eta < d \text{ and } f > -1, \\ (|\eta - d| \wedge |1 - \eta - d|)\,|f - f_d^*| & \text{if } d \leq \eta \leq 1-d, \\ |1 - \eta - d||f - f_d^*| & \text{if } \eta > 1-d \text{ and } f < 1, \\ (1-\eta)(1-d)|f - f_d^*| & \text{if } \eta > 1-d,\ f > 1. \end{cases} \\ & = \begin{cases} (1-d)\rho_\eta(f, f_d^*) & \text{if } \eta < d \text{ and } f < -1, \\ |\eta - d|\rho_\eta(f, f_d^*) & \text{if } \eta < d \text{ and } f > -1, \\ (|\eta - d| \wedge |1 - \eta - d|)\,\rho_\eta(f, f_d^*) & \text{if } d \leq \eta \leq 1-d, \\ |1 - \eta - d|\rho_\eta(f, f_d^*) & \text{if } \eta > 1-d \text{ and } f < 1, \\ (1-d)\rho_\eta(f, f_d^*) & \text{if } \eta > 1-d,\ f > 1. \end{cases} \\ & \geq (|\eta - d| \wedge |1 - \eta - d|)\,\rho_\eta(f, f_d^*). \end{aligned}$$

■

We shall also use the following inequalities.

Lemma 10 *If $\|f\|_\infty = B$, then for $\eta \in [0,1]$,*

$$\rho_\eta(f, f_d^*) \le |f - f_d^*|,$$

and

$$\eta\,|\phi_d(f) - \phi_d(f_d^*)|^2 + (1-\eta)\,|\phi_d(-f) - \phi_d(-f_d^*)|^2 \le \left(\frac{1-d}{d}\right)^2 (B+1)\rho_\eta(f, f_d^*).$$

Proof The first inequality is immediate from the definition of ρ_η. To see the second, use the fact that ϕ_d is flat to the right of 1 to notice that

$$\begin{aligned}
&\eta\,|\phi_d(f) - \phi_d(f_d^*)|^2 + (1-\eta)\,|\phi_d(-f) - \phi_d(-f_d^*)|^2 \\
&= \begin{cases} \eta\left|\phi_d(f) - \phi_d(f_d^*)\right|^2 & \text{if } \eta < d \text{ and } f < -1, \\ (1-\eta)\left|\phi_d(-f) - \phi_d(-f_d^*)\right|^2 & \text{if } \eta > 1-d \text{ and } f > 1. \end{cases}
\end{aligned}$$

Since ϕ_d has Lipschitz constant $a = (1-d)/d$, this implies

$$\begin{aligned}
&\eta\,|\phi_d(f) - \phi_d(f_d^*)|^2 + (1-\eta)\,|\phi_d(-f) - \phi_d(-f_d^*)|^2 \\
&\le \begin{cases} \eta a^2 |f - f_d^*|^2 & \text{if } \eta < d \text{ and } f < -1, \\ (1-\eta) a^2 |f - f_d^*|^2 & \text{if } \eta > 1-d \text{ and } f > 1, \\ a^2 |f - f_d^*|^2 & \text{otherwise} \end{cases} \\
&\le a^2(1+B)\rho_\eta(f, f_d^*),
\end{aligned}$$

where the last inequality uses the fact that $|f - f_d^*| \le B+1$. ■

Proof [Proof of Lemma 8] By Lemma 9, we have

$$L_{\phi_d}(f) - L_{\phi_d}^* \ge d^{-1}\mathbb{E}\rho_\eta(f, f_d^*)\left(|\eta - (1-d)|I_{E_-} + |\eta - d|I_{E_+}\right),$$

with

$$E_- = \{|\eta - (1-d)| \le |\eta - d|\}, \qquad E_+ = \{|\eta - (1-d)| > |\eta - d|\}.$$

Using the assumption on η, there is an $A \ge 1$ such that for all $t > 0$

$$\mathbb{P}\{|\eta(X) - d| \le t\} \le At^\alpha \text{ and } \mathbb{P}\{\eta(X) - (1-d)| \le t\} \le At^\alpha.$$

Thus, for any set E,

$$\begin{aligned}
\mathrm{P}\rho_\eta(f, f_d^*)|\eta - (1-d)|I_E &\ge t\mathrm{P}\rho_\eta(f, f_d^*)I_{\{|\eta-(1-d)|\ge t\}}I_E \\
&= t\mathrm{P}\rho_\eta(f, f_d^*)I_E - t\mathrm{P}\rho_\eta(f, f_d^*)I_{\{|\eta-(1-d)|<t\}}I_E \\
&\ge t\{\mathrm{P}\rho_\eta(f, f_d^*)I_E - (B+1)At^\alpha\},
\end{aligned}$$

where B is such that $|f| \le B$ and hence $\rho_\eta(f, f_d^*) \le |f - f_d^*| \le B+1$. Similarly,

$$\mathrm{P}\rho_\eta(f, f_d^*)|\eta - d|I_E \ge t\{\mathrm{P}\rho_\eta(f, f_d^*)I_E - (B+1)At^\alpha\},$$

and we obtain

$$\begin{aligned} L_{\phi_d}(f) - L^*_{\phi_d} &\geq d^{-1}t\left(\mathrm{P}\rho_\eta(f, f_d^*) I_{E_+ \cup E_-} - 2(B+1)At^\alpha\right) \\ &= d^{-1}t\left(\mathrm{P}\rho_\eta(f, f_d^*) - 2(B+1)At^\alpha\right). \end{aligned}$$

Choose

$$t = \left(\frac{\mathrm{P}\rho_\eta(f, f_d^*)}{4(B+1)A}\right)^{1/\alpha},$$

in the expression above, and we obtain

$$\mathbb{E}g_f(X,Y) = L_{\phi_d}(f) - L^*_{\phi_d} \geq \frac{1}{2d(4(B+1)A)^{1/\alpha}} \left(\mathrm{P}\rho_\eta(f, f_d^*)\right)^{(1+\alpha)/\alpha},$$

and so

$$\mathrm{P}\rho_\eta(f, f_d^*) \leq \left\{2d(4(B+1)A)^{1/\alpha}\right\}^{\alpha/(\alpha+1)} \left\{\mathbb{E}g_f(X,Y)\right\}^{\alpha/(1+\alpha)}.$$

In addition, by Lemma 10,

$$\begin{aligned} \mathbb{E}\{g_f(X,Y)\}^2 &= \mathbb{E}\mathbb{E}[\{g_f(X,Y)\}^2|X] \\ &= \mathrm{P}\left(\eta|\phi_d(f) - \phi_d(f_d^*)|^2 + (1-\eta)|\phi_d(-f) - \phi_d(-f_d^*)|^2\right) \\ &\leq (B+1)\left(\frac{1-d}{d}\right)^2 \mathrm{P}\rho_\eta(f, f_d^*). \end{aligned}$$

Combining these two inequalities shows that

$$\mathbb{E}\{g_f(X,Y)\}^2 \leq (B+1)\left(\frac{1-d}{d}\right)^2 \left(2d(4A(B+1))^{1/\alpha}\right)^{\alpha/(\alpha+1)} \left(\mathbb{E}g_f(X,Y)\right)^{\alpha/(1+\alpha)}.$$

■

Remark 11 *Specialized to the case $(\delta, d) = (0, 1/2)$, we note that Lemma 8 removes unnecessary technical restrictions on $\eta(X)$ near 0 and 1, imposed by Blanchard et al. (2008) and Tarigan and van de Geer (2006). This is consistent with results of Steinwart and Scovel (2007) on SVMs with Gaussian kernels.*

Lemma 8 provides the main ingredient for establishing fast rates of minimizers $\widehat{f}_d$ of the empirical risk $\widehat{L}_{\phi_d}(f)$.

In the theorem, we use the notation $N(\varepsilon, L_\infty, \mathcal{F})$ to denote the ε-covering number of $\mathcal{F}$ in L_∞, that is, the smallest number of closed ε-balls in L_∞ needed to cover $\mathcal{F}$. The countability assumption means that measurability is not an issue. It can be replaced by other mild sufficient conditions.

Theorem 12 *If η satisfies the margin condition at d with exponent α, $\mathcal{F}$ is a countable class of functions $f : \mathcal{X} \to \mathbb{R}$ satisfying $\|f\|_\infty \leq B$, and $\mathcal{F}$ satisfies*

$$\log N(\varepsilon, L_\infty, \mathcal{F}) \leq C\varepsilon^{-p}$$

for all $\varepsilon > 0$ *and some* $0 \le p \le 2$*, then there exists a constant* C' *independent of* n*, such that*

$$\mathbb{E}L_{\phi_d}(\widehat{f}_d) - L^*_{\phi_d} \le 2 \inf_{f\in\mathcal{F}} \left(L_{\phi_d}(f) - L^*_{\phi_d}\right) + C' n^{-\frac{1+\alpha}{2+p+\alpha+p\alpha}},$$

where $\widehat{f}_d = \arg\min_{f\in\mathcal{F}} \widehat{L}_{\phi_d}(f)$.

Proof We use the notation $\mathrm{P}g_f = \mathbb{E}g_f(X,Y)$ and

$$\mathbb{P}_n g_f = \frac{1}{n}\sum_{i=1}^n g_f(X_i,Y_i).$$

By definition of $\widehat{f}_d$, we have

$$\begin{aligned} L_{\phi_d}(\widehat{f}_d) - L^*_{\phi_d} &= \mathrm{P}g_{\widehat{f}_d} \\ &= 2\mathbb{P}_n g_{\widehat{f}_d} + (\mathrm{P}-2\mathbb{P}_n)g_{\widehat{f}_d} \\ &\le 2\inf_{f\in\mathcal{F}} \mathbb{P}_n g_f + \sup_{f\in\mathcal{F}} (\mathrm{P}-2\mathbb{P}_n)g_f. \end{aligned}$$

Taking expected values on both sides, yields,

$$\mathbb{E}L_{\phi_d}(\widehat{f}_d) - L^*_{\phi_d} \le 2\inf_{f\in\mathcal{F}} \left(L_{\phi_d}(f) - L^*_{\phi_d}\right) + \mathbb{E}\left[\sup_{f\in\mathcal{F}} (\mathrm{P}-2\mathbb{P}_n)g_f\right].$$

Since $|g_f - g_{f'}| \le |f-f'|(1-d)/d$, it follows that

$$\mathbb{E}\left[\sup_{f\in\mathcal{F}} (\mathrm{P}-2\mathbb{P}_n)g_f\right] \le \frac{1-d}{d}\varepsilon_n + \frac{1-d}{d}B\mathbb{P}\left\{\sup_{f\in\mathcal{F}_n} (\mathrm{P}-2\mathbb{P}_n)g_f \ge \varepsilon_n\right\},$$

where $\mathcal{F}_n$ is a minimal ε_n-covering net of $\mathcal{F}$ with

$$\varepsilon_n = Mn^{-(1+\alpha)/(2+p+\alpha+p\alpha)}$$

for some constant M to be selected later. The union bound and Bernstein's exponential inequality for the tail probability of sums of bounded random variables in conjunction with Lemma 8, yield

$$\begin{aligned} \mathbb{P}\left\{\sup_{f\in\mathcal{F}_n} (\mathrm{P}-2\mathbb{P}_n)g_f \ge \varepsilon_n\right\} &\le \sum_{f\in\mathcal{F}_n} \mathbb{P}\left\{(\mathrm{P}-\mathbb{P}_n)g_f \ge \frac{1}{2}(\mathrm{P}g_f + \varepsilon_n)\right\} \\ &\le |\mathcal{F}_n| \max_{f\in\mathcal{F}_n} \exp\left(-\frac{n}{8}\frac{(\varepsilon_n + \mathrm{P}g_f)^2}{\mathrm{P}g_f^2 + B(\varepsilon_n+\mathrm{P}g_f)/6}\right) \\ &\le \exp(C\varepsilon_n^{-p} - cn\varepsilon_n^{2-\beta}) \end{aligned}$$

with $0 \le \beta = \alpha/(1+\alpha) \le 1$ and some $c > 0$ independent of n. Conclude the proof by noting that

$$\exp(C\varepsilon_n^{-p} - cn\varepsilon_n^{2-\beta}) = \exp\left(-\frac{c}{2}n\varepsilon_n^{2-\beta}\right),$$

and by choosing the constant M in ε_n such that $C\varepsilon_n^{-p} = cn\varepsilon_n^{2-\beta}/2$ and $\exp(-n\varepsilon_n^{2-\beta}) = o(\varepsilon_n)$. ■

Remark 13 *The constant 2 in front of the minimal excess risk on the right could be made closer to* 1*, at the expense of increasing* C'*.*

Theorem 12 discusses minimizers of the empirical risk $\widehat{L}_{\phi_d}$ *over classes* $\mathcal{F}$ *of uniformly bounded functions. The analysis of SVMs that minimize* $\widehat{L}_{\phi_d}$ *plus a regularization term requires more work.*

Remark 14 *Consider for simplicity the case* $\mathcal{F}$ *is finite (*$p = 0$*). Then, if the margin condition holds for* $\alpha = +\infty$*, we obtain from the proof of Theorem 12 rates of convergence of order* $\log|\mathcal{F}|/n$*. If* $\alpha = 0$*, we in fact impose no restriction on* $\eta(X)$ *at all, and the rate equals* $(\log|\mathcal{F}|/n)^{1/2}$*.*

Remark 15 *The entropy condition is satisfied for many classes. For instance, Kolmogorov and Tichomirov (1961) prove the following result for Sobolev spaces with parameter* β*. Let* $\mathcal{X}$ *be a bounded, convex subset of* $\mathbb{R}^d$ *and for every* $k = (k_1, \ldots, k_d) \in \mathbb{N}^d$*, define the differential operator* D^k *by*

$$D^k = \frac{\partial^{k_1+\ldots+k_d}}{\partial x_1^{k_1} \ldots \partial x_d^{k_d}}.$$

Let $\mathcal{F} = \mathcal{F}(\beta, c_1, c_2)$ *be the class of real valued, continuous functions* f *on* $\mathcal{X}$ *with uniformly bounded partial derivatives of order* $k \leq \lfloor\beta\rfloor$ *(the greatest integer smaller than* β*),*

$$\max_{k_1+\ldots+k_n \leq \lfloor\beta\rfloor} \max_{x \in \mathcal{X}} \left|D^k f(x)\right| \leq c_1,$$

and which highest partial derivatives are Lipschitz of order $\beta - \lfloor\beta\rfloor$*,*

$$\max_{k_1+\ldots+k_n=\lfloor\beta\rfloor} \max_{x,y \in \mathcal{X},\ x \neq y} \frac{|D^k f(x) - D^k f(y)|}{\|x-y\|^{\beta-\lfloor\beta\rfloor}} \leq c_2.$$

The constants c_1 *and* c_2 *are independent of* f*. Such classes have covering numbers (Kolmogorov and Tichomirov, 1961; van der Vaart and Wellner, 1996)*

$$\log N(\varepsilon, L_\infty, \mathcal{F}) \leq C_d \left(\frac{1}{\varepsilon}\right)^{d/\beta},$$

for every $\varepsilon > 0$ *and some constant* C_d *depending on the dimension* d *and the constants* c_1 *and* c_2*, but not on* ε*. Applying the theorem with* $p = d/\beta$*, we obtain rates between* $n^{-\beta/(2\beta+d)}$ *(for* $\alpha = 0$*) and* $n^{-\beta/(d+\beta)}$ *(for* $\alpha = +\infty$*).*

Another example is the case where $\mathcal{F}$ *is a subset of a RKHS. For instance, let* $\mathcal{H}$ *be the RKHS corresponding to the Gaussian kernel* $K(x,y) = \exp(-\|x-y\|^2/\sigma^2)$ *and let* $\|f\|$ *be the norm of* f *in* $\mathcal{H}$*. For* $\mathcal{F} = \mathcal{F}_R = \{f \in \mathcal{H} : \|f\| \leq R\}$*, Zhou (2003) proves that, for* $\mathcal{X} = [0,1]^d$*, fixed* R *and fixed scale parameter* σ*, the entropy bound*

$$\log N(\varepsilon, L_\infty, \mathcal{F}) \leq C_d \log^{d+1}\left(\frac{R}{\varepsilon}\right)$$

for some $C_d < \infty$ *and the rates of convergence range between* $\sqrt{\log^{d+1}(n)/n}$ *(*$\alpha = 0$*) and* $\log^{d+1}(n)/n$ *(*$\alpha = \infty$*). See also the results of Guo et al. (2002).*

Appendix A. Proof of Proposition 4

First we compute

$$\begin{aligned}
\inf_{z\le -1} r_{\eta,\phi_d}(z) &= \frac{\eta}{d}, \\
\inf_{-1\le z\le -\delta} r_{\eta,\phi_d}(z) &= \frac{\eta}{d}\mathbf{1}[\eta\le d]+\left(\frac{\delta}{d}\eta+1-\delta\right)\mathbf{1}[\eta>d] \\
\inf_{-\delta\le z\le 0} r_{\eta,\phi_d}(z) &= \mathbf{1}[\eta\ge d]+\left(\frac{\delta}{d}\eta+1-\delta\right)\mathbf{1}[\eta<d] \\
\inf_{0\le z\le \delta} r_{\eta,\phi_d}(z) &= \mathbf{1}[\eta\le 1-d]+\left(1+\frac{\delta}{d}-\delta-\frac{\delta}{d}\eta\right)\mathbf{1}[\eta>1-d] \\
\inf_{\delta\le z\le 1} r_{\eta,\phi_d}(z) &= \frac{1-\eta}{d}\mathbf{1}[\eta>1-d]+\left(1+\frac{\delta}{d}-\delta-\frac{\delta}{d}\eta\right)\mathbf{1}[\eta\le 1-d] \\
\inf_{z\ge 1} r_{\eta,\phi_d}(z) &= \frac{1-\eta}{d}
\end{aligned}$$

It is now easy to verify that

$$\begin{aligned}
H_{-1}(\eta) &= \inf_{z<-\delta} \eta\phi_d(z)+(1-\eta)\phi_d(-z) \\
&= \frac{\eta}{d}\mathbf{1}[\eta<d]+\left(\frac{\delta}{d}\eta+1-\delta\right)\mathbf{1}[\eta\ge d]
\end{aligned}$$

so that

$$\begin{aligned}
&H_{-1}(\eta)-H(\eta)= \\
&\left(\frac{\delta}{d}\eta-\delta\right)\mathbf{1}[d\le\eta\le 1-d]+\left(\frac{1+\delta}{d}\eta+1-\delta-\frac{1}{d}\right)\mathbf{1}[\eta>1-d]
\end{aligned}$$

On the other hand,

$$\begin{aligned}
\xi_{-1}(\eta) &= \eta-\xi(\eta) \\
&= (\eta-d)\mathbf{1}[d\le\eta\le 1-d]+(2\eta-1)\mathbf{1}[\eta>1-d]
\end{aligned}$$

and we see that

$$\frac{\delta}{d}\xi_{-1}(\eta)\le H_{-1}(\eta)-H(\eta)$$

for all $0<\delta\le 1$. Next, we compute

$$\begin{aligned}
H_{\mathbb{R}}(\eta) &= \inf_{|z|\le\delta} \eta\phi_d(z)+(1-\eta)\phi_d(-z) \\
&= \left(1-\delta+\frac{\delta}{d}\eta\right)\mathbf{1}[\eta<d]+\mathbf{1}[d\le\eta\le 1-d] \\
&\qquad +\left(1-\delta+\frac{\delta}{d}-\frac{\delta}{d}\eta\right)\mathbf{1}[\eta>1-d]
\end{aligned}$$

and

$$H_{®}(\eta) - H(\eta) = \left(1 - \delta - \frac{1-\delta}{d}\eta\right)\mathbf{1}[\eta < d] + \left(1 - \delta - \frac{1-\delta}{d} + \frac{1-\delta}{d}\eta\right)\mathbf{1}[\eta > 1-d].$$

Since

$$\begin{aligned}\xi_{®}(\eta) &= d - \xi(\eta) \\ &= (d-\eta)\mathbf{1}[\eta < d] + (d-1+\eta)\mathbf{1}[\eta > 1-d]\end{aligned}$$

we find that

$$\frac{\delta}{d}\xi_{®}(\eta) \le H_{®}(\eta) - H(\eta)$$

provided $0 < \delta \le 1/2$. Finally, we find that

$$\begin{aligned}H_1(\eta) &= \inf_{z>\delta} \eta\phi_d(z) + (1-\eta)\phi_d(-z) \\ &= \frac{1-\eta}{d}\mathbf{1}[\eta > 1-d] + \left(\frac{\delta}{d} + 1 - \delta - \frac{\delta}{d}\eta\right)\mathbf{1}[\eta \le 1-d]\end{aligned}$$

and consequently

$$H_1(\eta) - H(\eta) = \left(1 - \delta + \frac{\delta}{d} - \frac{\delta}{d}\eta - \frac{\eta}{d}\right)\mathbf{1}[\eta < d] + \left(\frac{\delta}{d} - \delta - \frac{\delta}{d}\eta\right)\mathbf{1}[d \le \eta \le 1-d].$$

Now,

$$\begin{aligned}\xi_1(\eta) &= 1 - \eta - \xi(\eta) \\ &= (1-2\eta)\mathbf{1}[\eta < d] + (1-\eta-d)\mathbf{1}[d \le \eta \le 1-d],\end{aligned}$$

and we find that

$$\frac{\delta}{d}\xi_1(\eta) \le H_1(\eta) - H(\eta)$$

provided $0 < \delta \le 1$.

We now verify the second claim of Proposition 4. Assume that $d \le \delta \le 1-d$.

First we consider the case $\eta < d$. Then

$\xi_{-1}(\eta) \le H_{-1}(\eta) - H(\eta)$ holds trivially.

$\xi_{®}(\eta) \le H_{®}(\eta) - H(\eta) \iff (1-\delta-d)\eta \le (1-\delta-d)d$. As $\eta \le d$, we need that $\delta \le 1-d$.

$\xi_1(\eta) \le H_1(\eta) - H(\eta) \iff (1+\delta-2d)\eta \le \delta(1-d)$. As $\eta \le d$, we need that $(1+\delta-2d)d \le \delta(1-d)$, equivalently, $(\delta-d)(1-2d) \ge 0$.

Next, if $d \le \eta \le 1-d$, we see that

$\xi_{-1}(\eta) \leq H_{-1}(\eta) - H(\eta) \iff (\delta - d)\eta \geq d(\delta - d)$.

$\xi_{\circledR}(\eta) \leq H_{\circledR}(\eta) - H(\eta)$ holds trivially.

$\xi_1(\eta) \leq H_1(\eta) - H(\eta) \iff (\delta - d)\eta \leq (1-d)(\delta - d)$.

Finally, if $\eta > 1 - d$, we find that

$\xi_{-1}(\eta) \leq H_{-1}(\eta) - H(\eta) \iff (1 + \delta - 2d)\eta \geq (1 + d\delta - 2d)$. For $\eta \geq 1 - d$ this holds provided $(1 + \delta - 2d)(1 - d) \geq (1 + d\delta - 2d) \iff (\delta - d)(1 - 2d) \geq 0$.

$\xi_{\circledR}(\eta) \leq H_{\circledR}(\eta) - H(\eta) \iff (1 - \delta - d)\eta \geq (1 - d)(1 - \delta - d)$.

$\xi_1(\eta) \leq H_1(\eta) - H(\eta)$ holds trivially.

This concludes the proof of the second claim, since $d \leq \delta \leq 1 - d$. The last claim for the case $(\delta, d) = (0, 1/2)$ follows as well from the preceding calculations.

Abstract

When facing the question of learning languages in realistic settings, one has to tackle several problems that do not admit simple solutions. On the one hand, languages are usually defined by complex grammatical mechanisms for which the learning results are predominantly negative, as the few algorithms are not really able to cope with noise. On the other hand, the learning settings themselves rely either on too simple information (text) or on unattainable one (query systems that do not exist in practice, nor can be simulated). We consider simple but sound classes of languages defined via the widely used edit distance: the balls of strings. We propose to learn them with the help of a new sort of queries, called the correction queries: when a string is submitted to the Oracle, either she accepts it if it belongs to the target language, or she proposes a correction, that is, a string of the language close to the query with respect to the edit distance. We show that even if the good balls are not learnable in Angluin's MAT model, they can be learned from a polynomial number of correction queries. Moreover, experimental evidence simulating a human Expert shows that this algorithm is resistant to approximate answers.

Keywords: grammatical inference, oracle learning, correction queries, edit distance, balls of strings

1. Introduction

Do you know how many *Nabcodonosaur* were kings of Babylon? And do you know when *Arnold Shwartzeneger* was born? Just two decades ago, you would have had to consult encyclopedias and Who's Who dictionaries in order to get answers to such questions. At that time, you may have needed this information in order to participate to quizzes and competitions organized by famous magazines during the summers, but because of *these* questions, you might possibly have missed the very first prize. Why?... Nowadays, everything has changed: you naturally use the Web, launch

*. This paper is an extended version of "Learning Balls of Strings with Correction Queries" presented at the 2007 European Conference in Machine Learning (ECML'07).

your favorite search engine, type two keywords, follow three links and note down the answers. In this particular case, you discover...that no king of Babylon was called *Nabcodonosaur* but two *Nab***uc**h*odonos***o***r*'s reigned there many centuries ago. Again, the day *Arnold Shwartzeneger* was born is not clear, but it is easy to check that *Arnold S***c***hwa***rz***ene***g***ger* was born in 1947, July 30^{th}.

So you would probably win today the great competitions of the past. Indeed, the actual search engines are able to propose *corrections* when a keyword is not frequent. Those corrections are most often reliable because the reference dictionary is built from the billions of web pages indexed all over the world. Hence, a search engine is playing the role of an imperfect but powerful Oracle, able to validate a relevant query by returning relevant documents, but also to correct any suspect query. Such an Oracle is able to answer to what we shall call *correction queries*.

The first goal of this paper is to show, from a theoretical standpoint, that the concept of correction query allows one to get new challenging results in the field of Active Learning. In this framework, developed by Angluin in the 80's (Angluin, 1987b), a Learner (He) has access to an Oracle (She) that knows a concept he must discover. To this purpose, he submits different kinds of queries (e.g., Correction Queries) and she has to answer without lying. The game ends when he guesses the concept. Query-based Learners are often interesting from a practical viewpoint. For instance, instead of requiring a human expert to label huge quantities of data, this expert could be asked by the Learner, in an interactive situation, to provide a small amount of targeted information.

The second goal of this paper is to provide evidence that correction queries are suitable for this kind of real-life applications. However, assuming that the Oracle is a human expert introduces new constraints. On one hand, it is inconceivable to ask *a polynomial* number of queries: this may still be too much for a human. So the learning algorithm should aim at minimizing the number of queries even if we must pay for it with a worse time complexity. On the other hand, a human being (or even the Web) is fallible. Therefore the learning algorithm should also aim at learning functions or languages from *approximate* corrections.

In the above Web example, the search engine uses the frequency of words to propose corrections. In consequence, correct words (e.g., *malophile* = someone who loves apples) are sometimes subject to a correction (e.g., *halophile* = a cell which thrives in environments with high concentrations of salt). Another key point is the distance used to find a closest correct string; it is a variant of the *edit distance*, also called the *Levenshtein distance*, which measures the minimum number of deletion, insertion or substitution operations needed to transform one string into another (Levenshtein, 1965; Wagner and Fisher, 1974). This distance have been used in many fields including Computational Biology (Gusfield, 1997; Durbin et al., 1998), Language Modelling (Amengual et al., 2001; Amengual and Dupont, 2000) and Pattern Recognition (Navarro, 2001; Chávez et al., 2001).

Edit distance appears in specific Grammatical Inference problems, in particular when one wants to learn languages from noisy data (Tantini et al., 2006). In this domain, the classes of languages studied are not defined following the Chomsky Hierarchy. Indeed, even the easiest level of this hierarchy, the class of regular languages, is not at all robust to noise, since it includes all the parity functions, which can be defined as regular languages and are not learnable in the presence of noise (Kearns and Li, 1993). In order to avoid this difficulty, we shall consider only special finite languages, that may seem elementary to formal language theoreticians, but are relevant for topologists and complex for combinatorialists: the *balls of strings*.

Balls of strings are formed by choosing one specific string, called the centre, and all its neighbours up to a given length for the edit distance, called the radius. From a practical standpoint, balls of strings appear in a variety of settings: in approximate string matching tasks, the goal is to find all

close matches to some target string (Navarro, 2001; Chávez et al., 2001); in noisy settings, garbled versions of an unidentified string are given and the task is to recover the original string (Kohonen, 1985); when using dictionaries, the task can be described as that of finding the intersection between two languages, the dictionary itself and a ball around the target string (Schulz and Mihov, 2002); in the field of bioinformatics, extracting valid models from large data sets of DNA or proteins can involve looking for substrings at distance less than some given bound, and the set of these approximate substrings can also be represented by balls (Sagot and Wakabayashi, 2003).

Hence, in this paper, we study the problem of identifying balls of strings from correction queries. In Section 2, we present the motivations of our work; we discuss why noise is a problem (2.1), which queries should be used to learn languages (2.2), and the relevance of a fallible Oracle in real applications (2.3). Definitions are given in Section 3, where we pay special attention to the definitions of edit distance (3.1), balls of strings (3.2), and correction queries (3.3). On one hand, we prove that the balls are not learnable with Angluin's membership and equivalence queries, and on the other hand, that the deterministic finite automata are not learnable with correction queries.

The main result of the paper is shown in Section 4. It consists of a polynomial time algorithm that infers any ball from correction queries. We explain some technical results (4.1), and we present the algorithm (4.2). An important question is raised concerning the fact that only good balls can be learned with a polynomial number of correction queries (4.3). In Section 5, we study the effectiveness of our algorithm in more practical situations. First, we are concerned with the case where the Oracle is fallible (5.1). Next, we try to minimize the number of queries asked, considering the fact that the expensive resource is the expert playing the part of the Oracle, not the machine making the computations (5.2). We conclude in Section 6.

2. Motivations and Related Work

Several questions need to be addressed before tackling the core of the problem.

2.1 Why is it Hard to Learn Languages in Noisy Settings?

Languages can either be generated, recognized or defined by mechanisms like regular expressions, finite state automata or formal grammars (Harrison, 1978; Sakarovich, 2004; Salomaa, 2006). Alternatively equations can define properties that the strings in the language should verify (Clark et al., 2006). The techniques enabling to learn such formalisms are known as grammatical inference, and new algorithms are developed all the time. But there is one issue that is systematically problematic for such algorithms: that of dealing with noise.

Results obtained in the field of grammatical inference show that learning in noisy situations is hard (de la Higuera, 2006). Some attempts to deal with this problem can be found, for example, in the GOWACHIN (Lang et al., 1998) and GECCO competitions (Lucas, 2004), where the problem of learning DFA from noisy examples was the main challenge.

Noise over strings can, in the simplest case, just affect the labels: a string in the language will be classified as not belonging, whereas a string can be labeled inside the language when it is not. It is known since (Trakhtenbrot and Barzdin, 1973; Angluin, 1978) that with even small doses of noise, learning automata is hard.

The second sort of noise that one may encounter with strings, which is possibly most characteristic here, consists in having the strings slightly modified through some noisy channel. This type of

noise is invariably described by the edit distance (Levenshtein, 1965): individual symbols appear or disappear, or even are transformed into different ones.

Again, for the edit noise, the typical classes of languages belonging to the Chomsky hierarchy (Chomsky, 1957; Sakarovich, 2004) are far from robust. Consider for instance the set of strings over the alphabet $\{0,1\}$ whose parity of 0's is identical to the parity of 1's (see Figure 1). This typical

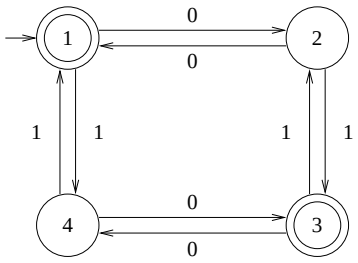

Figure 1: An automaton recognizing $\{w \in (0+1)^* : |w|_0 \bmod 2 = |w|_1 \bmod 2\}$.

regular language is clearly very sensitive to the noise: if any symbol is inserted or deleted in a string, the string will cease to belong to the language; and conversely, any string out of the language will be transformed into a string from the language, as the parity of either of the letters will change.

Unfortunately, the picture is even less clear with other regular languages such as 0^*1^* and $(010)^*$, or higher languages in the Chomsky hierarchy such as $\{ww : w \in (0+1)^*\}$ or the set of palindromes or $\{0^n1^n2^n : n \geq 0\}$. Indeed, these languages are sparse in the set of all strings, so trying to learn them from noisy data is like looking for a needle in a haystack: no string seems to belong to the target anymore.

The reader may think that probably, all these textbook languages are not relevant in practice. In which case, studying their learnability in the presence of noise would not be significative. Nevertheless, concerning randomly drawn regular languages, the picture is not better: the website developed by Coste et al. (1998) shows that despite a decade of efforts, no convincing solution has been yet found to take into account the noise during the learning process.

Therefore, if we are to learn languages in a noisy setting where the noise is modelled through the edit distance, we think that it is necessary to consider other classes of languages that could be much better adapted to this type of noise. The balls of strings are an example of such languages.

2.2 What Queries Should we Use?

Learning with queries was introduced by Angluin in order to provide a firm mathematical background to machine learning in a non statistical setting (Angluin, 1987b). In this paradigm, both positive and negative results are relevant. Indeed, if one cannot learn using a polynomial number of questions, then one cannot do it from data that one gets without choice from the environment. In this setting the questions are called queries and they are asked to a perfect abstract machine, called Oracle.

Several types of queries have been studied, and some classes were proved to be learnable from specific combination of queries (see Angluin, 2004, for a survey). The best known and most important of such positive results is that deterministic finite state automata are polynomially learnable

from a combination of membership queries and strong equivalence queries (Angluin, 1987a). The corresponding definitions will be given in Section 3.3.

We argue that equivalence queries are not realistic for the intended applications, and we choose to use the recently introduced correction queries instead (Becerra-Bonache and Yokomori, 2004). When making a correction query, we submit a string to the Oracle who answers YES if the string is in the target language, and if it is not then the Oracle returns a string from the language that is closest to the query. This string is called the correction.

In order to give an introductory intuition, let us consider the case where we want to learn disks in the plane using the Euclidean distance. Instead of learning from examples (with the possibility of them being labeled), let us suppose we have access to an Oracle that will answer the following query: a point is proposed, and is returned either the answer YES or a correction of this point, that is, the closest point in the disk.

Then we can proceed in three stages to learn a disk of centre O and radius R with correction queries as shown in Figure 2:

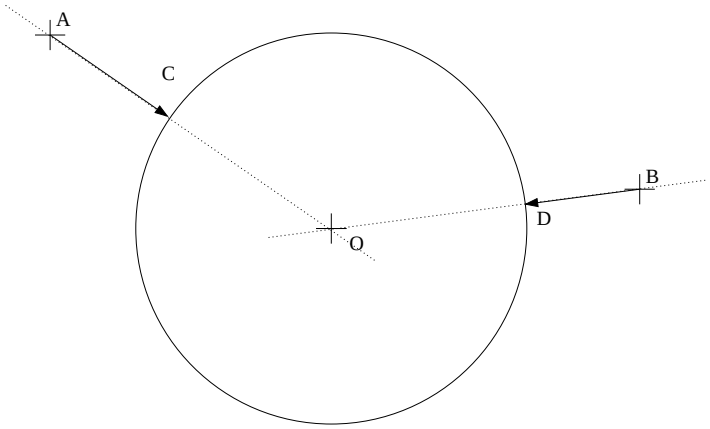

Figure 2: Three stages are sufficient to learn the disks of $\mathbb{R}^2$ with correction queries: (1) find two points A and B outside of the disk haphazardly using correction queries; (2) ask the Oracle for the corrections of A and B, which will result in C and D, respectively; (3) use a ruler to deduce the centre O and a compass to draw the circle.

1. We start by finding two points A and B outside of the disk we want to identify. Looking for them haphazardly by asking to the Oracle if such or such a point is in the disk is enough: intuitively, we are going to find them with very few queries.

2. We ask the Oracle for the corrections of A and B. Concerning A, the Oracle is going to return a point C inside the disk, as close as possible to A. Clearly, this point is at the intersection of the segment $[OA]$ and the boundary circle of the target disk. Likewise, let D be the correction of B.

3. We draw the lines (AC) and (BD) with a ruler: they intersect in O. Then we can draw the circle with a compass. We get the radius by measuring the distance between O and C.

Hence, it is easy to learn the balls of $\mathbb{R}^2$ with very few correction queries. Now, focusing on balls of strings, we may hope that the previous approach is good and try to reproduce it.

However, building the centre of a ball from strings on its periphery is difficult for at least two reasons. On one hand, (Σ^*, d) is a metric space with no vector space as underlying structure. This is similar to the case where we were trying to learn the disks of the plane with just a compass but no ruler.[1] On the other hand, the problem is formally *hard*:

Theorem 1 (de la Higuera and Casacuberta 2000) *Given a finite set of strings $W = \{w_1, \ldots, w_n\}$ and a constant K, deciding whether a string $u \in \Sigma^*$ exists such that $\max_{w \in W} d(u,w) < K$ (respectively $\sum_{w \in W} d(u,w) < K$) is $\mathcal{NP}$-complete.*

Therefore, we will have to study the balls in more detail and make the best possible use of the correction queries, so as not to build the centres from scratch.

2.3 Why might the Oracle be Fallible?

Above we argued that the active learning model was based on the strong assumption of a perfect Oracle. This corresponded to a reasonable assumption when dealing with mathematics and with the objective of being in a favorable setting in which negative results could be blamed on the complexity of the task and not on the adversarial nature of the Oracle.

But in recent years, the active learning setting (corresponding to learning from an Oracle) has been accepted as a plausible setting for real applications. Indeed we are faced with huge quantities of unlabeled data. Choosing which data is to receive attention by an expert (human or machine) is a difficult question. Interactive learning sessions, where the learning algorithm asks for specific information during runtime, is an interesting alternative to deal with such problems.

A typical example is system SQUIRREL (Carme et al., 2007) which induces a web wrapper through interaction with a human user. Another case is that of testing hardware (Hagerer et al., 2002): the specifications of the software correspond to the Oracle which can then allow to check if the constructed item obeys to the specifications. In both examples the Oracle is fallible: in the second one because testing equivalence is done through sampling.

A third situation in which active learning can be useful corresponds to that of rendering intelligible some black box learned through some statistical machine learning method. Indeed, even if hyper-planes (Clark et al., 2006) or recurrent neural networks (Giles et al., 2001) are difficult to interpret, one can try to use the learned numerical models as Oracles in an active learning algorithm whose result might be some rule based classifier (de la Higuera, 2006).

3. Definitions

An *alphabet* Σ is a finite nonempty set of symbols called *letters*. For the sake of clarity, we shall use $0, 1, 2, \ldots$ as letters in our examples and write $a, b, c, \ldots$ to denote variables for letters in an alphabet. A *string* $w = a_1 \ldots a_n$ is any finite sequence of letters. We write Σ^* for the set of all strings over Σ and λ for the empty string. Let $a \in \Sigma$, $|w|$ be the length of w and $|w|_a$ the number of occurrences of

1. Actually, this is still possible: a theorem due to Mohr (1672), rediscovered by Mascheroni (1797), states that every construction with a ruler and a compass can also be done with a compass only. We know an algorithm that uses 14 circles to learn a disk of the plane. If the reader knows a better method, please contact us!

a in w. We say that a string u is a *subsequence* of v, denoted $u \preceq v$, if $u = a_1 \dots a_n$ and there exist $u_0, \dots, u_n \in \Sigma^*$ such that $v = u_0 a_1 u_1 \dots a_n u_n$. A *language* is any subset $L \subseteq \Sigma^*$. Let $\mathbb{N}$ be the set of non negative integers. For all $k \in \mathbb{N}$, let $\Sigma^k = \{w \in \Sigma^* : |w| = k\}$ and $\Sigma^{\leq k} = \{w \in \Sigma^* : |w| \leq k\}$. Let $\mathbb{R}$ denote the set of real numbers. We say that a real number $\rho \in \mathbb{R}$ is *irrational* if $|\rho| \neq \frac{p}{q}$ for all $p, q \in \mathbb{N}$.

3.1 Edit Distance

The *edit distance* $d(w, w')$ between two strings w and w' is the minimum number of *edit operations* needed to transform w into w' (Levenshtein, 1965).

More precisely, we say that *w rewrites to w' in one step*, written $w \to w'$, if either

1. $w = uav$ and $w' = uv$ (*deletion* of a letter), or
2. $w = uv$ and $w' = uav$ (*insertion* of a letter), or
3. $w = uav$ and $w' = ubv$ (*substitution* of a letter by another letter),

where $u, v \in \Sigma^*$, $a, b \in \Sigma$ and $a \neq b$.

Let $\xrightarrow{k}$ denote a *rewriting derivation* made of k rewriting steps. The edit distance $d(w, w')$ is the minimum $k \in \mathbb{N}$ such that $w \xrightarrow{k} w'$. For instance, $d(0100, 001) = 2$ since $0\underline{1}00 \to 00\underline{0} \to 001$ and rewriting 0100 into 001 cannot be achieved with less than two steps. Notice that $d(w, w')$ can be computed in time $O(|w| \cdot |w'|)$ by means of dynamic programming (Wagner and Fisher, 1974).

The following basic property states that $d(w, w')$ is at least the number of insertions needed to equalize the lengths of w and w':

Proposition 2 *For all $w, w' \in \Sigma^*$, $d(w, w') \geq \big||w| - |w'|\big|$. Moreover, $d(w, w') = \big||w| - |w'|\big|$ iff ($w \preceq w'$ or $w' \preceq w$).*

In all the parts of this paper but in Section 5.2.1, we shall use the standard edit distance defined above. However, for practical reasons, people often use variants of this definition. Sometimes, new edit operations are defined such as the exchange of two adjoining letters in a string. And often, the edit operations are weighted. We shall give more details when needed.

3.2 Balls of Strings

It is well-known that the edit distance is a *metric* (Crochemore et al., 2007), so it conveys to Σ^* the structure of a *metric space*.

Definition 3 (Ball of Strings) *The ball of centre $o \in \Sigma^*$ and radius $r \in \mathbb{N}$, denoted $B_r(o)$, is the set of all the strings whose distance to o is at most r:*

$$B_r(o) = \{w \in \Sigma^* : d(o, w) \leq r\}.$$

For instance, if $\Sigma = \{0, 1\}$, then $B_1(10) = \{0, 1, 00, 10, 11, 010, 100, 101, 110\}$ and $B_r(\lambda) = \Sigma^{\leq r}$ for all $r \in \mathbb{N}$.

The previous example illustrates the fact that the number of strings in a ball grows exponentially with the radius. Experimentally (see Table 1), we clearly notice that for center strings of fixed length, the average number of strings is more than twice larger when the radius is incremented by 1. This

Length of the centre	Radius					
	1	2	3	4	5	6
0	3.0	7.0	15.0	31.0	63.0	127.0
1	6.0	14.0	30.0	62.0	126.0	254.0
2	8.6	25.6	56.5	119.7	246.8	501.6
3	10.8	41.4	101.8	222.8	468.6	973.0
4	13.1	61.4	173.8	402.9	870.9	1850.8
5	16.3	91.0	285.1	698.5	1584.4	3440.9
6	17.9	125.8	441.2	1177.5	2771.3	6252.9
7	21.2	166.9	678.0	1908.8	4835.8	11233.5
8	24.3	200.2	1034.2	3209.9	8358.1	19653.6
9	26.0	265.4	1390.9	5039.6	13677.8	34013.1

Table 1: Average number of strings in a ball. The alphabet has 2 letters. Each value is computed over 20 random centres (possibly the same).

combinatorial explosion occurs as soon as $|\Sigma| \geq 2$, although we leave open the question of finding a general formula that would assess the volume of any ball $B_r(o)$.

The combinatorial explosion noted before raises the problem of the representation scheme that we should use to learn the balls, that is to say, the format of the output space of any learning algorithm. Basically, we need representations whose size is "reasonable", which is not the case of an exhaustive enumeration. An alternative representation could be based on automata, since the balls of strings are finite and thus regular languages.

It is not difficult to see that every ball $B_r(o)$ is recognized by a *non deterministic finite automaton with λ-transitions* having $O(|o| \cdot r)$ states. However, the non deterministic automata are bad candidates from the learning standpoint. Indeed, they are not learnable in most paradigms (Angluin and Kharitonov, 1995; de la Higuera, 1997).

The corresponding *deterministic finite automata* (DFA) do not have this drawback. However, experiments show that these DFA often have an exponential number of states. More precisely, several efficient algorithms exist to build a DFA that recognizes $B_r(o)$ (Ukkonen, 1985; Melichar, 1995; Schulz and Mihov, 2002). For instance, Schulz and Mihov (2002) have recently introduced the so-called *Levenshtein automaton*. Denoting by $n(o,r)$ the number of states of this automaton, they state: $n(o,1) = O(5 \cdot |o|)$, $n(o,2) = O(30 \cdot |o|)$, $n(o,3) = O(180 \cdot |o|)$, $n(o,4) = O(1353 \cdot |o|)$. Basically, $n(o,r)$ is linear in $|o|$ but exponential in r (In their construction, the size of the alphabet only plays a role in the number of transitions, not in the number of states).

Unfortunately, proving that the minimal DFA has the same property is a challenging combinatorial problem. So we only claim here:

Conjecture 4 *The minimal* DFA *recognizing the ball $B_r(o)$ has $\Omega(2^r \cdot |o|)$ states in the worst case.*

On the other hand, why not represent the ball $B_r(o)$ by the pair (o,r) itself? Indeed, its size is $|o| + \log r$, which is reasonable (Garey and Johnson, 1979). Besides, deciding whether $w \in B_r(o)$ or not is immediate: one only has to (1) compute $d(o,w)$ and (2) check whether this distance is $\leq r$,

which is achievable in time $O(|o| \cdot |w| + \log r)$. Finally, when the alphabet has at least two letters, (o, r) is a unique thus *canonical* representation of $B_r(o)$:

Theorem 5 *If $|\Sigma| \geq 2$ and $B_{r_1}(o_1) = B_{r_2}(o_2)$, then $o_1 = o_2$ and $r_1 = r_2$.*

Proof

- *Claim 1: if $B_{r_1}(o_1) = B_{r_2}(o_2)$, then $|o_1| + r_1 = |o_2| + r_2$.* Indeed, let $w \in \Sigma^{r_1}$, then $d(o_1, o_1 w) = |w| = r_1$ by Proposition 2. So $o_1 w \in B_{r_1}(o_1)$, thus $o_1 w \in B_{r_2}(o_2)$, that is to say, $d(o_1 w, o_2) \leq r_2$. Now $d(o_1 w, o_2) \geq |o_1 w| - |o_2|$ from Proposition 2. So we deduce that $r_2 \geq |o_1 w| - |o_2| = |o_1| + r_1 - |o_2|$. The same reasoning yields $|o_1| + r_1 \geq |o_2| + r_2$.
- *Claim 2: if $|\Sigma| \geq 2$ and $o_2 \not\preceq o_1$, then there exists $w \in \Sigma^*$ such that (1) $|w| = r_1 + |o_1|$ and (2) $o_1 \preceq w$ and (3) $o_2 \not\preceq w$.* Indeed, assume that $\Sigma = \{0, 1, \ldots\}$ and o_2 begins with an 0. Then we define $w = 1^{r_1} o_1$ and get the result.

Theorem itself: Assume that $o_1 \neq o_2$. Then either $o_1 \not\preceq o_2$, or $o_2 \not\preceq o_1$. Suppose that $o_2 \not\preceq o_1$, without loss of generality. By Claim 2, there exists a string w such that (1) $|w| = r_1 + |o_1|$ and (2) $o_1 \preceq w$ and (3) $o_2 \not\preceq w$. As $o_1 \preceq w$, Proposition 2 yields $d(o_1, w) = |w| - |o_1| = r_1$. So $w \in B_{r_1}(o_1)$. On the other hand, $o_2 \not\preceq w$, so Proposition 2 yields $d(o_2, w) > \big||w| - |o_2|\big| = \big|r_1 + |o_1| - |o_2|\big| = r_2$, so $w \notin B_{r_2}(o_2)$. In consequence, $B_{r_1}(o_1) \neq B_{r_2}(o_2)$, that is impossible. Therefore, $o_1 = o_2$, and by Claim 1, $r_1 = r_2$. ■

Notice however that if $\Sigma = \{0\}$, then $B_2(0) = B_3(\lambda) = \{\lambda, 0, 00, 000\}$, for instance.

3.3 Queries

Query learning is a paradigm introduced by Angluin (1987b). Her model brings a Learner and an Oracle into play. The goal of the Learner is to identify the representation of an unknown language, by submitting queries to the Oracle. The latter knows the target language and answers properly to the queries (she does not lie). The Learner is bounded by efficiency constraints at each step of the learning process: the runtime of the Learner to make its next query must be polynomial in the size of the target representation and in the length of the information returned by the Oracle up to that point. Notice that certain types of queries require answers that may be of unbounded length (examples or counter-examples). In that case, it is impossible not to take into account the length of this information in the amount of time and queries the Learner is allowed.

Between the different combinations of queries, one, called MAT (Minimally Adequate Teacher), is sufficient to learn the DFA (Angluin, 1987a). Two kinds of queries are used:

Definition 6 (Membership and Equivalence Queries) *Let Λ be a class of languages on Σ^* and $L \in \Lambda$ a target language known by the Oracle, that the Learner aims at guessing.*

In the case of membership queries, the Learner submits a string $w \in \Sigma^*$ to the Oracle; her answer, denoted by $\mathrm{MQ}(w)$, is either YES if $w \in L$, or NO if $w \notin L$.

In the case of equivalence queries, the Learner submits (the representation of) a language $K \in \Lambda$ to the Oracle; her answer, denoted by $\mathrm{EQ}(K)$, is either YES if $K = L$, or a string belonging to the symmetric difference $\big((K \setminus L) \cup (L \setminus K)\big)$ if $K \neq L$.

Although membership queries and equivalence queries have established themselves as a standard combination, there are real grounds to believe that equivalence queries are too powerful to

exist or even be simulated. From a cognitive point of view, we may imagine that a child could ask to his mother whether some sentence is correct or not (that would be a membership query), but not whether he knows English or not (that would be an equivalence query). As suggested by Angluin (1987a), in practice, we may be able to substitute the equivalence queries with a random draw of strings that are then submitted as membership queries (*sampling*). However, in many cases, sampling is not possible because the relevant distribution is unknown and/or inaccessible (de la Higuera, 2006).

Besides, we will not consider membership queries and equivalence queries together because they do not help to learn balls:

Theorem 7 *Assume* $|\Sigma| \geq 2$. *Let* $m,n \in \mathbb{N}$ *and* $\mathcal{B}_{\leq m,n} = \{B_r(o) : r \leq m, o \in \Sigma^*, |o| \leq n\}$. *Any algorithm that identifies every ball of* $\mathcal{B}_{\leq m,n}$ *with equivalence queries and membership queries necessarily uses* $\Omega(|\Sigma|^n)$ *queries in the worst case.*

Proof Following Angluin (1987b), we describe a malevolent Oracle who forces any method of exact identification using membership and equivalence queries to make $\Omega(|\Sigma|^n)$ queries in the worst case. The Oracle is an Adversary: she changes the target ball during the process of identification in order to penalize the Learner. However, all her answers will have to be consistent with the final ball. Technically, she maintains a set S of all the possible balls. At the beginning, $S = \mathcal{B}_{\leq m,n}$. As long as S contains at least two balls, she proceed as follows: her answer to the equivalence query $L = B_r(o)$ is the counterexample o; her answer to the membership query o is NO; in other words, she always declares that o is not in the target ball. After such an answer, every ball of S that contains o cannot be a possible target anymore, so she eliminates them from S. At this point, many balls might disappear, but only one of centre o and radius 0. As there are $\Omega(|\Sigma|^n)$ such balls in $\mathcal{B}_{\leq m,n}$, the Learner will need $\Omega(|\Sigma|^n)$ queries to identify one of them. ■

It should be noted that if the Learner is given one string from the ball, then he can learn using a polynomial number of membership queries.[2] We shall see that the *correction queries*, introduced below, allow to get round these problems:

Definition 8 (Correction Queries) *Let L be a target language known by the Oracle and w a string submitted by the Learner to the Oracle. Her answer, denoted* $\text{CQ}(w)$*, is either* YES *if* $w \in L$*, or a correction of w with respect to L if* $w \notin L$*, that is a string* $w' \in L$ *at minimum edit distance from w:*

$$\text{CQ}(w) = \textit{one string of } \left\{w' \in L : d(w,w') \textit{ is minimum}\right\}.$$

Notice that other milder definitions of correction queries have been proposed in the literature such as Becerra-Bonache et al. (2006) and Kinber (2008). However, the correction queries defined above can easily be simulated knowing the target language. Moreover, we have seen in the introduction that they naturally exist in real-world applications such as the search engines of the Web. Also, we can note that the correction queries are relevant from a cognitive point of view: there is growing evidence that corrective input for grammatical errors is widely available to children (Becerra-Bonache, 2006).

And last but not least, the correction queries as well as the balls rely on a distance, that foreshadows nice learning results. This is not the case for every class of languages:

2. More precisely, the best algorithm we know uses $O\big(|\Sigma|(|o|+r)\big)$ membership queries.

Theorem 9 *Assume $|\Sigma| \geq 2$. Let $n \geq 2$ and $\mathcal{D}_{\leq n}$ the set of all* DFA *with fewer than n states. Any algorithm that identifies every* DFA *of $\mathcal{D}_{\leq n}$ with correction queries necessarily uses $\Omega(|\Sigma|^n)$ queries in the worst case.*

Proof Remember that the number of states of a DFA is a reasonable measure of its size. Let A_w denote the minimal DFA that recognizes $\Sigma^* \setminus \{w\}$. The reader may check that A_w has $|w|+2$ states (see Figure 3 for an example). So basically, $\{A_w : w \in \Sigma^{n-2}\} \subseteq \mathcal{D}_{\leq n}$. Following Angluin (1987b) again, we describe an Adversary that maintains a set S of all the possible DFA. At the beginning, $S = \mathcal{D}_{\leq n}$. Each time the correction of any string w is demanded, the Adversary answers YES and eliminates $\mathcal{A}_w$ from S (and a lot of other DFA) in order to be consistent. As there are $\Omega(|\Sigma|^n)$ such DFA in $\mathcal{D}_{\leq n}$, identifying one of them requires $\Omega(|\Sigma|^n)$ queries. ■

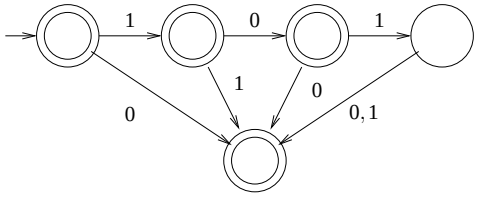

Figure 3: The minimal DFA A_{101} that recognizes $\Sigma^* \setminus \{101\}$ has $5 (= |101|+2)$ states.

4. Identifying Balls of Strings using Corrections

In this section, we propose an algorithm that learns the balls of strings using correction queries. We follow the method described for the disks of the plane. However, several details distinguish the balls of strings and the balls in $\mathbb{R}^2$.

4.1 Technicalities

In this section we introduce four related mathematical results. The first is an analysis of the corrections the Oracle can make. The second corresponds to the definition of the set of the longest strings in a ball (what we call the *upper border* of the ball). The third result is an algorithm allowing to extract the centre of the ball if we are given some elements from this upper border. And finally we explain how to find a string from the upper border using corrections.

4.1.1 A CHARACTERIZATION OF THE CORRECTIONS

When the Learner submits a string outside of a ball to the Oracle, she answers with a string that belongs to the 'circle' delimiting the ball. However, a string often has a lot of different possible corrections, contrarily to what happens in the plane. For instance, the possible corrections for the string 0000 with respect to the ball $B_2(11)$ are $\{00, 001, 010, 100, 0011, 0101, 0110, 1001, 1010, 1100\}$.

By the definition of a correction query, the Oracle will choose one of them arbitrarily, possibly the worst one from the Learner's point of view. Nevertheless, the Oracle's potential malevolence is limited by the following result, that characterizes the set of *all* the possible corrections for a string:

Lemma 10 *Let $B_r(o)$ be a ball and $v \notin B_r(o)$. Then the set of possible corrections of v is exactly $\{u \in \Sigma^* : d(o,u) = r \text{ and } d(u,v) = d(o,v) - r\}$.*

Proof Let $k = d(o,v)$ and consider a derivation from o to v of minimum length: $o \xrightarrow{k} v$. As $v \notin B_r(o)$, we get $k > r$, so this derivation passes through a string w_0 such that $o \xrightarrow{r} w_0 \xrightarrow{k-r} v$. Let us define the set $W = \{w \in \Sigma^* : d(o,w) = r \text{ and } d(w,v) = k-r\}$. Basically, $w_0 \in W$, so $W \neq \emptyset$. Moreover, $W \subseteq B_r(o)$. Now let U denote the set of all the possible corrections of v. We claim that $U = W$. Indeed, let $u \in U$ and $w \in W$. If $d(u,v) > d(w,v)$, then w is a string of $B_r(o)$ that is closer to v than u, so u cannot be a correction of v. On the other hand, if $d(u,v) < d(w,v)$, then as $d(o,v) \leq d(o,u) + d(u,v)$, we deduce that $d(o,u) \geq d(o,v) - d(u,v) > d(o,v) - d(w,v)$. As $d(o,v) = k$ and $d(w,v) = k-r$, we get $d(o,u) > r$, which is impossible since $u \in U \subseteq B_r(o)$. Hence, $d(u,v) = d(w,v) = k-r$. In consequence, all the strings $w \in W$ and corrections $u \in U$ are at the same distance from v, thus $W \subseteq U$. Moreover, we have $d(o,v) \leq d(o,u) + d(u,v)$, so $k \leq d(o,u) + k - r$, thus $d(o,u) \geq r$. As $u \in B_r(o)$, we deduce that $d(o,u) = r$. Finally, as we have stated that $d(u,v) = k-r$, we can conclude that $U \subseteq W$. ■

Here is a geometric interpretation of the result above. Let us define the *segment* $[o,v] = \{w \in \Sigma^* : d(o,w) + d(w,v) = d(o,v)\}$ and the *circle* $C_r(o) = \{w \in \Sigma^* : d(o,w) = r\}$. Lemma 10 states that a string u is a possible correction of v *iff* $u \in [o,v] \cap C_r(o)$. The fact that v has several possible corrections shows that the geometry of Σ^* is very different from that of $\mathbb{R}^2$.

4.1.2 THE BORDERLINE STRINGS OF MAXIMUM LENGTH

We begin by distinguishing the longest strings of any ball:

Definition 11 (Upper Border) *The upper border of a ball $B_r(o)$, denoted $B_r^{max}(o)$, is the set of all the strings that belong to $B_r(o)$ and are of maximum length:*

$$B_r^{max}(o) = \{u \in B_r(o) : \forall w \in B_r(o), |w| \leq |u|\}.$$

For instance, given $\Sigma = \{0,1\}$, we get $B_1^{max}(10) = \{010, 100, 101, 110\}$.

The strings of $B_r^{max}(o)$ are remarkable because they are all built from the centre o by doing r insertions. So from a string $w \in B_r^{max}(o)$, one 'simply' has to guess the inserted letters and delete them to find o again. We get:

Proposition 12 *$w \in B_r^{max}(o)$ iff ($o \preceq w$ and $d(o,w) = |w| - |o| = r$).*

Proof Let us assume that $o \preceq w$ and $d(o,w) = |w| - |o| = r$. Then $w \in B_r(o)$. Let w' be a string such that $|w'| > |w|$. Then, by Proposition 2, $d(o,w') \geq |w'| - |o| > |w| - |o| = r$, so $w' \notin B_r(o)$. Therefore, $w \in B_r^{max}(o)$. Conversely, let $w \in B_r^{max}(o)$. Consider an arbitrary letter $a \in \Sigma$ and the string $a^r o$. Basically, $d(o,a^r o) = r$, so $a^r o \in B_r(o)$. As $w \in B_r^{max}(o)$, we deduce that $|w| \geq |a^r o| = |o| + r$. Therefore, by Proposition 2, $d(o,w) \geq |w| - |o| \geq r$. On the other hand, $r \geq d(o,w)$ holds since $w \in B_r^{max}(o)$. So we deduce that $d(o,w) = |w| - |o| = r$, that also brings $o \preceq w$, by Proposition 2. ■

4.1.3 FINDING THE CENTRE GIVEN STRINGS FROM THE UPPER BORDER

Some strings of $B_r^{max}(o)$ are even more informative. Indeed, let $a \in \Sigma$ be an arbitrary letter. Then $a^r o \in B_r^{max}(o)$. So, if we know r, we can easily deduce o. We claim that the correction queries allow us to get hold of $a^r o$ from any string $w \in B_r^{max}(o)$ by swapping the letters. This is the goal of EXTRACT_CENTRE (see Algorithm 1).

Let us run this procedure on an example. Consider the ball $B_2(11)$. Then it is easy to check that $B_2^{max}(11) = \{0011, 0101, 0110, 0111, 1001, 1010, 1011, 1100, 1101, 1110, 1111\}$. Running EXTRACT_CENTRE on the string $w = 0110$ and radius $r = 2$ transforms, at each loop, the i^{th} letter of w to a 0 that is put at the beginning and then submits it to the Oracle. We get:

i	w	w'	CQ(w')	w changes
1	$\underline{0}110$	0110	YES	yes
2	$0\underline{1}10$	0010	0110	no
3	$01\underline{1}0$	0010	0110	no
4	$011\underline{0}$	0011	YES	yes

Therefore, EXTRACT_CENTRE stops with $w = 0011$ and returns $o = 11$ (since $r = 2$).

Algorithm 1 EXTRACT_CENTRE

Require: A string $w = a_1 \dots a_n \in B_r^{max}(o)$, the radius r
Ensure: The centre o of the ball $B_r(o)$

```
x ← a_n        (* x is an arbitrary letter *)
for i = 1 to n do
    Assume w = a_1 ... a_n and let w' = x a_1 ... a_{i-1} a_{i+1} ... a_n
    if CQ(w') = YES then w ← w' end if
end for
Assume w = a_1 ... a_n and return a_{r+1} ... a_n
```

Proposition 13 *Given $w \in B_r^{max}(o)$ and the radius r, Algorithm* EXTRACT_CENTRE *returns o using $O(|o| + r)$ correction queries.*

Proof (Sketch) Let us show that the swapping operation is correct. Consider the string $w = a_1 \dots a_n \in B_r^{max}(o)$ and let $w' = x a_1 \dots a_{i-1} a_{i+1} \dots a_n$ for some $0 \leq i \leq n$. If there exists at least one derivation $o \xrightarrow{r} w$ where the letter a_i of w comes from an insertion in o, then deleting a_i and doing the insertion of a x in front of o yields a string w' that satisfies $o \preceq w'$ and $|w'| = |w|$. By Proposition 2, we get $d(o, w') = |w'| - |o| = |w| - |o| = r$, so by Proposition 12, $w' \in B_r^{max}(o)$ and CQ(w') = YES. On the other hand, if there is no derivation where a_i is introduced by an insertion, then deleting a_i and inserting a x yields a string w' such that $o \not\preceq w'$. By Proposition 2, we get $d(o, w') > |w'| - |o|$. As $|w'| = |w|$, we deduce that $d(o, w') > r$. So $w' \notin B_r^{max}(o)$ and CQ(w') $\neq$ YES. ■

4.1.4 FINDING ONE BORDERLINE STRING OF MAXIMUM LENGTH

Hence, we are now able to deduce the centre of a ball as soon as we know its radius and a string from its upper border. The following technical result is a step towards finding this string (although we have no information about r and $|o|$ yet):

Proposition 14 *Suppose that $\Sigma = \{a_1, \ldots, a_n\}$ and consider the string $v = (a_1 \ \ldots \ a_n)^k$ with $k \geq |o| + r$. Then every correction of v belongs to $B_r^{max}(o)$.*

Proof Let U be the set of all the possible corrections of v. Let us show that $U = B_r^{max}(o)$. As $v = (a_1 \ldots a_n)^k$ with $k \geq |o| + r$, we get $o \preceq v$, so $d(o,v) = |v| - |o|$, by Proposition 2. Let $w \in B_r^{max}(o)$. By Proposition 12, we get $o \preceq w$ and $d(o,w) = |w| - |o| = r$. Moreover, as $v = (a_1 \ldots a_n)^k$ with $k \geq |o| + r$, we get $w \preceq v$. So $d(w,v) = |v| - |w| = |v| - |o| - r = d(o,v) - r$ by Proposition 2. As $d(o,w) = r$ and $d(w,v) = d(o,v) - r$, Lemma 10 yields $B_r^{max}(o) \subseteq U$. Conversely, let $u \in U$. We get $d(o,u) = r$, again by Lemma 10. If $o \preceq u$, then $u \in B_r^{max}(o)$ by Proposition 12. If $o \not\preceq u$, then Proposition 2 yields $d(o,u) > |u| - |o|$, that is to say, $|u| < |o| + r$. But then, $d(u,v) \geq |v| - |u| > |v| - |o| - r = d(w,v)$ for all $w \in B_r^{max}(o)$, so $u \notin U$, that is impossible. Therefore, $U \subseteq B_r^{max}(o)$. ■

If one submits $(a_1 \ldots a_n)^k$ with a sufficiently large k, then one is sure to get a string of $B_r^{max}(o)$. So the last problem is to find such an interesting k. The following lemma states that if one asks to the Oracle the correction of a string made of a lot of 0's, then this correction contains precious informations about the radius and the number of occurrences of 0's in the centre:

Lemma 15 *Consider the ball $B_r(o)$. Let $a \in \Sigma$ be any letter and $j \in \mathbb{N}$ an integer such that $a^j \notin B_r(o)$. Let w denote a correction of a^j. If $|w| < j$, then $|w|_a = |o|_a + r$.*

Proof Let $a^j \notin B_r(o)$ and $w = \mathrm{CQ}(a^j)$. By Lemma 10, we get $d(o,w) = r$ and $d(w,a^j) = d(o,a^j) - r$. As $|w| < |a^j|$, the computation of $d(w,a^j)$ consists in (1) substituting all the letters of w that are not a's, thus doing $|w| - |w|_a$ substitutions, and (2) completing this string with further a's in order to reach a^j, thus doing $j - |w|$ insertions of a's. So we deduce that $d(w,a^j) = |w| - |w|_a + j - |w| = j - |w|_a$. Let us compute $d(o,a^j)$. Clearly, if $|o| \leq |w| < j$, then we can use the same arguments as before and get $d(o,a^j) = j - |o|_a$. Finally, since $d(w,a^j) = d(o,a^j) - r$, we deduce that $j - |w|_a = j - |o|_a - r$, *that is*, $|w|_a = |o|_a + r$.

Now suppose that $|o| > |w|$. Then we cannot use the same arguments as before, because it is possible that $|o| \geq |a^j|$, thus that deletions are needed to compute $d(o,a^j)$. However, this case is impossible. Indeed, consider a derivation $o \xrightarrow{r} w$. Since $|o| > |w|$, there is at least one deletion along this derivation. Now, instead of deleting a letter, suppose that we substitute it by an a and do not change anything else. This leads us to a new derivation $o \xrightarrow{r} w'$ (or $o \xrightarrow{r-1} w'$ if the deleted letter was an a) with $|w'| = |w| + 1$ and $|w'|_a = |w|_a + 1$. Moreover, $d(o,w') \leq r$, thus $w' \in B_r(o)$. Finally, as $|w| < j$, we get $|w'| \leq j$, so with the same arguments as before, only substitutions and insertions are necessary to compute $d(w',a^j)$. More precisely, we have $d(w',a^j) = (|w'| - |w'|_a) + (j - |w'|) = -|w|_a - 1 + j = d(w,a^j) - 1$, thus $d(w',a^j) < d(w,a^j)$. Since $w' \in B_r(o)$, w cannot be a correction of a^j. ■

Finally, let us assume that the alphabet is $\Sigma = \{a_1, \ldots, a_n\}$ and let $j_1, \ldots, j_n \in \mathbb{N}$ be large integers. If we define $k = \sum_{i=1}^n |\mathrm{CQ}(a_i^{j_i})|_{a_i}$, then Lemma 15 brings $k = \sum_{i=1}^n (|o|_{a_i} + r) = |o| + |\Sigma| \cdot r \geq |o| + r$. So we can plug k into Proposition 14 and get a string $w = \mathrm{CQ}\left((a_1 \ldots a_n)^k\right) \in B_r^{max}(o)$. Moreover, we have $|w| = |o| + r$ and $k = |o| + |\Sigma| \cdot r$. So, we deduce that the radius is $r = (k - |w|)/(|\Sigma| - 1)$.

4.2 An Algorithm to Learn Balls from Correction Queries

Let us summarize, by assuming that $\Sigma = \{a_1, \ldots, a_n\}$ and that the target is the ball $B_r(o)$. (1) For each letter a_i, the Learner asks for the correction of a_i^j where j is sufficiently large to get a correction whose length is smaller than j; (2) the Learner sets $k = \sum_{i=1}^{n} |\text{CQ}(a_i^{j_i})|_{a_i}$ and gets the correction w of the string $v = (a_1 \ldots a_n)^k$; (3) from k and $|w|$, he deduces r; (4) he uses EXTRACT_CENTRE on w and r, and he gets o. In other words, he is able to guess the balls with correction queries (see Algorithm IDF_BALL and Proposition 16).

Algorithm 2 IDF_BALL

Require: The alphabet $\Sigma = \{a_1, \ldots, a_n\}$
Ensure: The representation (o, r) of the target ball $B_r(o)$
1: $j \leftarrow 1; k \leftarrow 0$
2: **for** $i = 1$ **to** n **do**
3: **while** $\text{CQ}(a_i^j) = \text{YES}$ **or else** $|\text{CQ}(a_i^j)| \geq j$ **do**
4: $j \leftarrow 2 \cdot j$
5: **end while**
6: $k \leftarrow k + |\text{CQ}(a_i^j)|_{a_i}$
7: **end for**
8: $w \leftarrow \text{CQ}((a_1 a_2 \ldots a_n)^k)$
9: $r \leftarrow (k - |w|)/(|\Sigma| - 1)$
10: $o \leftarrow \text{EXTRACT\_CENTRE}(w, r)$
11: **return** (o, r)

For instance, consider the ball $B_2(11)$ defined over $\Sigma = \{0, 1\}$. IDF_BALL begins by looking for the corrections of 0^j and 1^j with a sufficiently large j. We might observe: $\text{CQ}(0) = \text{YES}$, $\text{CQ}(0^2) = \text{YES}$, $\text{CQ}(0^4) = 0011$, $\text{CQ}(0^8) = 0110$, $\text{CQ}(1^8) = 1111$. So $k = |0110|_0 + |1111|_1 = 2 + 4 = 6$. Then $\text{CQ}\left((01)^6\right) = \text{CQ}(010101010101) = 0110$, for instance, so $r = (6-4)/(2-1) = 2$. Finally, $\text{EXTRACT\_CENTRE}(0110, 2)$ returns 11. So the algorithm returns $(11, 2)$, which is the representation of the target ball.

Proposition 16 *Given any fixed ball $B_r(o)$, the Algorithm* IDF_BALL *returns the representation (o, r) using $O(|\Sigma| + |o| + r)$ correction queries.*

Proof The correction of IDF_BALL is clear. Concerning the number of queries, the corrections of all the strings a_i^j require $O(|\Sigma| + \log(|o| + r))$ correction queries (lines 2-5). Indeed, $O(\log(|o| + r))$ queries are necessary to get long enough corrections, plus one query per letter, thus $|\Sigma|$ queries. Then EXTRACT_CENTRE needs $O(|o| + r)$ correction queries (line 8) to find the centre, by Proposition 13. So the total amount of queries is $O(|\Sigma| + |o| + r)$. ■

4.3 Only the Good Balls are Learnable with IDF_BALL

We now have an algorithm that guesses all the balls $B_r(o)$ with $O(|\Sigma| + |o| + r)$ correction queries. Is this result relevant?

In Section 3, we have decided to represent every ball $B_r(o)$ by the pair (o,r). The size of this representation, $|o|+\log r$, is basically related to the number of bits needed to encode this representation. Notice that $|o|+r$ *is not* a correct measure of the size: this would correspond to an encoding in base 1 of the radius r, which is not considered reasonable (Garey and Johnson, 1979). Therefore, the number of correction queries used by IDF_BALL is exponential in $\log r$. In consequence, if r is too large with respect to $|o|$, (e.g., $r > 2^{|o|}$), then our algorithm is not able to identify efficiently the target ball.

In order to avoid this problem, we introduce the following definition that allows us to rewrite Proposition 16 in a more relevant way:

Definition 17 (Good Balls)

- *Let $q()$ be any fixed polynomial. We say that a ball $B_r(o)$ is* $q()$-good *if $r \leq q(|o|)$.*
- *We say that $B_r(o)$ is* very good *if $r \leq |o|$.*

A very good ball is thus a $q()$-good ball for the polynomial $q(x) = x$.

Then, Proposition 16 yields:

Theorem 18

- *Let $q()$ be any fixed polynomial. The set of all $q()$-good balls $B_r(o)$ is identifiable with an algorithm that uses $O(|\Sigma| + |o| + q(|o|))$ correction queries and a polynomial amount of time.*
- *The set of all very good balls is identifiable with a linear number $O(|\Sigma| + |o|)$ of correction queries and a polynomial amount of time.*

Finally, the reader may wonder if a better learnability result could be established, which would include the huge balls. Unfortunately, there is not a unique answer to this question. On one hand, if the number of correction queries authorized to learn can also depend on the length of the longest correction provided by the Oracle during a run of IDF_BALL, then the answer is positive: all the balls are learnable. On the other hand, in de la Higuera et al. (2008), it has been proved that the set of all the balls was not polynomially identifiable in the limit, nor in most relevant online learning paradigms, whereas positive results were established for the good balls in most paradigms. From this point of view, Theorem 18 is satisfying.

5. Learning in a Realistic Environment

The setting of learning with queries itself occurs in many circumstances: when a human being is asked to provide data for a learning program, an alternative to have the human expert labeling huge quantities of data can be to have the learning system interact with the human expert, who then only labels those items required. Nevertheless, assuming that the Oracle is a human expert introduces new constraints. On one hand, asking billions of queries is unacceptable: there is no chance to get enough answers in reasonable time. So the learning algorithm should aim at minimizing the number of queries even if we must pay for it with a worse time complexity. On the other hand, a human (or even the Web) is fallible. Therefore, the learning algorithm should aim at learning functions or languages that are robust from corrections that may not be ideal, thus approximative.

These issues are discussed in de la Higuera (2006). Some examples of this alternative approach (imperfect Oracle) are: system SQUIRREL, which makes use of queries to a human expert to allow

wrapper induction (Carme et al., 2007); learning test sets (Bréhélin et al., 2001) and testing hardware (Hagerer et al., 2002), where the actual electronic device can be physically tested by entering a sequence, and the device will then be able to answer a membership query (note that in that setting equivalence queries will be usually simulated by sampling). Another typical question occurs when learning some non intelligible function, defined perhaps by a complex kernel (Clark et al., 2006) or neural networks (Giles et al., 2001): a representation of these complex functions in another setting can be obtained if we use the complex function as an Oracle to learn from.

5.1 Faced with a Fallible Oracle

The algorithm IDF_BALL has been designed in an ideal setting, where we have assumed that the Oracle was a perfect machine: her answers were so precise that we could scrupulously characterize them (see Lemma 10). However, as described in the introduction, in practice, an Oracle is often an expert, thus a human being, or is simulated through sampling. In such settings, our assumption is no longer correct. Indeed, computing the correction of $(101)^{127}$ *w.r.t.* the ball $B_{217}((1011)^{32})$ is probably out of the cognitive capacities of any human being. So our algorithm should not believe unwisely the answers he gets since they can be approximate. In this section, we would like to show, with a series of experiments, that our algorithm withstands such approximate (that is to say, inaccurate, noisy) answers.

5.1.1 DESIGNING THE APPROXIMATE ORACLE

We want here to design an approximate Oracle that might look like a human being. So let us consider a string w and a ball $B_r(o)$. Let $\mathrm{CQ}_h(w)$ denote the answer of the approximate Oracle, and $\mathrm{CQ}(w)$ the answer that would be returned by a perfect Oracle (as before).

Firstly, we assume that an expert can easily determine whether an example fulfills a concept or not, thus here, whether w belongs to $B_r(o)$ or not. So we assume that if $\mathrm{CQ}(w) = \mathrm{YES}$, then $\mathrm{CQ}_h(w) = \mathrm{YES}$. Secondly, what is really hard for the expert is to *compute* the best correction of w when $w \notin B_r(o)$, and more precisely, a string of the ball that is *as close to w as possible*. Again, $\mathrm{CQ}_h(w)$ will probably be inside the ball rather than on its frontier.

Staying a step ahead, let $X = d(w, \mathrm{CQ}_h(w)) - d(w, \mathrm{CQ}(w))$ measure the distance between an approximate correction and a perfect one. Intuitively, an approximate but strong Oracle will often provide corrections such that $X = 0$, sometimes $X = 1$ and rarely $X \geq 2 \ldots$ To formalize this idea, we introduce a confidence parameter $0 < p \leq 1$, called the *accuracy level of the Oracle*, that translates the quality of her answers, and use a geometric distribution: $Pr(X = k) = (1-p)^k p$, for all $k \in \mathbb{N}$.

Therefore, with probability $(1-p)^k p$, the correction $\mathrm{CQ}_h(w)$ of a string w will be in the target ball, at distance k of $\mathrm{CQ}(w)$. Basically, we get $E(X) = (1/p) - 1$. So when the Oracle is very accurate, say $p = 0.8$, then the average distance between an approximate and a perfect correction is low (0.25). Conversely, an expert with limited computation capacities, say $p = 0.4$, will often provide inaccurate corrections, at distance 1.5 on average.

Our model of approximate Oracle is simple. For instance, we do not suppose that she has any memory, thus by submitting twice every string w, we would probably get 2 different corrections that could be used to correct the corrections! We want here to study the resistance of IDF_BALL to approximate answers, not to design the best possible algorithm, able to beat the approximate Oracle. So from this standpoint, our basic model is sufficient.

5.1.2 BEHAVIOR OF THE ALGORITHM FACED WITH AN APPROXIMATE ORACLE

Following Theorem 18, IDF_BALL systematically guesses the target ball with the help of a perfect Oracle. But of course, he is sometimes going to fail in front of an approximate Oracle. So, in order to assess the resistance of IDF_BALL to approximate corrections, we conduct the following experiment. We randomly choose a set of 100 balls $B_r(o)$ such that $|o| + r = 200$. More precisely, we make the radius r vary between 10 and 190 by step of 20, and randomly choose 10 centres o of length $200 - r$ for each radius. Then, for every accuracy level $0.5 \leq p \leq 1$, we ask IDF_BALL to learn all of them and we compute the percentage of balls he is able to retrieve, that we call the *precision of the algorithm*. We show the result in Figure 4. We notice that IDF_BALL is able to identify about 75% of the balls faced with an accuracy level of $p = 0.9$. Of course, as one can expect, with lower levels of accuracy, his performances quickly drop (15% for $p = 0.5$).

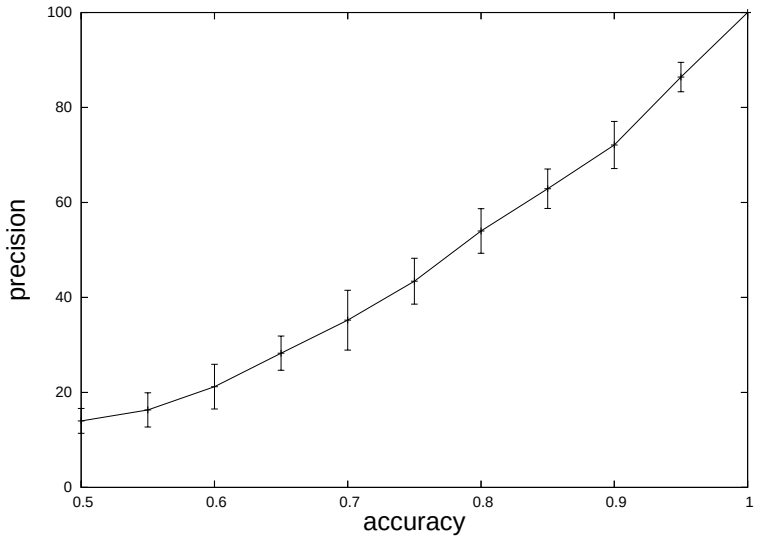

Figure 4: Precision of IDF_BALL faced with an approximate Oracle in function of the accuracy level p. Each point is assessed on 100 balls.

We also show, in Figure 5, the average distances between the centres of the target balls and the centres of the the learnt balls when he fails to retrieve them. We observe that these distances are not that important: even with an accuracy level of $p = 0.5$, the difference is less than 3. The last curve in Figure 6 is the difference between the radii, that basically follow the same trend.

5.1.3 IMPROVING THE PRECISION WITH *a posteriori* HEURISTICS

We have seen that IDF_BALL was able to assimilate the approximations of the Oracle up to a certain level of accuracy. Moreover, the centres and the radii returned by the algorithm are generally not far from the target. Therefore, it is reasonable to think that we could improve the precision by exploring the neighborhood of the learnt centre, using local edit modifications. This kind of approaches has been pioneered by Kohonen (1985) and is surveyed in Martínez-Hinarejos et al. (2000).

Suppose that the learnt ball is $B_k(u)$ and let Q be the set of all the corrections returned by the Oracle during the process of IDF_BALL. The heuristics is composed of two steps:

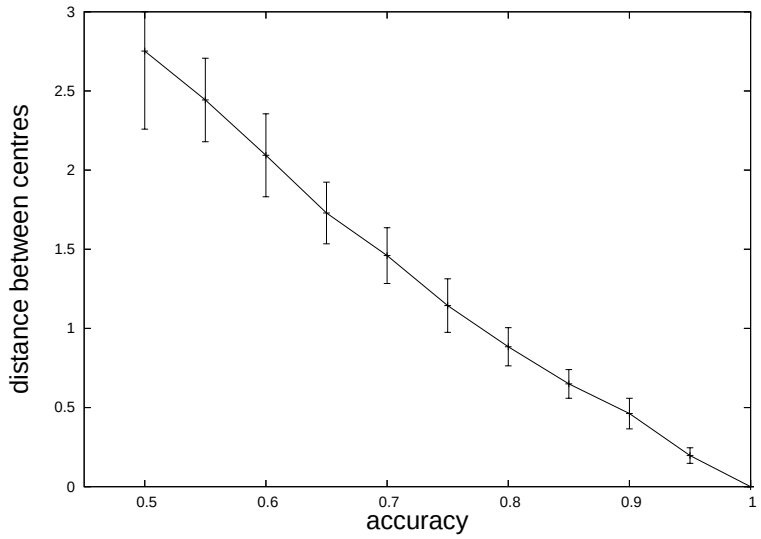

Figure 5: Average distances (and standard deviation) between the centres of the target balls and the centres of the learnt balls, when IDF_BALL fails in retrieving them.

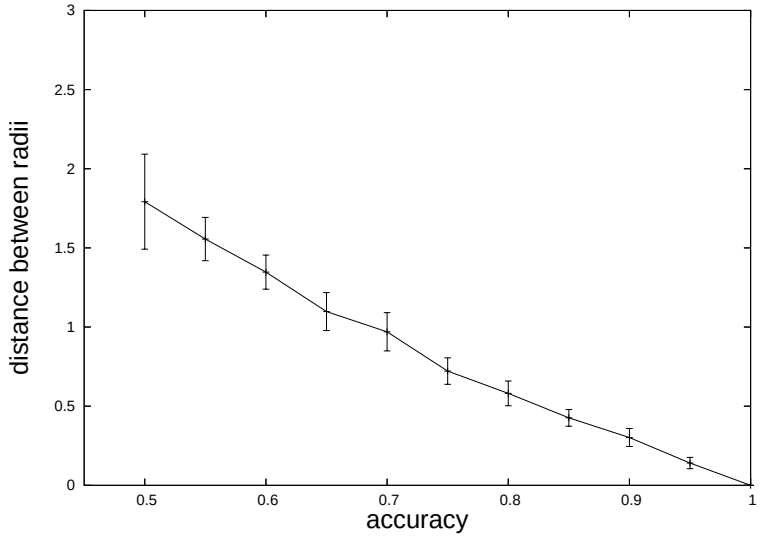

Figure 6: Average difference (and standard deviation) between the radii of the target balls and the radii of the learnt balls, when IDF_BALL fails in retrieving them.

1. We test each neighbor u' (at distance 1) of the learnt centre u and examine if it is a better centre with respect to Q, that is to say, if there exists $k' \in \mathbb{N}$ such that $k' < k$ and $Q \subseteq B_{k'}(u')$. Then we keep the representations (u', k') of the smallest balls that contain all the corrections seen so far.

2. From this set, we select all the pairs (u', k') that maximize the number of corrections (of Q) at distance k', in such a way as to get the maximum number of corrections on the border of the new ball. Then we randomly choose and return one of them.

This heuristics will be very good each time u is at distance 1 from the target centre. But as soon as this distance grows, IDF_BALL will fail again. In order to enhance the one-step heuristics, we iterate the process and design a second until-convergence heuristics by repeating the local search described above, until the size of the ball cannot decrease anymore.

In order to show that the balls learnt by IDF_BALL can be corrected *a posteriori*, we compare, in a series of experiments, the precision of the algorithm without any post-treatment, with the one-step heuristics and with the until-convergence heuristics. We fix $|o| + r = 200$ and make the radius vary from 10 to 190. For each radius, we randomly draw 50 centres of length $200 - r$. Then, we make the accuracy level vary from 0.5 to 1. For each pair (accuracy, radius), we ask IDF_BALL to retrieve the 50 balls and note the precision. In order to be able to reduce the variance due to the approximations of the Oracle, we repeat the experiment 10 times using the same set of balls and finally plot the average precisions in Figure 7.

We can remark that whatever the accuracy level, using the until-convergence heuristics is never worse than the one-step heuristics, which is never worse than no post-treatment at all. However, our heuristics do not always improve the precision of the algorithm: this depends on the ratio between the radius of the target ball and the length of its centre. In order to detail this, we have extracted two transverse sections, shown in Figures 8 and 9, where we fix the radii.

Figure 8 describes the precision of IDF_BALL for target balls such that $r = 170$ and $|o| = 30$. In this case, we gain little using the heuristics. This is probably due to the fact that the size of the set Q, which is used to control the heuristics, is incomparably smaller than the volume of such balls. In other words, the heuristics are not sufficiently guided by Q towards the targets, because Q is not informative enough.

On the other hand, Figure 9 describes the precision for target balls such that $r = 10$ and $|o| = 190$. Basically, our heuristics outperform the precision with respect to the algorithm without any post-treatment, whatever the accuracy level of the Oracle. Moreover, the benefit is all the more important as the accuracy level is bad. For instance, when $p = 0.6$, the until-convergence heuristics is able to dramatically boost the precision from 12% to 86%.

So in this setting, with no further enhancement, IDF_BALL produces balls that are so close to the targets that they can easily be improved using only basic local modifications.

5.2 Using Less Correction Queries

We have seen that the good balls were identifiable with $O(|\Sigma| + |o| + r)$ correction queries. However, as discussed in the introduction, such a number of queries is excessive if the Oracle is a human being. Moreover, if the reader thinks of what happens in the plane (see Figure 2), then very few queries are needed to identify the disks. Hence, our result might seem to be a bit disappointing.

If one takes a closer look at IDF_BALL, one can notice that the first part of the identification, that is to say, the search for a string of $B_r^{max}(o)$, is done with $O(|\Sigma| + \log(|o| + r))$ correction queries

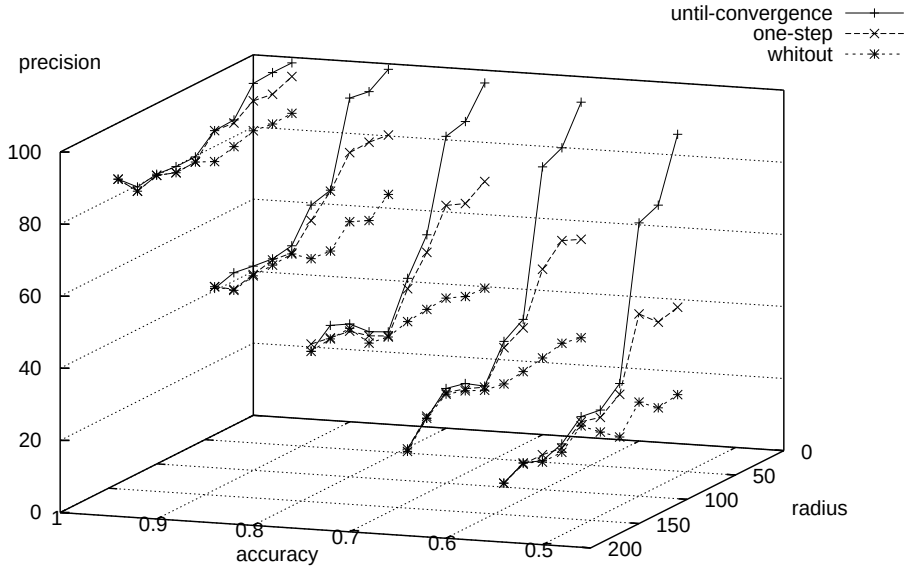

Figure 7: Precision of IDF_BALL with and without heuristics in function of accuracy and radius when $|o| + r = 200$. For each pair (accuracy, radius), we compute the average over 50 balls.

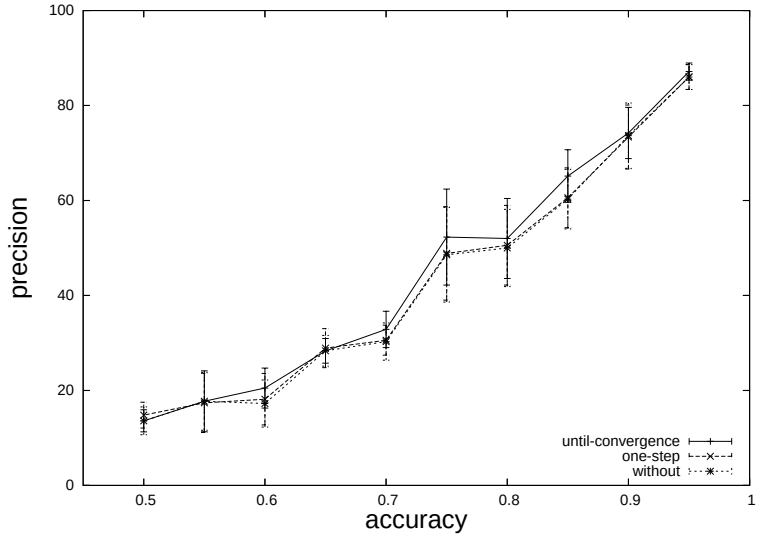

Figure 8: Precision of IDF_BALL when $|o| + r = 200$ for $r = 170$. For each accuracy, we compute the average over 50 balls. We run the experiment 10 times in order to reduce the variance.

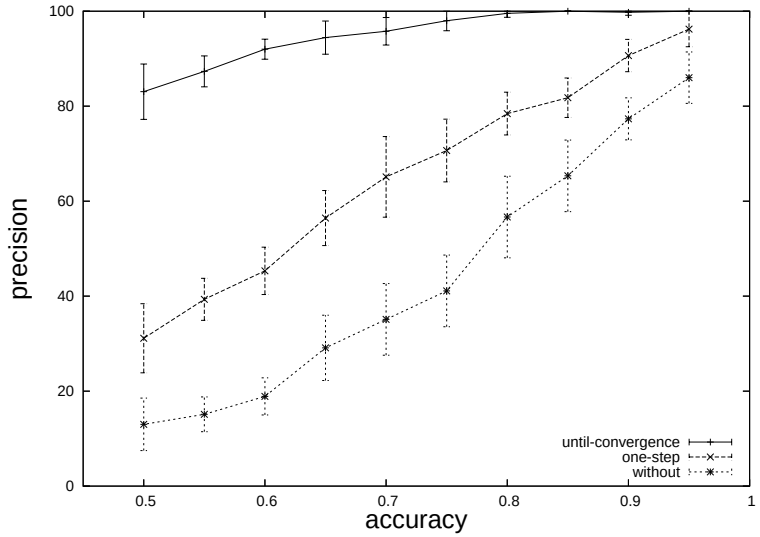

Figure 9: Precision of IDF_BALL when $|o| + r = 200$ for $r = 10$. For each accuracy, we compute the average over 50 balls. We run the experiment 10 times in order to reduce the variance.

(thus, a logarithmic number). What is really expensive is to find the centre of the ball using the function EXTRACT_CENTRE. We are going to show below that this function can be eliminated from the learning stage, and thus, that the complexity can be dramatically reduced, but in a slightly different setting.

For reasons that we shall develop later, we now suppose that the alphabet has at least three letters: $\Sigma = \{a_1, \ldots, a_n\}$ with $n \geq 3$.

5.2.1 THE USE OF A WEIGHTED EDIT DISTANCE

Up to now, we have considered the standard edit distance defined by Levenshtein (1965). However, for practical reasons, people often use variants of this definition where the edit operations are weighted. In this case, every derivation $w \xrightarrow{k} w'$ has a weight which is the sum of the weights of the edit operations along the derivation. Then the *weighted edit distance* $d(w, w')$ is the minimum weight of every derivation transforming w into w'. Clearly, if the weight of all the edit operations is 1, then we get the standard edit distance.

The different combinations of weights will impose alternative algorithms when using correction queries. As we aim at showing that the number of correction queries can be dramatically reduced, we assume that:

1. the weight of every insertion and every deletion is 1 (as before),

2. the weight of every substitution is an irrational number ρ such that $0 < \rho < 1$.

For instance, the weight of the substitution could be $\rho = \frac{\pi}{4} \simeq 0.7854$.

It is worth noting that the low cost of a substitution operation is usual from a linguistic point of view. For instance, works on Phonology make this assumption in order to enforce the alignment of phonetically similar segments (Albright and Hayes, 2003).

Nevertheless, the fact that ρ is not rational may be confusing for the reader. Actually, from the Learner standpoint, we will see that he never needs to compute the weighted edit distance (that is probably not the case of the Oracle). So the fact that ρ is not a fraction will not be a problem.

We can show that this set of weights induces an edit distance that can be computed using dynamic programming.[3] Moreover, Proposition 2, stating that (1) $d(w,w') \geq \big||w|-|w'|\big|$ and (2) $d(w,w') = \big||w|-|w'|\big|$ *iff* ($w \preceq w'$ or $w' \preceq w$), still holds, because the weight of the insertions and deletions is 1. Finally, the fact that ρ is irrational allows us to establish strong properties:

Proposition 19 *Let $o,w,w' \in \Sigma^*$ be three strings. The following statements are equivalent:*

1. *There exists a derivation of minimum weight from w to w' that uses $x \in \mathbb{N}$ insertions and deletions, and $y \in \mathbb{N}$ substitutions;*
2. *$d(w,w') = x + \rho y$;*
3. *All the derivations of minimum weight from w to w' use $x \in \mathbb{N}$ insertions and deletions, and $y \in \mathbb{N}$ substitutions.*

In consequence, if $d(o,w) = d(o,w')$, then all the derivations from o to w and from o to w' use the same number of insertions and deletions, and the same number of substitutions.

Proof

- 3. $\Longrightarrow$ 1.: straightforward.
- 1. $\Longrightarrow$ 2.: since the weight of the insertions and deletions is 1, and the weight of the substitutions is ρ, and the derivation has a minimum weight, we get $d(w,w') = x + \rho y$.
- 2. $\Longrightarrow$ 3.: consider another derivation from w to w' of minimum weight that uses $x' \in \mathbb{N}$ insertions and deletions, and $y' \in \mathbb{N}$ substitutions. Then we get $d(w,w') = x' + \rho y' = x + \rho y$, so $x - x' = \rho(y' - y)$. As ρ is irrational and x, x', y, y' are integers, we deduce that $y' - y = 0$ and $x - x' = 0$, thus $x' = x$ and $y' = y$.

■

Of course, this result would not hold if ρ was a rational number, for instance $\rho = \frac{1}{2}$, because two substitutions would have the same weight as one insertion, which might induce two very different derivations of minimum weight between two strings.

5.2.2 THE NEW GOOD BALLS AND CORRECTIONS

Basically, changing the edit distance also changes the balls. For instance, using the standard edit distance, we get $B_1(011) = \{01, 11, 001, 010, 011, 111, 0011, 0101, 0110, 1011, 0111\}$. But the use of the weighted edit distance with $\rho = \frac{\sqrt{2}}{4} \simeq 0.3536$ adds $\{000, 101, 110\}$ as new strings.

3. Indeed, its restriction to $\Sigma \cup \{\lambda\}$ is a distance, so following Crochemore et al. (2007), the standard dynamic programming algorithm of Wagner and Fisher (1974) can be used to compute the weighted edit distance over Σ^*.

The reader may also wonder whether the radius of the balls should still be an integer or not. Actually, we shall not consider balls whose radius is not an integer, because otherwise, the balls $B_r(o)$ and $B_{r+\frac{\rho}{2}}(o)$ might represent the same set. In other words, Theorem 5, that states the uniqueness of the representation, would not hold anymore. Conversely, if we only consider balls with an integer radius, then the reader can check that Theorem 5 still holds (because Proposition 2 still holds).

Concerning the corrections, their properties become more intricate due to the weights. In particular, Lemma 10 was stating that the set of possible corrections of any string $v \notin B_r(o)$ was exactly $\{u \in \Sigma^* : d(o,u) = r \text{ and } d(u,v) = d(o,v) - r\}$. This result does not hold anymore. Indeed, consider the ball $B_1(011)$ when $\rho = \frac{\sqrt{2}}{4}$. Then any correction u of the string 100 is in $\{000, 101, 110\}$. Basically, $d(011,u) = 2\rho < 1$ and $d(u,100) = \rho > d(011,100) - 1 = 3\rho - 1$. In other words, a correction is not necessarily on the circle that delimits the ball.

Nevertheless, we get a more sophisticated result that characterizes the set of all the possible corrections:

Lemma 20 *Let $B_r(o)$ be a ball and $v \notin B_r(o)$. Given any $\alpha \in \mathbb{R}$, we define*

$$C_\alpha = \{u \in \Sigma^* : d(o,u) = \alpha \text{ and } d(u,v) = d(o,v) - \alpha\}.$$

All the nonempty C_α define concentric arcs of circles of strings around the centre o. Let α_0 be the radius of biggest one inside the ball of strings:

$$\alpha_0 = \max_{0 \leq \alpha \leq r} \{\alpha : C_\alpha \neq \emptyset\}.$$

Then the set of possible corrections of v is exactly C_{α_0}.

Proof The proof is the same as that of Lemma 10, except that W is replaced by C_{α_0} and r is replaced by α_0. The key point is that W could be empty with the weighted edit distance whereas C_{α_0} cannot, by definition. ■

5.2.3 THE BORDERLINE STRINGS OF MAXIMUM LENGTH

Let us tackle the problem of learning the balls. As in Section 4, we study the longest strings of $B_r(o)$ since they are very informative. Indeed, we are going to show as in Lemma 15, that if one asks for the correction w of a string made of a lot of 0's, then $|w|_0 = |o|_0 + r$. In addition, in our setting, we also get $w \in B_r^{max}(o)$ directly. Nevertheless, we must pay for it by assuming that we know the polynomial $q()$ for which $B_r(o)$ is a good ball.

Lemma 21 *Let $q()$ be a fixed polynomial with coefficients in $\mathbb{N}$. Consider the $q()$-good ball $B_r(o)$, a letter $a \in \Sigma$ and an integer $j \in \mathbb{N}$ such that $a^j \notin B_r(o)$. Let $u = \mathrm{CQ}(a^j)$ and $v = \mathrm{CQ}(a^{j+q(j)})$. If $|u| < j$, then $v \in B_r^{max}(o)$ and $|v|_a = |o|_a + r$.*

This subsection aims at proving this lemma, using two intermediate results:

Proposition 22 *Consider the ball $B_r(o)$, a letter $a \in \Sigma$ and an integer $j \in \mathbb{N}$ such that $a^j \notin B_r(o)$. Let $u = \mathrm{CQ}(a^j)$. If $|u| < j$, then $|o| < j$.*

Proof Let us show that $|o| \leq |u|$; as $|u| < j$, we shall get the result. Hence, suppose that $|u| < |o|$ and consider a rewriting derivation $o \xrightarrow{k} u$ of minimum weight $d(o,u) = x + \rho y$. Since $|o| > |u|$, there is at least one deletion along this derivation. Suppose that, instead of deleting a letter, we substitute it by an a and do not change anything else. This leads us to a new derivation $o \xrightarrow{k} u'$ (or $o \xrightarrow{k-1} u'$ if the deleted letter was an a) with $|u'| = |u| + 1$ and $|u'|_a = |u|_a + 1$. Moreover, $d(o,u') \leq (x-1) + \rho(y+1) = d(o,u) - 1 + \rho$. Since $d(o,u) \leq r$, we deduce that $d(o,u') < r$, thus $u' \in B_r(o)$. Finally, as $|u| < j$, we get $|u'| \leq j$, so only substitutions and insertions are necessary to compute both $d(u,a^j)$ and $d(u',a^j)$. More precisely, we have $d(u',a^j) = (j - |u'|) + \rho(|u'| - |u'|_a) = (j - |u| - 1) + \rho(|u| - |u|_a) = d(u,a^j) - 1$, thus $d(u',a^j) < d(u,a^j)$. As $u' \in B_r(o)$, u cannot be a correction of a^j, which is a contradiction. So $|u| \geq |o|$, thus $|o| < j$. ■

Proposition 23 *Consider the ball $B_r(o)$, a letter $a \in \Sigma$ and an integer $\ell \in \mathbb{N}$ such that $a^\ell \notin B_r(o)$. Let $v = \mathrm{CQ}(a^\ell)$. If $|o| + r < \ell$, then $v \in B_r^{max}(o)$ and $|v|_a = |o|_a + r$.*

Proof As $|o| + r < \ell$, we have $|o| < \ell$, so the computation of $d(o,a^\ell)$ necessarily uses $\ell - |o|$ insertions of a's and $|o| - |o|_a$ substitutions by a's. Let us define a reference derivation from o to a^ℓ, where the $\ell - |o|$ insertions are performed first at the beginning of o, and then the $|o| - |o|_a$ substitutions by a's in o: $o \xrightarrow{\ell-|o|} a^{\ell-|o|}o \xrightarrow{|o|-|o|_a} a^{\ell-|o|}a^{|o|} = a^\ell$. As $\ell - |o| > r$, the string $a^{\ell-|o|}o$ is not in the ball, so this derivation passes through the string $a^r o$ before reaching $a^{\ell-|o|}o$. In other words, the reference derivation looks as follows: $o \xrightarrow{r} a^r o \xrightarrow{\ell-|o|-r} a^{\ell-|o|}o \xrightarrow{|o|-|o|_a} a^\ell$. Now consider Lemma 20. Basically, $d(o,a^r o) = r$ and $d(a^r o,a^\ell) = \ell - |o| - r + \rho(|o| - |o|_a) = d(o,a^\ell) - r$, so $C_r \neq \emptyset$. Therefore, as $v = \mathrm{CQ}(a^\ell)$, we deduce that $d(o,v) = r$ and $d(v,a^\ell) = d(o,a^\ell) - r$. We claim that only insertions of a's can occur along the derivation $o \xrightarrow{r} v$. Indeed, we have $d(o,v) = r \in \mathbb{N}$, so by Proposition 19, no substitution occurs. Moreover, no deletion occurs since any minimal derivation from o to a^ℓ only uses insertions of a's and substitutions by a's. In consequence, $v \in B_r^{max}(o)$ and $|v|_a = |o|_a + r$. ■

Proof [of Lemma 21] By Proposition 22, we get $|o| < j$. Then we have $|o| + r \leq |o| + q(|o|)$. Moreover, as $|o| < j$ and all the coefficients of $q()$ are in $\mathbb{N}$, we deduce that $|o| + r < j + q(j)$. So plugging $\ell = j + q(j)$ in Proposition 23 yields the result. ■

5.2.4 LEARNING THE BALLS LOGARITHMICALLY

As a consequence of Lemma 21, the correction of a long string of 0's leads to a string of $B_r^{max}(o)$. But we get more properties, if the alphabet has at least three letters, say $0,1,2\ldots$ Indeed, let $u_0 = \mathrm{CQ}(0^j)$ with $|u_0| < j$, and $v_0 = \mathrm{CQ}(0^{j+q(j)})$. Thanks to Lemma 21, v_0 is obtained from o with r insertions of 0's. So all the letters in v_0, but the occurrences of 0, are those of o and appear in the correct order.

More formally, let E_a be the function that erases every occurrence of any letter $a \in \Sigma$ in a string:

1. $E_a(\lambda) = \lambda$,
2. $E_a(a.z) = E_a(z)$, and

3. $E_a(b.z) = b.E_a(z)$, for all $b \neq a$.

Then, for every $a \in \Sigma$, $E_a(v_a) = E_a(o)$.

For instance, consider the ball $B_1(o)$ with $o = 10302$. If the corrections of the strings 0^ℓ, 1^ℓ and 2^ℓ (with ℓ big enough) are $v_0 = 103020$, $v_1 = 101302$ and $v_2 = 103202$ respectively, then $E_0(v_0) = E_0(o) = 132$, $E_1(v_1) = E_1(o) = 0302$ and $E_2(v_2) = E_2(o) = 1030$.

Furthermore, we can easily deduce o by *aligning* the strings $E_0(o)$ and $E_1(o)$ and $E_2(o)$:

$E_0(o)$	1	·	3	·	2
$E_1(o)$	·	0	3	0	2
$E_2(o)$	1	0	3	0	·
o	1	0	3	0	2

This procedure does not use any new correction query and runs in time $O(|o|)$ which is clearly more efficient than EXTRACT_CENTRE. Notice that if $|\Sigma| > 3$, we only need three corrections to align and deduce the center. So we finally obtain Algorithm 3 and Theorem 24.

Algorithm 3 IDF_WEIGHTED_BALLS

Require: The alphabet $\Sigma = \{a_1, \ldots, a_n\}$ with $n \geq 3$, and the polynomial $q()$
Ensure: The representation (o, r) of the target $q()$-good ball $B_r(o)$

$j \leftarrow 1$
for $i = 1$ to 3 **do**
  while $\text{CQ}(a_i^j) = \text{YES}$ **or else** $|\text{CQ}(a_i^j)| \geq j$ **do**
    $j \leftarrow 2 \cdot j$
  end while
  $v_i \leftarrow \text{CQ}\left(a_i^{j+q(j)}\right)$
  $e_i \leftarrow E_{a_i}(v_i)$
end for
$o \leftarrow \text{ALIGN}(e_1, e_2, e_3)$
$r \leftarrow |v_1| - |o|$
return (o, r)

Theorem 24 *Assume* $|\Sigma| \geq 3$.

- *Let $q()$ be any fixed polynomial with coefficients in* $\mathbb{N}$. *The set of all $q()$-good balls $B_r(o)$ is identifiable with an algorithm that uses $O(\log(|o| + q(|o|)))$ correction queries and a polynomial amount of time.*
- *The set of all very good balls is identifiable with a logarithmic number $O(\log |o|)$ of correction queries and a polynomial amount of time.*

Therefore, assuming that the weight of the substitutions is an irrational < 1 allows us to reduce dramatically the complexity of the learning stage. Of course, this gain is not possible with all weighted distances, which leaves room for further research. Moreover, if the Learner does not know the polynomial $q()$, we believe that learning is still possible.

6. Discussion and Conclusion

In this work, we have used correction queries to learn a particular class of languages from an Oracle. The intended setting is that of an inexact Oracle, and experiments show that the proposed algorithm can learn a language sufficiently close to the target for simple local modifications (with no extra queries). In order to do this, the languages we consider are good balls of strings defined with the edit distance. Studying them allowed us to catch a glimpse of the geometry of sets of strings, which is very different from the Euclidean geometry. A number of questions and research directions are left open by this work.

A first question concerns the distance we use. We have chosen to work with the unitary edit distance, but in many applications, the edit operations can have different weights. Preliminary work has allowed us to notice that the geometry of sets of strings, thus the algorithmics, could change considerably depending on the sorts of weights we used: with the substitutions costing less than the other two operations, a much faster algorithm exists, requiring only $O(\log(|o|+r))$ correction queries. Alternative conditions over the weights require new interesting learning algorithms.

A second question concerns the inaccuracy model we are using: as noticed in Section 5.1, with the current model it would be possible to repeat the same query various times, getting different corrections, but possibly being able, through some majority vote scheme, to get the adequate correction with very little extra cost. Just asking for *persistent* corrections is not enough to solve this problem: a good model should require that if one queries from a close enough string (a^{999} instead of a^{1000}) then the corrections should also remain close. Topologically, we would expect the Oracle to be k-Lipschitz continuous (with $0 < k < 1$).

A third more challenging problem then arises: our choice here was to learn supposing the Oracle was exact, and correcting later. But a more direct approach might be better, by taking into account the inexactitude of the Oracle when interpreting the correction.

Acknowledgments

The authors wish to thank Jose Oncina for his help in proving Theorem 5, Rémi Eyraud for fruitful discussions about this paper, Dana Angluin for constructive comments and Baptiste Gorin for his helpful pointers towards the Mohr-Mascheroni constructions. We would also like to thank the anonymous referees that have carefully read this manuscript and allowed us to improve the results based on the weighted edit distance. Their remarks led us to formulate Conjecture 4 that was discussed with Ron Greensberg, Borivoj Melichar, Klaus Schultz and Stoyan Mihov. This work was supported in part by the IST Programme of the European Community, under the PASCAL Network of Excellence, IST-2006-216886, and by a Marie Curie International Fellowship within the 6th European Community Framework Programme. This publication only reflects the authors' views.

Abstract

LIBLINEAR is an open source library for large-scale linear classification. It supports logistic regression and linear support vector machines. We provide easy-to-use command-line tools and library calls for users and developers. Comprehensive documents are available for both beginners and advanced users. Experiments demonstrate that LIBLINEAR is very efficient on large sparse data sets.

Keywords: large-scale linear classification, logistic regression, support vector machines, open source, machine learning

1. Introduction

Solving large-scale classification problems is crucial in many applications such as text classification. Linear classification has become one of the most promising learning techniques for large sparse data with a huge number of instances and features. We develop LIBLINEAR as an easy-to-use tool to deal with such data. It supports L2-regularized logistic regression (LR), L2-loss and L1-loss linear support vector machines (SVMs) (Boser et al., 1992). It inherits many features of the popular SVM library LIBSVM (Chang and Lin, 2001) such as simple usage, rich documentation, and open source license (the BSD license[1]). LIBLINEAR is very efficient for training large-scale problems. For example, it takes only several *seconds* to train a text classification problem from the Reuters Corpus Volume 1 (rcv1) that has more than 600,000 examples. For the same task, a general SVM solver such as LIBSVM would take several hours. Moreover, LIBLINEAR is competitive with or even faster than state of the art linear classifiers such as Pegasos (Shalev-Shwartz et al., 2007) and SVM$^{\text{perf}}$ (Joachims, 2006). The software is available at `http://www.csie.ntu.edu.tw/~cjlin/liblinear`.

This article is organized as follows. In Sections 2 and 3, we discuss the design and implementation of LIBLINEAR. We show the performance comparisons in Section 4. Closing remarks are in Section 5.

1. The New BSD license approved by the Open Source Initiative.

2. Large Linear Classification (Binary and Multi-class)

LIBLINEAR supports two popular binary linear classifiers: LR and linear SVM. Given a set of instance-label pairs $(\mathbf{x}_i, y_i), i = 1, \ldots, l,\ \mathbf{x}_i \in R^n,\ y_i \in \{-1, +1\}$, both methods solve the following unconstrained optimization problem with different loss functions $\xi(\mathbf{w}; \mathbf{x}_i, y_i)$:

$$\min_{\mathbf{w}} \quad \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum_{i=1}^{l}\xi(\mathbf{w}; \mathbf{x}_i, y_i), \tag{1}$$

where $C > 0$ is a penalty parameter. For SVM, the two common loss functions are $\max(1 - y_i\mathbf{w}^T\mathbf{x}_i, 0)$ and $\max(1 - y_i\mathbf{w}^T\mathbf{x}_i, 0)^2$. The former is referred to as L1-SVM, while the latter is L2-SVM. For LR, the loss function is $\log(1 + e^{-y_i\mathbf{w}^T\mathbf{x}_i})$, which is derived from a probabilistic model. In some cases, the discriminant function of the classifier includes a bias term, b. LIBLINEAR handles this term by augmenting the vector $\mathbf{w}$ and each instance $\mathbf{x}_i$ with an additional dimension: $\mathbf{w}^T \leftarrow [\mathbf{w}^T, b], \mathbf{x}_i^T \leftarrow [\mathbf{x}_i^T, B]$, where B is a constant specified by the user. The approach for L1-SVM and L2-SVM is a coordinate descent method (Hsieh et al., 2008). For LR and also L2-SVM, LIBLINEAR implements a trust region Newton method (Lin et al., 2008). The Appendix of our SVM guide.[2] discusses when to use which method. In the testing phase, we predict a data point $\mathbf{x}$ as positive if $\mathbf{w}^T\mathbf{x} > 0$, and negative otherwise. For multi-class problems, we implement the one-vs-the-rest strategy and a method by Crammer and Singer. Details are in Keerthi et al. (2008).

3. The Software Package

The LIBLINEAR package includes a library and command-line tools for the learning task. The design is highly inspired by the LIBSVM package. They share similar usage as well as application program interfaces (APIs), so users/developers can easily use both packages. However, their models after training are quite different (in particular, LIBLINEAR stores $\mathbf{w}$ in the model, but LIBSVM does not.). Because of such differences, we decide not to combine these two packages together. In this section, we show various aspects of LIBLINEAR.

3.1 Practical Usage

To illustrate the training and testing procedure, we take the data set news20,[3] which has more than one million features. We use the default classifier L2-SVM.

```
$ train news20.binary.tr
[output skipped]
$ predict news20.binary.t news20.binary.tr.model prediction
Accuracy = 96.575% (3863/4000)
```

The whole procedure (training and testing) takes less than 15 seconds on a modern computer. The training time without including disk I/O is less than one second. Beyond this simple way of running LIBLINEAR, several parameters are available for advanced use. For example, one may specify a parameter to obtain probability outputs for logistic regression. Details can be found in the README file.

2. The guide can be found at http://www.csie.ntu.edu.tw/~cjlin/papers/guide/guide.pdf.
3. This is the news20.binary set from http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets. We use a 80/20 split for training and testing.

3.2 Documentation

The LIBLINEAR package comes with plenty of documentation. The `README` file describes the installation process, command-line usage, and the library calls. Users can read the "Quick Start" section, and begin within a few minutes. For developers who use LIBLINEAR in their software, the API document is in the "Library Usage" section. All the interface functions and related data structures are explained in detail. Programs `train.c` and `predict.c` are good examples of using LIBLINEAR APIs. If the `README` file does not give the information users want, they can check the online FAQ page.[4] In addition to software documentation, theoretical properties of the algorithms and comparisons to other methods are in Lin et al. (2008) and Hsieh et al. (2008). The authors are also willing to answer any further questions.

3.3 Design

The main design principle is to keep the whole package as simple as possible while making the source codes easy to read and maintain. Files in LIBLINEAR can be separated into source files, pre-built binaries, documentation, and language bindings. All source codes follow the C/C++ standard, and there is no dependency on external libraries. Therefore, LIBLINEAR can run on almost every platform. We provide a simple `Makefile` to compile the package from source codes. For Windows users, we include pre-built binaries.

Library calls are implemented in the file `linear.cpp`. The `train()` function trains a classifier on the given data and the `predict()` function predicts a given instance. To handle multi-class problems via the one-vs-the-rest strategy, `train()` conducts several binary classifications, each of which is by calling the `train_one()` function. `train_one()` then invokes the solver of users' choice. Implementations follow the algorithm descriptions in Lin et al. (2008) and Hsieh et al. (2008). As LIBLINEAR is written in a modular way, a new solver can be easily plugged in. This makes LIBLINEAR not only a machine learning tool but also an experimental platform.

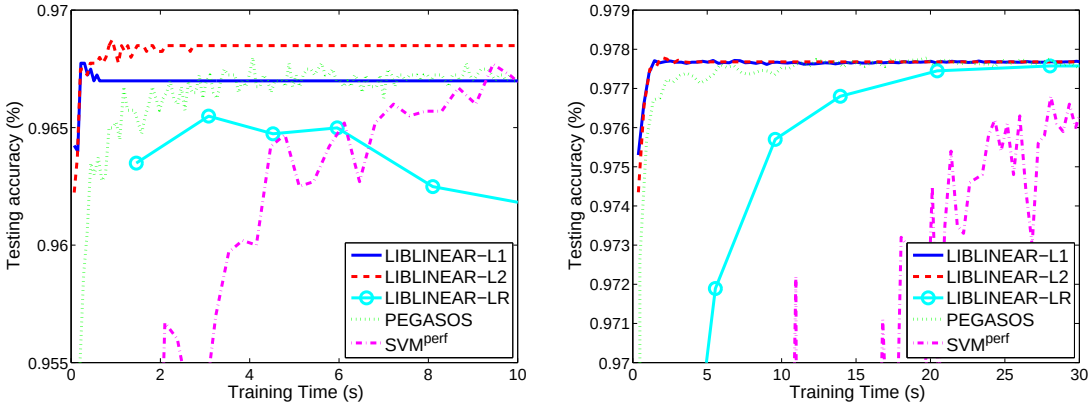
Making extensions of LIBLINEAR to languages other than C/C++ is easy. Following the same setting of the LIBSVM MATLAB/Octave interface, we have a MATLAB/Octave extension available within the package. Many tools designed for LIBSVM can be reused with small modifications. Some examples are the parameter selection tool and the data format checking tool.

4. Comparison

Due to space limitation, we skip here the full details, which are in Lin et al. (2008) and Hsieh et al. (2008). We only demonstrate that LIBLINEAR quickly reaches the testing accuracy corresponding to the optimal solution of (1). We conduct five-fold cross validation to select the best parameter C for each learning method (L1-SVM, L2-SVM, LR); then we train on the whole training set and predict the testing set. Figure 1 shows the comparison between LIBLINEAR and two state of the art L1-SVM solvers: Pegasos (Shalev-Shwartz et al., 2007) and SVM$^{\text{perf}}$ (Joachims, 2006). Clearly, LIBLINEAR is efficient.

To make the comparison reproducible, codes used for experiments in Lin et al. (2008) and Hsieh et al. (2008) are available at the LIBLINEAR web page.

4. FAQ can be found at `http://www.csie.ntu.edu.tw/~cjlin/liblinear/FAQ.html`.



(a) news20, l: 19,996, n: 1,355,191, #nz: 9,097,916 (b) rcv1, l: 677,399, n: 47,236, #nz: 156,436,656

Figure 1: Testing accuracy versus training time (in seconds). Data statistics are listed after the data set name. l: number of instances, n: number of features, #nz: number of nonzero feature values. We split each set to 4/5 training and 1/5 testing.

5. Conclusions

LIBLINEAR is a simple and easy-to-use open source package for large linear classification. Experiments and analysis in Lin et al. (2008), Hsieh et al. (2008) and Keerthi et al. (2008) conclude that solvers in LIBLINEAR perform well in practice and have good theoretical properties. LIBLINEAR is still being improved by new research results and suggestions from users. The ultimate goal is to make easy learning with huge data possible.

Abstract

We show that the relevant information of a supervised learning problem is contained up to negligible error in a finite number of leading kernel PCA components if the kernel matches the underlying learning problem in the sense that it can asymptotically represent the function to be learned and is sufficiently smooth. Thus, kernels do not only transform data sets such that good generalization can be achieved using only linear discriminant functions, but this transformation is also performed in a manner which makes economical use of feature space dimensions. In the best case, kernels provide efficient implicit representations of the data for supervised learning problems. Practically, we propose an algorithm which enables us to recover the number of leading kernel PCA components relevant for good classification. Our algorithm can therefore be applied (1) to analyze the interplay of data set and kernel in a geometric fashion, (2) to aid in model selection, and (3) to denoise in feature space in order to yield better classification results.

Keywords: kernel methods, feature space, dimension reduction, effective dimensionality

1. Introduction

Kernel machines implicitly map the data into a high-dimensional feature space in a non-linear fashion using a kernel function. This mapping is often referred to as an *empirical kernel map* (Schölkopf et al., 1999; Vapnik, 1998; Müller et al., 2001; Schölkopf and Smola, 2002). By virtue of the empirical kernel map, the data is ideally transformed in a way such that a linear discriminative function can separate the classes with low generalization error by a canonical hyperplane with large margin. Such large margin hyperplanes provide an appropriate mechanism of capacity control and thus "protect" against the high dimensionality of the feature space.

However, this picture is incomplete as it does not explain why the typical variants of capacity control cooperate well with the induced feature map. This paper adds a novel aspect as the key idea

[*]. Also at Fraunhofer FIRST.IDA, Kekuléstr. 7, 12489 Berlin, Germany.

to this picture. We show theoretically that if the learning problem matches the kernel well, the relevant information of a supervised learning data set is always contained in the subspace spanned by a finite and typically small number of leading kernel PCA components (principal component analysis in the feature space induced by the kernel, see below and Section 2), up to negligible error. This result is based on recent approximation bounds for the eigenvectors of the kernel matrix which show that if a function can be reconstructed using only a few kernel PCA components asymptotically, then the same already holds in a finite sample setting, even for small sample sizes.

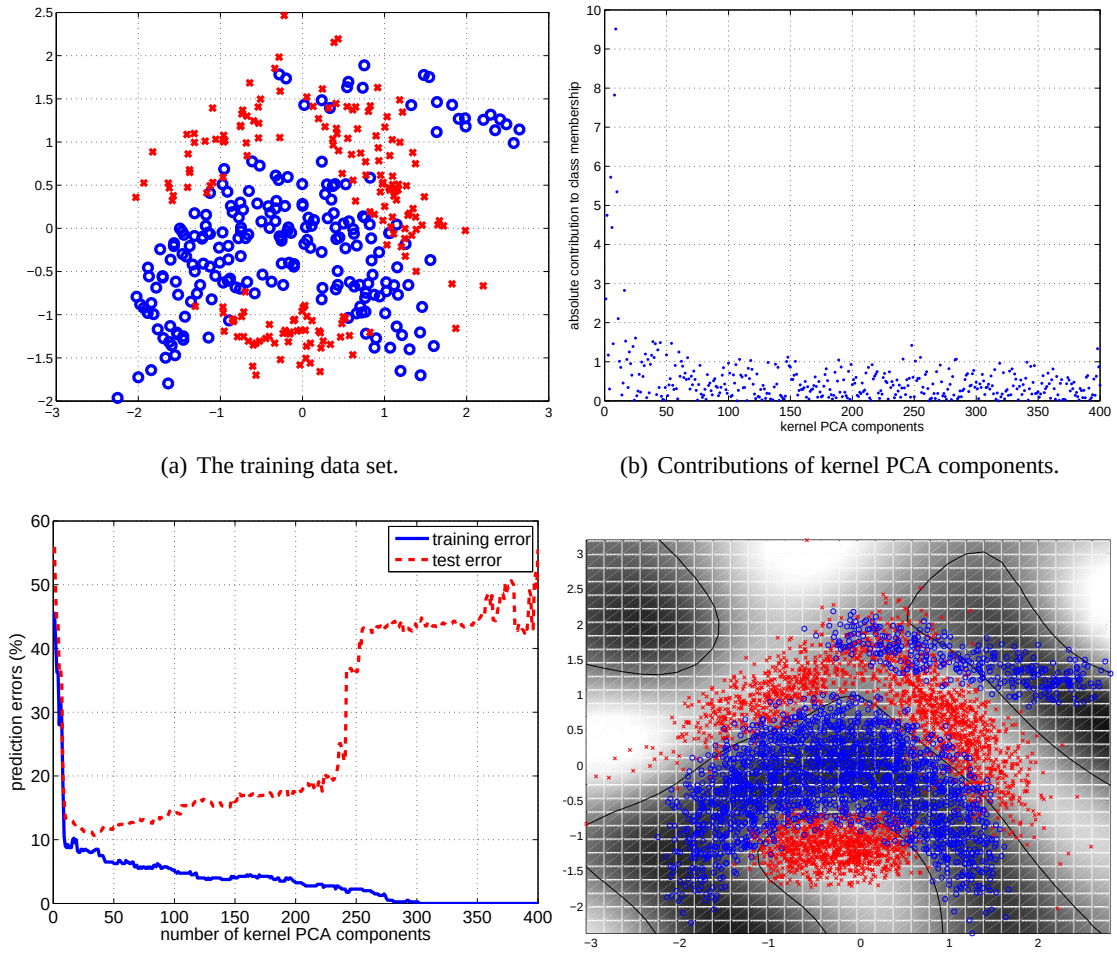
Consequently, the use of a kernel function not only greatly increases the expressive power of linear methods by non-linearly transforming the data, but it does so ensuring that the high dimensionality of the feature space does not become overwhelming: the relevant information for learning stays confined within a comparably *low*-dimensional subspace. This finding underlines the efficient use of data that is made by kernel machines if the kernel works well for the learning problem. A smart choice of kernel permits to make better use of the available data at a favorable "number of data points per effective dimension"-ratio, even for infinite-dimensional feature spaces. The kernel induces an efficient representation of the data in feature space such that even unregularized methods like linear least squares regression are able to perform well on the reduced feature space.

Let us consider an example. Figure 1(a) shows a two-dimensional classification problem (the *banana* data set from Rätsch et al., 2001). We can visualize the contributions of the individual kernel PCA components[1] to the class membership by plotting the absolute values of scalar products between the labels and the kernel PCA components. Figure 1(b) shows the resulting contributions sorted by decreasing principal value (variance along principal direction). We can observe that the contributions are concentrated in the leading kernel PCA directions, but a large fraction of the information is contained in the later components as well.

Note, however, that the class membership information in the data set also contains a certain amount of noise. Therefore, Figure 1(b) actually shows a mixture of relevant information and noise. We need to devise a different procedure for assessing the amount of task-relevant information in certain kernel PCA components. This can be accomplished by incorporating a second data set from the same source for testing. One first projects onto the subspace spanned by a number of leading kernel PCA components, trains a linear classifier (for example, by least squares regression) and then measures the prediction error on the test set. The test error is large either if the considered subspace did not capture all of the relevant information, or if it already contained too much noise leading to overfitting. If the minimal test error is on par with a state-of-the-art method independently trained using the same kernel then the subspace has successfully captured all of the relevant information.

If we apply this procedure to our data set, we obtain training and test errors as shown in Figure 1(c). By definition, the training error decreases as more and more dimensions are used. However, after decreasing quickly initially, the test error eventually starts to increase again. The minimal test error also coincides with the actually achievable test error using, for example, support vector machines. Therefore, we see that the later components only contain noise, and the relevant information is contained in the leading kernel PCA components. In this paper, our goal is to understand

1. Recall that kernel PCA (Schölkopf et al., 1998) amounts to implicitly performing PCA in the feature space. Roughly, instead of the covariance matrix, one considers the eigenvalues and eigenvectors of the kernel matrix, which is built from all pairwise evaluations of the kernel matrix on the inputs. Principal values (variances) are still given by the eigenvalues of the kernel matrix, but principal directions (which would be potentially infinite-dimensional vectors) are replaced by principal components, which are scalar products with the principal directions. Also see Section 2.



(a) The training data set.

(b) Contributions of kernel PCA components.

(c) Training and test errors using only leading kernel PCA components.

(d) The solution on the test data set.

Figure 1: A more complex example (resample 1 of the "banana" data set, see Section A). This time, the information is not contained in a single component. Nevertheless, the test error of a hyperplane learned using only the first d components has a clear minimum at $d = 34$ at optimal error rate (cf. Table 3), showing that the relevant information is contained in the leading 34 directions.

more thoroughly why and when this effect occurs, and to estimate the dimensionality of a concrete data set given a kernel.

Our claim—that the relevant information about a learning problem is contained in the space spanned by the leading kernel PCA components—is similar to the idea that the information about the learning problem is contained in the kernel PCA components with the largest contributions. However, our results show that the magnitude of the contribution of a kernel PCA component to the label information is only partially indicative of the relevance of that component. Instead, we show that the leading kernel PCA components (sorted by corresponding principal value) contain

the relevant information. Components which contain only little variance will therefore not contain relevant information. If such a component manages to contribute much to the label information, it will only reflect noise.

What practical implications follow from these results? We explore several possibilities of using these ideas to assess the suitability of a kernel or a family of kernels to a specific data set. The main idea is that the observed dimensionality of the data set in feature space is characteristic for the relation between a data set and a kernel. Roughly speaking, the relevant dimensionality of the data set corresponds to the complexity of the learning problem when viewed through the "lens" of the kernel function. Using the estimated dimensionality, one can project the labels onto the corresponding subspace and obtain a noise free version of the labels. By comparing the denoised labels to the original labels, one can estimate of the amount of noise contained in the labels. One therefore obtains a more detailed measure of the fit between the kernel and the data set as compared to, for example, the cross-validation error alone. This allows us to take a closer look at data sets on which the achieved error is quite large. In such cases, we are able to distinguish whether the data set is highly complex and the amount of data is insufficient, or the amount of intrinsic noise is very large. This is practically relevant as one has to deal with both these cases quite differently, either by providing more data, or by thinking about means to obtain less noisy or ambiguous features.

We summarize the main contributions of this paper: (1) We provide theoretical bounds showing that the relevant information (defined in Section 2) is actually contained in the leading projected kernel principal components under appropriate conditions. (2) We propose an algorithm which estimates the relevant dimensionality and related estimates of the data set and permits to analyze the appropriateness of a kernel for the data set, and thus to perform model selection among different kernels. (3) We validate the accuracy of the estimates experimentally by showing that non-regularized methods perform on the reduced feature space on par with state-of-the-art kernel methods. We analyze some well-known benchmark data sets in Section 5. Note that we do not claim to obtain better performance within our framework when compared to, for example, cross-validation techniques. Rather, we are on par. Our contribution is to foster an understanding about a data set and to gain better insights of whether a mediocre classification result is due to intrinsic high dimensionality of the data (and consequently insufficient number of examples), or an overwhelming noise level.

2. Preliminaries

Let us start to formalize the ideas introduced so far. As usual, we consider a data set (X_1,Y_1), $\ldots,(X_n,Y_n)$ where the inputs X lie in some space $\mathcal{X}$ and the outputs Y to be predicted are in $\mathcal{Y} = \{\pm 1\}$ for classification or $\mathcal{Y} = \mathbb{R}$ for regression. We often refer to the outputs Y_i as the "labels" irrespective of whether we are considering a classification or regression task. We assume that the (X_i,Y_i) are drawn i.i.d. from some probability measure $\mathrm{P}_{\mathcal{X}\times\mathcal{Y}}$. In kernel methods, the data is nonlinearly mapped into some feature space $\mathcal{F}$ via the feature map Φ. Scalar products in $\mathcal{F}$ can be computed by the kernel k in closed form: $\langle \Phi(x), \Phi(x')\rangle = k(x,x')$. Summarizing all the pairwise scalar products results in the (normalized) kernel matrix $\mathbf{K}$ with entries $k(X_i,X_j)/n$.

In the discussion below, we study the relationship between the *label vector* $Y = (Y_1,\ldots,Y_n)$ and the kernel PCA components which are introduced next. Kernel PCA (Schölkopf et al., 1998) is a kernelized version of PCA. Since the dimensionality of the feature space might be too large to deal

Symbol	Meaning
n	number of training examples
$X_i \in \mathcal{X}$	input examples
$Y_i \in \mathcal{Y}$	output labels
$k\colon \mathcal{X} \times \mathcal{X} \to \mathbb{R}$	kernel function
$\mathbf{K} = (k(X_i, X_j))/n$	(normalized) kernel matrix
$Y = (Y_1, \ldots, Y_n)$	label vector
$\Phi\colon \mathcal{X} \to \mathcal{F}$	feature map
$l_m \in \mathbb{R}_{\geq 0}$	mth kernel PCA value (in descending order), mth eigenvalue of kernel matrix $\mathbf{K}$
$v_m \in \mathcal{F}$	mth kernel PCA direction
$f_m(x) = \langle \Phi(x), v_m \rangle$	mth kernel PCA component
$u_m = (f_m(X_1), \ldots, f_m(X_n))$	mth kernel PCA component evaluated on $X_1, \ldots, X_n$, mth eigenvector of kernel matrix $\mathbf{K}$
$\pi_d(Y) = \sum_{i=1}^{d} u_i u_i Y$	projection onto first d kernel PCA components
$G = (\mathrm{E}(Y_1 \mid X_1), \ldots, \mathrm{E}(Y_n \mid X_n))$	relevant information vector
$z_i = u_i^\top G$	contribution of ith eigenvector to relevant information
$g(x) = \mathrm{E}(Y \mid X = x)$	relevant information function
$\mathcal{L}^2(\mathcal{X}, \mathrm{P}_\mathcal{X})$	set of all square integrable functions with respect to $\mathrm{P}_\mathcal{X}$
$T_k f(s) = \int_\mathcal{X} k(s,t) f(t) \mathrm{P}_\mathcal{X}(dt)$	integral operator associated with k
$\lambda_i \in \mathbb{R}_{\geq 0}$	ith eigenvalue of T_k
$\psi_i \in \mathcal{L}^2(\mathcal{X}, \mathrm{P}_\mathcal{X})$	ith eigenfunction of T_k
$\zeta_i = \langle \psi_i, g \rangle$	contribution of ith eigenfunction to relevant information
$\hat{d}$	estimated relevant dimension
$\mathrm{cv}_{\mathrm{loo}}$	leave-one-out cross-validation error
$\hat{G}$	estimated relevant information vector
$\mathbf{S} = \sum_{i=1}^{d} u_i u_i^\top$	"hat"-matrix
$\hat{\mathrm{err}}$	estimated noise-level

Table 1: Overview of notation used in this paper.

with the vectors directly, the principal directions are represented using the points X_i of the data set:

$$v_m = \sum_{i=1}^{n} \alpha_i \Phi(X_i),$$

where $\alpha_i = [u_m]_i / l_m$, $[u_m]_i$ is the ith component of the mth eigenvector of the kernel matrix $\mathbf{K}$, and l_m the corresponding eigenvalue.[2] Still, v_m can usually not be computed explicitly such that one instead works with *kernel PCA components*

$$f_m(x) = \langle \Phi(x), v_m \rangle.$$

We are interested in the relation between f_m and a label vector Y. As we have seen in the introduction, it seems that only a finite number of leading kernel PCA components are necessary to represent the relevant information about the learning problem up to a small error.

2. As usual, we assume that l_m and u_m have been sorted such that $l_1 \geq \ldots \geq l_n$.

Therefore, we would like to compare f_m with the values $Y_1,\ldots,Y_n$ at the points $X_1,\ldots,X_n$. The following easy lemma summarizes the relationship between the sample vector of f_m and Y.

Lemma 1 *The mth kernel PCA component f_m evaluated on the X_is is equal to the mth eigenvector of the kernel matrix* $\mathbf{K}$*: $(f_m(X_1),\ldots,f_m(X_n)) = u_m$. Consequently, the sample vectors are orthogonal, and the projection of a vector $Y \in \mathbb{R}^n$ onto the leading d kernel PCA components is given by $\pi_d(Y) = \sum_{m=1}^{d} u_m u_m^\top Y$.*

Proof The mth kernel PCA component for a point X_j in the training set is

$$f_m(X_j) = \langle \Phi(X_j), v_m \rangle = \frac{1}{l_m} \sum_{i=1}^{n} \langle \Phi(X_j), \Phi(X_i) \rangle [u_m]_i = \frac{1}{l_m} \sum_{i=1}^{n} k(X_j, X_i)[u_m]_i.$$

The sum computes the jth component of $\mathbf{K}u_m$, and $\mathbf{K}u_m = l_m u_m$, because u_m is an eigenvector of $\mathbf{K}$. Therefore

$$f_m(X_j) = \frac{1}{l_m}[l_m u_m]_j = [u_m]_j.$$

Since $\mathbf{K}$ is a symmetric matrix, its eigenvectors u_m are orthonormal, and the projection of Y onto the space spanned by the first d kernel PCA components is given by $\sum_{m=1}^{d} u_m u_m^\top Y$. ■

Since the kernel PCA components are orthogonal, the coefficients of a vector $Y \in \mathbb{R}^n$ with respect to the basis $u_1,\ldots,u_n$ is easily computed by forming the scalar products. We call the coefficients

$$z_m = u_m^\top Y \tag{1}$$

of Y w.r.t. the basis formed from the kernel PCA components the *kernel PCA coefficients*. They are the central object of our discussion.

The projection of Y to a kernel PCA component can be thought of as the least squares regression of Y using only the direction along the kernel PCA component in feature space.

Using the kernel PCA coefficients, we can extend the projected labels to new points via

$$\hat{Y}(x) = \sum_{m=1}^{d} z_m f_m(x),$$

which amounts to the prediction of least squares regression on the reduced feature space.

3. The Label Vector and Kernel PCA Components

In the introduction, we have discussed an example which suggests that a small number of leading kernel PCA components might suffice to capture the relevant information about the output variable. It is clear that we cannot expect this behavior for all possible data sets and kernels. It seems plausible though, that under certain conditions, the distribution of the data and the kernel fit together well. Then we can expect to observe this behavior with high probability for a random sample from this distribution through some form of concentration or convergence property.

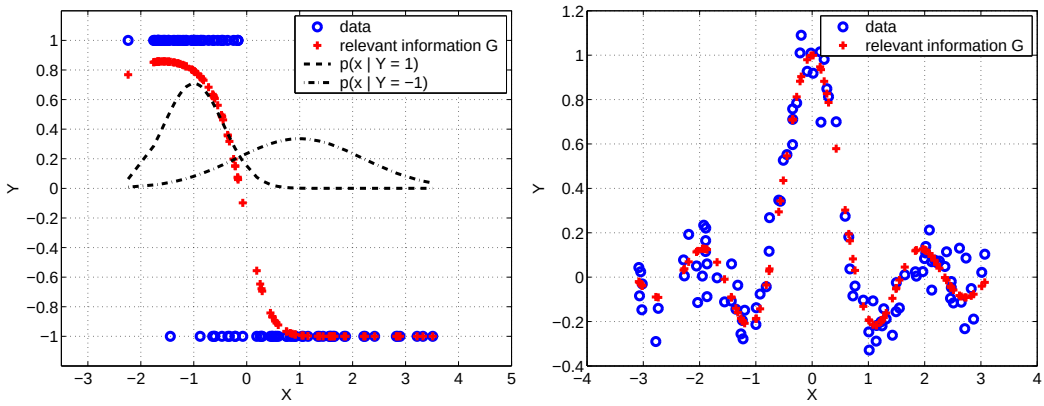


Figure 2: Relevant information vectors visualized for the classification and the regression case. In the (two-class) classification case (left) it encodes the posterior probability (scaled between -1 and 1), in the regression case it is the sample vector of the function to be learned.

3.1 Decomposing the Label Vector Information

We start the discussion by defining formally what the relevant information contained in the labels is. Given a label vector Y, we define the relevant information vector as the vector of the expected labels:

$$G = (\mathrm{E}(Y_1|X_1), \ldots, \mathrm{E}(Y_n|X_n)).$$

Intuitively speaking, G is a noise-free version of Y. This vector contains all the relevant information about the outputs Y of the learning problem: For regression, G amounts to the values of the true function. For the case of two-class classification, the vector G contains all the information about the optimal decision boundary. Since $\mathrm{E}(Y|X) = \mathrm{P}(Y = 1|X) - \mathrm{P}(Y = -1|X)$, the sign of G contains the relevant information on the true class membership by telling us which class is more probable (see Figure 2 for examples). Thus, using this denoised label information, the learning problem becomes much easier as the denoised labels already contain the Bayes optimal prediction at that point.[3]

Using G we obtain a very useful additive decomposition of the labels into "signal" and "noise":

$$Y = G + N.$$

In this setting, we are now interested in showing that G is contained in the leading kernel PCA components, such that projecting G onto the leading kernel PCA components leads to only negligible error. In the following, we treat the signal and noise part of Y separately. This is possible because the projection π_d is a linear operation such that $\pi_d(Y) = \pi_d(G+N) = \pi_d(G) + \pi_d(N)$.

3. Also note that the capacity control typically employed in kernel methods amounts to some form of regularization, or "implicit denoising" (Smola et al., 1998). Therefore, we do not expect that the results using G are generally better than with the original labels. However, as we will see below, *unregularized* methods perform on par with kernel methods with capacity control using the estimated relevant information vector G.

3.2 The Relevant Information Vector

We first treat the relevant information vector G. The location of G with respect to the kernel PCA components is characterized by scalar products with the eigenvectors of the kernel matrix. We start by discussing this relationship in an asymptotic setting and then transfer the results back to the finite sample setting using convergence results for the spectral properties of the kernel matrix

Using the kernel function k, we define the integral operator

$$T_k f(s) = \int_{\mathcal{X}} k(s,t) f(t) \mathrm{P}_{\mathcal{X}}(dt),$$

where $\mathrm{P}_{\mathcal{X}}$ is the marginal distribution which generates the inputs X_i. It is well known that the linear operator

$$\tilde{T}_k f(s) = \frac{1}{n} \sum_{i=1}^{n} k(s, X_i) f(X_i)$$

represented by the kernel matrix approximates T_k as the number of points tend to infinity (see, for example, von Luxburg, 2004). While this follows easily for a fixed f and s, making the argument theoretically exact for operators (this means uniform over all functions) is not trivial.

As a consequence, the eigenvalues and eigenvectors of $\tilde{T}_k$, which are equal to those of the kernel matrix, converge to those of T_k (see Koltchinskii and Giné, 2000; Koltchinskii, 1998). In particular, scalar products of sample functions and eigenvectors of $\mathbf{K}$ converge to scalar products with eigenfunctions of T_k. The asymptotic counterpart of the relevant information vector G is the function

$$g(x) = \mathrm{E}(Y|X = x).$$

These correspondences are summarized in Figure 3. In summary, we can think of $z_i = u_i^\top G$ (properly scaled) as an approximation to $\zeta_i = \langle \psi_i, g \rangle$.

finite sample setting
$[\mathbf{K}x]_i = \frac{1}{n} \sum_{j=1}^{n} k(X_i, X_j) x_j$
l_i eigenvalue of $\mathbf{K}$
u_i eigenvector of $\mathbf{K}$
$G = \big(\mathrm{E}(Y_1\|X_1), \ldots \mathrm{E}(Y_n\|X_n)\big)$
$z_i = u_i^\top G$

$\rightsquigarrow$

asymptotic setting
$T_k f(s) = \int_{\mathcal{X}} k(s,t) f(t) \mathrm{P}_{\mathcal{X}}(dt)$
λ_i eigenvalue of T_k
ψ_i eigenfunction of T_k
$g(x) = \mathrm{E}(Y\|X = x)$
$\zeta_i = \langle \psi_i, g \rangle$

Figure 3: Transition from the finite sample size and asymptotic setting.

In the asymptotic setting, it is now fairly easy to specify conditions such that g is contained in the subspace spanned by a finite number of leading eigenfunctions ψ_i. Since it is unrealistic that g is exactly contained in a finite dimensional subspace, we relax that requirement and instead only require that ζ_i decays to zero at the same rate as the eigenvalues of T_k.

The decay rate of the eigenvalues depends on the interplay between the kernel and the distribution $\mathrm{P}_{\mathcal{X}}$. However, expressing this connection in closed form is in general not possible. As a rule of thumb, the eigenvalues decay quickly when the kernel is smooth at the scale of the data. Since one usually uses smooth kernels to prevent from overfitting, the eigenvalues typically decay rather quickly. As we will see, most of the information about g is then contained in a few kernel PCA components.

A natural assumption is that the learning problem can be asymptotically represented by the given kernel function k. By this we mean that there exists some function $h \in \mathcal{L}^2(\mathcal{X}, \mathrm{P}_\mathcal{X})$ such that $g = T_k h$. Using the spectral decomposition of T_k, this implies

$$g = T_k h = \sum_{i=1}^{\infty} \lambda_i \langle \psi_i, h \rangle \psi_i. \tag{2}$$

Since the sequence of $\alpha_i = \langle \psi_i, h \rangle$ is square summable, it follows that

$$\zeta_i = \langle \psi_i, g \rangle = \lambda_i \alpha_i = O(\lambda_i).$$

Intuitively speaking, (2) translates to asymptotic representability of the learning problem: As $n \to \infty$, it becomes possible to represent the optimal labels using the kernel function k.

Furthermore, we assume that k is bounded. This technical requirement is mainly necessary to ensure that g is also bounded. The requirement holds for common radial basis function kernels like the Gaussian kernel, and also if the underlying space $\mathcal{X}$ is compact and the kernel is continuous.

Note that the requirement that g lies in the range of T_k is essential. If this is not the case, we cannot expect that the scalar products decay at a given rate. Also note that it is in fact possible to break this condition. For example, if k is continuous, every non-continuous function does not lie in the range of T_k.

The question is now whether the same behavior can be expected for a finite data set. This question is not trivial, because eigenvector stability is known to be linked to the gap between the corresponding eigenvalues, which is fairly small for small eigenvalues (see, for example, Zwald and Blanchard, 2006).

The main theoretical result of this paper (Theorem 1 in the Appendix) provides a bound of the form

$$\frac{1}{n} |u_i^\top G| \leq l_i C + E$$

which expresses an essential equivalence between the finite sample setting and the asymptotic setting with two modifications: The decay rate $O(\lambda_i)$ of the scalar products $\langle \psi_i, g \rangle$ holds for the finite sample up to a (small) additive error E with λ_i replaced by its finite sample approximation l_i.

The technical details of this theorem and the proof are deferred to the appendix. Let us discuss how the absolute term occurs in the bound and why it can be expected to be small. An exact scaling bound (without additive term E) can only be derived (at least following the approach taken in this paper) for the case where the kernel function is degenerate, that is, T_k has only finitely many non-zero eigenvalues. The same finiteness restriction also holds for the expansion of g in terms of the eigenfunctions of T_k. The proof thus contains a truncation step of general kernels and general functions g, leading to a scaling bound on the scalar product and an additive term arising from the truncation. However, as the name suggests, the truncation error E can be made arbitrarily small by considering approximations with many non-zero eigenvalues. At the same time, considering such kernels with more terms in the expansion leads to a larger constant C in the actual scaling part. Thus, both terms have to be balanced by the order of truncation, which permits to control the additive term well practically.

Note that the problem considered here is significantly different from the problem studying the performance of kernel PCA itself (see, for example, Blanchard et al., 2007; Shawe-Taylor et al., 2005; Mika, 2002). There, only the projection error using the Xs is studied. Here, we are specifically interested in the relationship between the Ys and the Xs.

In view of our original concern, the bound shows that the relevant information vector G (as introduced in Section 2) is contained in a number of leading kernel PCA components up to a negligible error. The number of dimensions depends on the asymptotic coefficients α_i and the decay rate of the asymptotic eigenvalues of k. Since this rate is related to the smoothness of the kernel function, the dimension is small for smooth kernels whose leading eigenfunctions ψ_i permit good approximation of g.

3.3 The Noise

To study the relationship between the noise and the eigenvectors of the kernel matrix, no asymptotic arguments are necessary. The key insight is that the eigenvectors are independent of the noise in the labels, such that the noise vector N is typically evenly distributed over all coefficients $u_i^\top N$: Let $\mathbf{U}$ be the matrix whose ith column is equal to u_i. The coefficients of N with respect to the eigenbasis of $\mathbf{K}$ are then given by $\mathbf{U}^\top N$. Note that since $\mathbf{U}$ is orthogonal, multiplication by its transpose amounts to a (random) rotation. In particular, this rotation is independent of the noise N as the u_i depend on the Xs only. Now if the noise has a spherical distribution, for example, N is normally distributed with covariance matrix $\sigma_\varepsilon^2\mathbf{I}$, it follows that $\mathbf{U}^\top N \sim \mathcal{N}(0,\sigma_\varepsilon^2\mathbf{I})$. For heteroscedastic noise in a regression setting, or for classification, this simple analysis is not sufficient. In that case, the individual $u_i^\top N$ are no longer uncorrelated. However, because of the independence of the N_i, the variance of $u_i^\top N$ is upper bounded by

$$\operatorname{Var}(u_i^\top N) = \sum_{j=1}^{n} u_{i,j}^2 \operatorname{Var}(N_j) \leq \max_{1\leq j\leq n} \operatorname{Var}(N_j)$$

since $\sum_{j=1}^n u_{i,j}^2 = \|u_i\|^2 = 1$. Therefore, the variance of the $u_i^\top N$ is not concentrated in any single coefficient as the total variance does not increase by rotating the basis and the individual variances are bounded by the maximum individual variance before the rotation.

The practical relevance of these observations is that the relevant information and noise part have radically different properties with respect to the kernel PCA components, allowing us to practically estimate the number of relevant dimension for a given kernel and data set. In the next section, we will propose two different algorithms for this task.

4. Relevant Dimension Estimation and Related Estimates

We have seen that the number of leading kernel PCA components necessary to capture the relevant information about the labels of a finite size data set is bounded under the mild assumptions that the learning problem can be represented asymptotically and the kernel is smooth such that the eigenvalues of the kernel matrix decay quickly. The actual number of necessary dimensions depends on the interplay between kernel and learning data set, giving insights into the suitability of the kernel. For example, a kernel might fail to provide an efficient representation of the learning problem, leading to an embedding requiring many kernel PCA components to capture the information on Y. Or, even worse, a kernel might completely fail to model some part of the learning problem, such that a part of the information appears to be just noise. Therefore, in order to make practical use of the presented insights, we need to devise a method to estimate the number of relevant kernel PCA components for a given concrete data set and choice of kernel.

In this section we propose methods for estimating the actual dimensionality of a data set, and two related estimators. Based on the dimensionality estimate, one can denoise the labels by projecting

onto the respective subspace and obtain an estimate for the relevant information vector G. By comparing the denoised labels with the original labels, one can then estimate the overall noise level of the data source. Based on these estimates, we discuss how to use the dimensionality estimate for model-selection and to further analyze data sets which so far show inferior performance. Figure 4 summarizes the information flow for the different estimates.

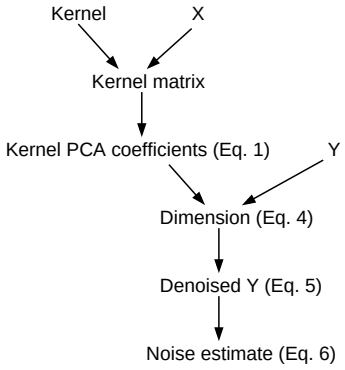

Figure 4: Information flow for the estimates.

4.1 Relevant Dimension Estimation (RDE)

The most basic estimate is the number of relevant kernel PCA components. We also call this number simply the *relevant dimension* or the *dimensionality* (also see the discussion in Section 6.3). Recall that we have decomposed the labels into $Y = G + N$, with $G_i = \mathrm{E}(Y_i|X_i)$ (see Section 3.1). This decomposition carries over to the kernel PCA coefficients $z_i = u_i^\top Y = u_i^\top G + u_i^\top N$. We want to estimate $\hat{d}$ such that $|u_i^\top G|$ is negligible for $i > \hat{d}$.

We propose two algorithms for solving this relevant dimension estimation (RDE) task which are based on different approaches to the problem but lead to comparable performance. The first algorithm fits a parametric model to the kernel PCA coefficients, while the second one is based on leave-one-out cross-validation.

4.1.1 RDE BY FITTING A TWO-COMPONENT MODEL (TCM)

The first algorithm works only on the coefficients $z_i = u_i^\top Y$. Recall that $\mathbf{U}$ is the matrix whose columns are the eigenvectors of the kernel matrix u_i such that $z = \mathbf{U}^\top Y = \mathbf{U}^\top G + \mathbf{U}^\top N = \tilde{G} + \tilde{N}$. In Section 3, we have seen that both parts have significantly different structure. From Theorem 1, we know that $|\tilde{G}_i| \approx O(l_i)$, and that the $\tilde{G}_i$ are close to zero for all but a leading number of coefficients. On the other hand, as discussed in Section 3.3, the transformed noise $\tilde{N}$ is typically evenly distributed over all coefficients. Thus, the coefficients of the noise have the shape of an evenly distributed "noise floor" $\tilde{N}_i$ from which the coefficients $\tilde{G}_i$ of the relevant information arise (see Figure 1(b) for an example).

The idea is now to find a cut-off point such that the coefficients are divided into two parts $z_1, \ldots, z_d$ and $z_{d+1}, \ldots, z_n$ such that the first part contains the relevant information and the latter part consists of evenly distributed noise. We model the coefficients by two zero-mean Gaussians with

individual variances

$$z_i \sim \begin{cases} \mathcal{N}(0,\sigma_1^2) & 1 \le i \le d, \\ \mathcal{N}(0,\sigma_2^2) & d < i \le n. \end{cases}$$

Of course, in order to be able to extract meaningful information, it should hold that $\sigma_1 \gg \sigma_2$. Alternatively, one could assume that $z_i \sim \mathcal{N}(0,\sigma_1^2+\sigma_2^2)$, for $1 \le i \le d$, which nevertheless leads to the exact same choice of d.

For real data, both parts need not be actually Gaussian distributed. However, due to lack of additional a priori knowledge on the signal or the noise, the Gaussian distribution represents the optimal choice among all distributions with the same variance according to the maximum entropy principle (Jaynes, 1957).

The negative log-likelihood is proportional to

$$-\log \ell(d) \sim \frac{d}{n}\log\sigma_1^2 + \frac{n-d}{n}\log\sigma_2^2, \qquad \text{with} \qquad \sigma_1^2 = \frac{1}{d}\sum_{i=1}^{d} z_i^2,\ \sigma_2^2 = \frac{1}{n-d}\sum_{i=d+1}^{n} z_i^2. \tag{3}$$

The estimated dimension is then given as the maximum likelihood fit

$$\hat{d} = \operatorname*{argmin}_{1\le d\le n'}(-\log \ell(d)) = \operatorname*{argmin}_{1\le d\le n'}\left(\frac{d}{n}\log\sigma_1^2 + \frac{n-d}{n}\log\sigma_2^2\right). \tag{4}$$

Due to numerical instabilities of kernel PCA components corresponding to small eigenvalues, the choice of d should be restricted to $1 \le d \le n' < n$: The coefficients z_i are computed by taking scalar products with eigenvectors u_i. For small eigenvalues (small meaning of the order of the available numerical precision, for double precision floating point numbers, this is typically around 10^{-16}), individual eigenvectors cannot be computed accurately, although the space spanned by all these eigenvectors is accurate. Therefore, coefficients z_i for large i are not be reliable. To systematically stabilize the algorithm, one should therefore limit the range of possible effective dimensions. We have found the choice of $1 \le d \le n/2$ to work well as this choice ensures that at least half of the coefficients are interpreted as noise. For very small and very complex data sets, this choice might prove suboptimal and better thresholds based, for example, on the actual decay of eigenvalues might be advisable. However, on all data sets discussed in this paper, the above choice performed very well.

4.1.2 RDE BY LEAVE-ONE-OUT CROSS-VALIDATION (LOO-CV)

We propose a second algorithm which is based on cross validation, a more general concept than parametric noise modeling. This algorithm only depends on our theoretical results to the extent that it searches for subspaces spanned by leading kernel PCA components. We later compare the two methods to see whether our assumptions were justified.

As stated in Lemma 1, the projection of Y onto the space spanned by the d leading kernel PCA components is given by $\sum_{i=1}^{d} u_i u_i^\top Y$, where u_i are the eigenvectors of the kernel matrix. The matrix $\mathbf{S} = \sum_{i=1}^{d} u_i u_i^\top$ can be interpreted as a "hat matrix" in the context of regression.[4] The idea is now to choose the dimension which minimizes the leave-one-out cross-validation error. This subspace then captures all of the relevant information about Y without overfitting.

4. Recall that for regression methods where the fitted function depends linearly on the labels, the matrix $\mathbf{S}$ which computes $\hat{Y} = \mathbf{S}Y$ is called the "hat matrix" since it "puts the hat on Y."

Computationally, note that one can write the squared error leave-one-out cross-validation in closed form, similar to kernel ridge regression (see Wahba, 1990):

$$\mathrm{cv}_{\mathrm{loo}}(d) = \frac{1}{n}\sum_{i=1}^{n}\left(\frac{[\mathbf{S}Y]_i - Y_i}{1-\mathbf{S}_{ii}}\right)^2.$$

It is possible to organize the computation in a way such that given the eigendecomposition of $\mathbf{K}$, each value $\mathrm{cv}_{\mathrm{loo}}(d)$ can be computed in $O(n)$ (instead of $O(n^2)$ if one naively implements the above formula): Note that $\mathbf{S}_{ii}$ is equal to $\sum_{j=1}^{d}(u_j)_i^2$, therefore, one can compute $\mathbf{S}_{ii}$ iteratively by

$$\begin{aligned}\mathbf{S}_{ii}^0 &\leftarrow 0\\ \mathbf{S}_{ii}^{d+1} &\leftarrow \mathbf{S}_{ii}^d + (u_{d+1})_i^2.\end{aligned}$$

In the same way, since $\hat{Y} = \mathbf{S}Y = \sum_{j=1}^{d} u_j u_j^\top Y$, we get that

$$\begin{aligned}\hat{Y}^0 &\leftarrow 0\\ \hat{Y}^{d+1} &\leftarrow \hat{Y}^d + u_{d+1}u_{d+1}^\top Y.\end{aligned}$$

The squared error is in principle not the most appropriate loss function for classification problems. But as we will see below, it nevertheless works well also for classification problems.

4.2 Denoising the Labels and Estimating the Noise Level

One direct application of the dimensionality estimate is the projection of Y onto the first $\hat{d}$ kernel PCA components. By Lemma 1, this projection is

$$\hat{G}' = \sum_{i=1}^{\hat{d}} u_i u_i^\top Y.$$

Then, an estimate of the noiseless labels is given by

$$\hat{G} = \begin{cases}\operatorname{sign}\hat{G}' & \text{classification against } \pm 1 \text{ labels}\\ \hat{G}' & \text{regression}\end{cases}. \tag{5}$$

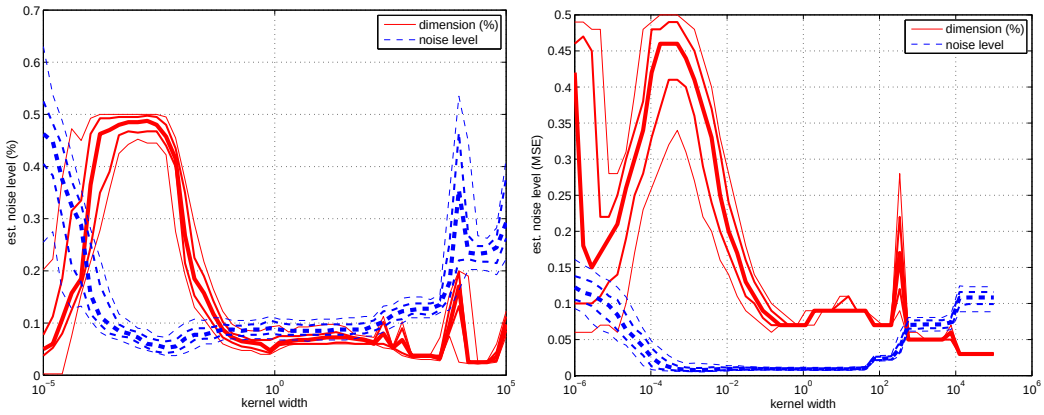
Note that this amounts to computing the in-sample fit using kernel principal component regression (kPCR).

The estimated dimension can also be used to estimate the noise level present in the data set by

$$\hat{\mathrm{err}} = \frac{1}{n}\sum_{i=1}^{n} L(\hat{Y}_i, Y_i), \tag{6}$$

where L is the loss function.

The accuracy of both these estimates depends on a number of factors. Basically, the estimation error is small if the first $\hat{d}$ kernel PCA components capture most of G and $\hat{d}$ is small such that most of the noise is removed. Note that our assumption that the kernel suits the data set is crucial for both these requirements. If g does not lie in the span of the associated integral operator T_k, the coefficients decay only slowly and a huge number of dimensions are necessary to capture most information about G, leading to a huge amount of residual noise.



(a) Classification ("banana" data set) (b) Regression (noisy sinc function)

Figure 5: Dimensions and estimated noise levels for varying kernel widths are not suited for model selection as it is unclear how to combine both estimates and they become instable for very small kernel widths. Shown are the 10%, 25%, 50%, 75%, and 90% percentiles over 100 resamples. **Legend:** "dimension (%)"—estimated dimensionality divided by number of samples. "noise level"—estimated noise level using the ℓ_1-norm for classification, and the (unnormalized) ℓ_2-norm for regression.

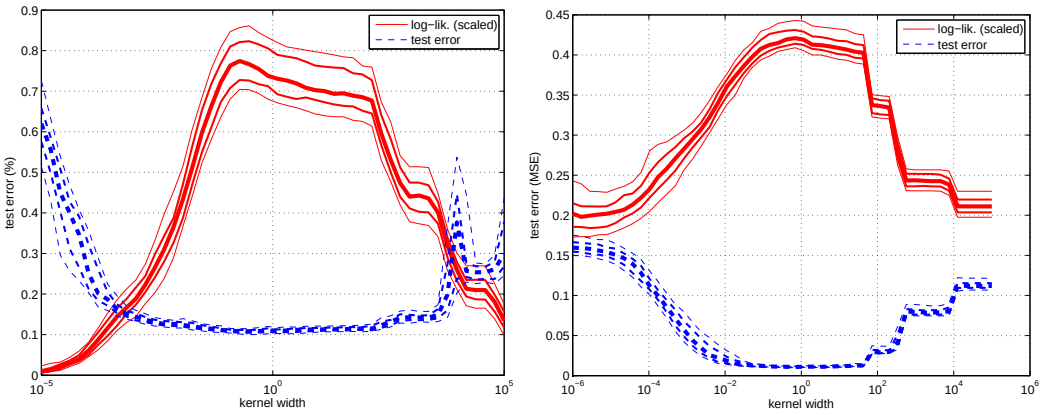
4.3 Applications to Model Selection

A highly relevant problem in the context of kernel methods is the selection of a kernel from a number of possible candidates which fits the problem best. This problem is usually solved by extensive cross-validation.

We would like to discuss possibilities to use the estimates introduced so far for model selection. Choosing the model based on either dimensionality or noise level alone is not sufficient, since one wants to optimize a combination of both. However, as the two terms live on quite different scales, it is unclear how to combine them effectively. Furthermore, as we will see below, both estimates alone become unstable for very small or very large kernel widths. The log-likelihood which achieves the optimum in (4) overcomes both problems and can be used for effective model selection.

Let us first discuss how the relation between the scale of the kernel and the data set can affect the dimensionality of the embedding in feature space. The standard example for a family of kernels with a scale parameter is the rbf-kernel (also known as Gaussian kernel, see Appendix A). Figure 5 shows the dimension and noise level estimates for a classification data set (the "banana" data set), and a regression data set (the "noisy sinc function" with 100 data points for training, and 1000 data points for testing) over a range of kernel widths. Generally speaking, if the scale of the kernel is too coarse for the problem, the problem tends to appear to be very low-dimensional with a large amount of noise. On the other hand, if the scale of the kernel is too fine the learning problem appears to be very complex with almost no noise.

Now, the log-likelihood $\ell(\hat{d})$ solves both problems. It combines the dimension and the noise level into a single meaningful number, and its value is stable across the whole scale range. In Figure 6, we have plotted the log-likelihood (scaled to fit into the plot) against the test error, both



(a) Classification ("banana" data set) (b) Regression (noisy sinc function)

Figure 6: Comparison of test errors and the negative log-likelihood from Equation (3) shows that the negative log-likelihood is highly correlated with the test error and can thus be used for model selection. Shown are the 10%, 25%, 50%, 75%, and 90% percentiles over 100 resamples. **Legend:** "log-lik. (scaled)"—log-likelihood (scaled). "test error"—test error using the ℓ_1-norm for classification, or the (unnormalized) ℓ_2-norm for regression.

with respect to the classification and least squares error. We see that the estimated log-likelihoods can be estimated well over the whole range, and that the likelihoods are highly correlated with the actual test error. Thus, the log-likelihood is a reliable indicator for the test errors based on the best separation between signal and noise.

Another alternative, which is somewhat more straight-forward, but conceptually also less interesting, is to use the leave-one-out cross-validation error. This quantity also measures how well the kernel can separate the noise from the relevant information, and is directly linked to the test error on an independent data set. We validate both model selection approaches experimentally in Section 5.

4.4 Applications to Data Set Assessment

When working on a concrete data set in a kernel setting, one is faced with the problem of finding a suitable kernel. This problem is usually approached with a mix of hard-won experience and domain knowledge. The main tool for guiding the search are prediction performance measures, the classical one being prediction accuracy. Measurements like the ROC (receiver-operator-curve), or the AUC (area-under-the-curve) give more fine-grained measurements of prediction quality, in particular in areas where many false positives or false negatives are not acceptable.

If, after testing a number of sensible candidates, the achieved prediction quality is satisfying, this approach is perfectly adequate, but more often than not, prediction quality is not as good as desirable. In such a case, it is important to identify the cause for the inferior performance. In principle, three alternatives are possible:

1. The kernels which have been used so far are not suited for the problem.

2. The learning problem is very complex and requires more data.

data set	RDE method	dimension	noise-level
complex data set	TCM	50	16.07%
	LOO-CV	25	40.59%
noisy data set	TCM	9	40.71%
	LOO-CV	9	40.71%

Table 2: Estimated dimensions for the two data sets from Figure 7. Methods are "TCM" for RDE by fitting a two-component model, "LOO-CV" for RDE by leave-one-out cross-validation. "noise-level" is measured as normalize mean square error (see Appendix A).

3. Better performance cannot be achieved since the learning problem is intrinsically noisy.

Each of these alternatives requires different approaches. In the first case, a better kernel has to be devised, in the second case, more data has to be acquired, and in the last case, one can either stop searching for a better kernel, or try to improve the quality of the data or the features used.

Ultimately, these questions cannot be answered without knowledge of the true distribution of the data, but the important observation here is that performance measures do not provide enough information to distinguish these cases.

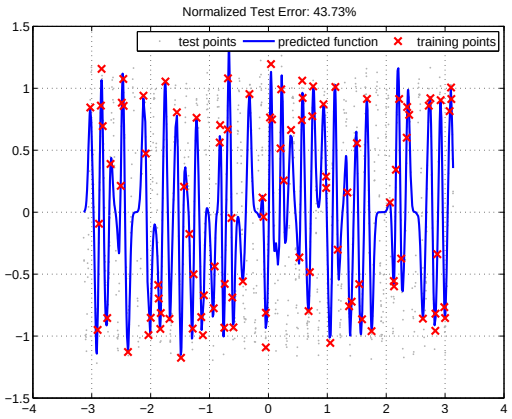
The estimates introduced so far can now be used to obtain evidence for distinguishing between the second and third case. On the one hand, the dimensionality of the problem is related to the complexity of the problem, while the noise level measures the inherent noise. Note that both these estimates depend on the chosen kernel.

Consider the following example: We study two data sets, a simple data set built from a noisy sinc function, and a complex data set based on a high-frequency sine function (see Figure 7). For the same number of data points $n = 100$, both data sets lead to comparable normalized test errors[5] for the best model selected (A normalized test error of 43.7% on the complex data set and 44.4% on the noisy data set using kernel ridge regression with model selection by leave-one-out cross-validation. Widths were selected from 20 logarithmically spaced points from 10^{-6} to 10^{2}, regularization constant was selected from 10 logarithmically spaced points from 10^{-6} to 10^{3}). However, the reason for the large error on the complex data set is clearly due to the small number of samples. If we increase the data set size to 1000 points, the normalized test error becomes 2.4%.

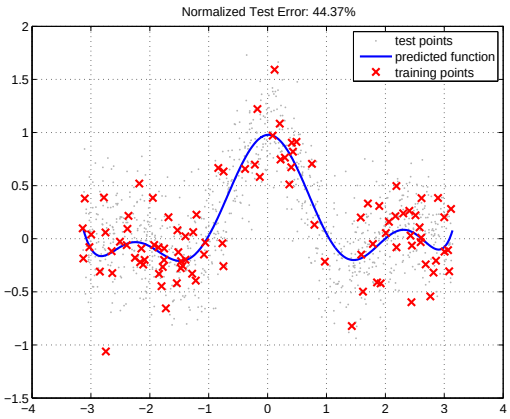
The question is now whether we can distinguish these two cases based on the kernel PCA coefficients. In fact, even on visual inspection, the kernel PCA coefficients display significant differences (see Figures 7(c) and 7(d)). We estimate the effective dimension and the resulting noise-level using the two methods we have proposed, the results are shown in Table 2. While both methods lead to different estimates, they both agree on the fact that the noisy data set has comparably low complexity and high noise, while the complex data set is quite high-dimensional, in particular if one takes into account that the data set contains only 100 data points. In fact, the RDE analysis on the larger complex data set with 1000 data points gives a dimension of 142, and a noise-level of 1.96%. Thus, the RDE measure correctly indicates that the large test error is due to the insufficient amount of data in the one case, and due to the large noise level in the other case.

This simple example demonstrates how the RDE measure can provide further information beyond the error rates. Below, we discuss this approach for several benchmark data sets.

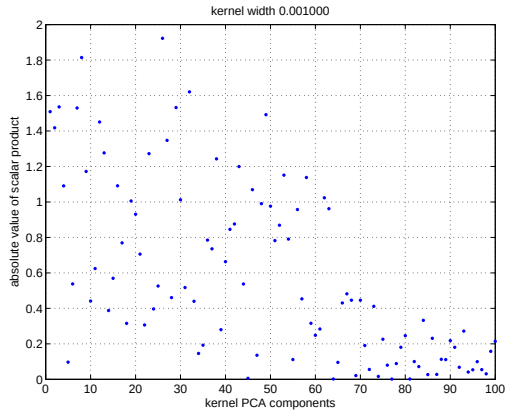
5. See Appendix A for a definition of the normalized error.



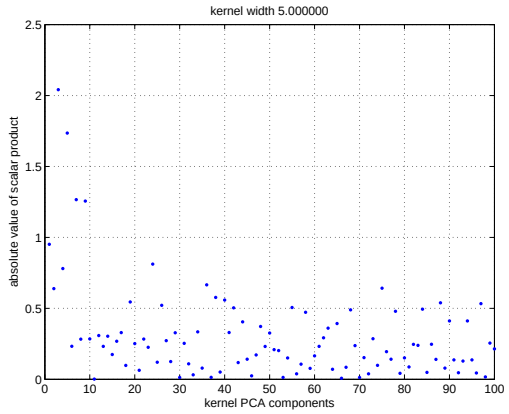
(a) A complex data set.



(b) A noisy data set.



(c) Kernel PCA coefficients for the complex data set.



(d) Kernel PCA coefficients for the noisy data set.

Figure 7: For both data sets, the X values were sampled uniformly between $-\pi$ and π. For the complex data set, $Y = \sin(35X) + \varepsilon$ where ε has mean zero and variance 0.01. For the noisy data set, $Y = \mathrm{sinc}(X) + \varepsilon'$ where ε' has mean zero and variance 0.09. Errors are reported as normalized mean squared error (see Appendix A). Below, the kernel PCA coefficients (scalar products with eigenvectors of the kernel matrix) for the optimal kernel selected based on the RDE (TCM) estimates are plotted. Coefficients are sorted by decreasing corresponding eigenvalue.

5. Experiments

We test our methods on several benchmark data sets. As discussed in the introduction, in order to validate whether our dimension estimates are accurate, we compare the achieved test error rates on the reduced feature space to other state-of-the-art algorithms. If the estimate is accurate, the test errors should be on par with these algorithms. Furthermore, we apply our method to estimate the complexity and noise level of the various data sets.

5.1 Benchmark Data Sets

We performed experiments on the classification data sets from Rätsch et al. (2001). For each of the data sets, we analyze it using a family of rbf kernels (see Appendix A). The kernel width is selected automatically using the achieved log-likelihood as described above. The width of the rbf kernel is selected from 20 logarithmically spaced points between 10^{-2} and 10^4 for each data set.

Table 3 shows the resulting dimension estimates using both RDE methods, with the cross-validation based RDE method being slightly biased towards higher dimensions. We see that both methods perform on par, which shows that the strong structural prior assumption underlying RDE is justified.

To assess the accuracy of the dimensionality estimate, we compare an unregularized least-squares fit in the reduced feature space (RDE+kPCR) with kernel ridge regression (KRR) and support vector machines (SVM) on the original data set. The resulting test errors are also shown in Table 3. Note that the combination of RDE and kPCR is conceptually very similar to the kernel projection machine (Vert et al., 2005) which also produces comparable results. However, in that paper, no practical method for estimating the dimension (beyond cross-validation) has been proposed. From the resulting test errors, we see that a relatively simple method on the reduced features performs on par with the state-of-the-art competitors. We conclude that the identified reduced feature space really contains all of the relevant information. Also note that the estimated noise levels match the actually observed error rates quite well, although there is a slight tendency to under-estimate the true error.

As discussed in Section 4.4, while the test errors only suggest a linear ordering of the data sets by increasing difficulty, using the dimension and noise level estimates, a more fine-grained analysis is possible. We can roughly divide the data sets into four classes (see Table 4), depending on whether the dimensionality is small or large, and the noise level is low or high. Data sets with small noise level show good results, almost irrespective of the dimensionality. The data set *image* seems to be particularly noise free, given that one can achieve a small error in spite of the large dimensionality.

The data sets *breast-cancer*, *diabetes*, *flare-solar*, *german*, and *titanic*, which all have test errors of 20% or more, have only moderately large dimensionalities. This means that the complexity of the underlying optimal decision boundary is not overly large (at least when viewed through the lens of the rbf-kernel), but a large inherent noise level prevents better results. Since this holds for rbf-kernels over a wide range of kernel widths, these results can be taken as a strong indicator that the Bayes error is in fact large.

The *splice* data set seems to be a good candidate for improvement. The noise level is moderately high, while the dimensionality with respect to the rbf-kernel seems quite high. We would like to use our dimensionality and noise level estimate as a tool to examine different kernel choices. (See Section C for further details).

Closer inspection of the data set reveals that a plain rbf-kernel is a suboptimal choice. The task of the splice data set consists in predicting whether there is a *splice-site* in the middle of a string of DNA (such sites encode the beginning and endings of coding regions on the DNA). In the data set, the four amino-acids A, C, G, T are encoded as numbers 1, 2, 3, and 4. Therefore, an rbf-kernel incorrectly assumes that C and G are more similar than A and T. One alternative which is more suited to this data set consists in encoding A, C, G, and T as binary four-vectors. The resulting kernel matrix has much smaller dimension, and also a smaller error rate (see Table 5).

data set	TCM	LOO-CV	TCM-noise level	RDE+kPCR	KRR	SVM
banana	24	26	8.8 ± 1.5	*11.3* $\pm$ *0.7*	**10.6** $\pm$ **0.5**	11.5 ± 0.7

"KRR"—kernel ridge regression with parameters determined by leave-one-out cross-validation. "SVM"—the original error rates from Rätsch et al. (2001). **Best** and *second best* results are highlighted.

	low noise	high noise
low dimensional	banana, thyroid, waveform	breast-cancer, diabetes flare-solar, german heart, titanic
high dimensional	image, ringnorm	splice

Table 4: The data sets by noise level and complexity.

Still, there is further room for improvement. Using a *weighted-degree kernel*, which has been specifically designed for this problem (Sonnenburg et al., 2005), we obtain even better results: While the dimension is again slightly larger (but still moderate compared to the number of 1000 training examples), the noise level is even smaller. The reason is that the weighted degree kernel weights longer consecutive matches on the DNA differently while the rbf kernel just compares individual matches. Again, learning hyperplanes on the subspace of the estimated dimension leads to classification results on the test sets which are close to those predicted by the error level estimate.

6. Discussion

We discuss some implications of our results to learning theory. In particular we show how the "standard picture" on kernels and feature spaces is extended by our results. With respect to practical

kernel	RDE	est. error rate	RDE+kPCR
rbf	87	9.4 ± 1.0	12.9 ± 0.9
rbf (binary)	11	7.1 ± 1.0	7.6 ± 0.7
wdk	29	4.5 ± 0.7	5.5 ± 0.7

Table 5: Different kernels for the splice data set (for fixed kernel width $w = 50$). **Legend:** "rbf"—plain rbf-kernel, "rbf (binary)"—rbf-kernel on A, C, G, T encoded in binary four-vectors, "wdk"—weighted degree kernel (Sonnenburg et al., 2005).

applications we explain the role of RDE as a diagnosis tool for kernels. We close by contrasting our notion of dimension with two closely related dimensions, the dimension of the minimal subspace necessary to capture the relevant information about a learning problem, and the dimension of the data sub-manifold.

6.1 Connections to Learning Theory

We start with some informal reasoning about our findings much like in the spirit of Vapnik (1995). Although our ideas are not developed to all formal details, they are intended to provide some interesting insights on extensions to the general statistical learning theory picture (see Figure 8). The standard picture (see, for example, Burges, 1998; Müller et al., 2001) can be summarized as follows: The learning problem is given in terms of a finite data set in $\mathcal{X} \times \mathcal{Y}$. The kernel k implicitly embeds $\mathcal{X}$ in some (potentially) high-dimensional feature space $\mathcal{F}$ via the feature map Φ. Now since the feature space can be high-dimensional, it is argued that one needs to employ some form of appropriate complexity control in order to be able to learn. A prominent example are large margin classifiers, leading to support vector machines. Other examples include penalization of the norm of the weight vectors, which relates to a penalization of the norm in the resulting reproducing kernel Hilbert space (RKHS).

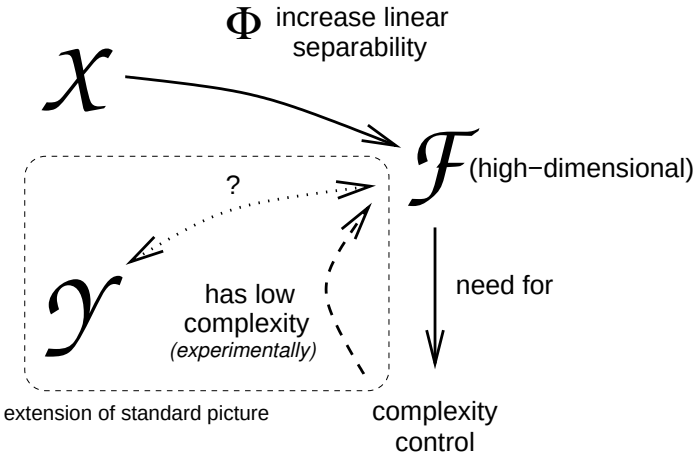

Figure 8: Learning in kernel feature spaces.

This picture is not entirely conclusive since it is not a priori clear that the feature map and the complexity control interact in a benign fashion. For example, it might be possible that the

feature map transforms the data such that a good representation can be learned, but the solution is incompatible with the kind of complexity one is penalizing. On the other hand, the large body of successful applications of kernel methods to real world problems is ample experimental verification of the fact that this seems to be the case and choosing a good kernel leads to an embedding which has low complexity, permitting, for example, large margin classifiers.

The question of the complexity of the image of $\mathcal{X}$ under the feature map actually has two parts. Part 1 concerns the complexity of the embedded object features $\Phi(X)$, while part 2 concerns the relation between the labels Y and the embedded object features $\Phi(X)$.

The first part has already been studied in several works. For example, Blanchard et al. (2007) and Braun (2006) have derived approximation bounds which show that the principal component values approximate the true principal values quickly (see also Mika, 2002; Shawe-Taylor et al., 2005). And since the asymptotic principal values decay rapidly, these results show that most of the variance of the X in feature space is contained in a finite dimensional subspace in feature space. Considering the function class generated by the feature map, Shawe-Taylor et al. (1998) first dealt with the complexity of kernel classes showing that the complexity can be bounded in the spirit of the structural risk minimization framework if a properly regularized class is picked depending on the data, for example by using large margin hyperplanes. Williamson et al. (2001) have further refined these results by using the concept of entropy numbers for compact operators that the complexity of the resulting hypothesis class is actually finite at any given positive scale. Evgeniou and Pontil (1999) show, using the concept of V_γ-dimension, which directly translates to a constraint on the RKHS-norm of the functions, that the resulting hypothesis classes have finite complexity. In summary, the embedding of $\mathcal{X}$ is known to have finite complexity (up to a small residual error).

The second part addresses the question if the embedding also relates favorably to the labels. In this work we have studied this question and answered it positively. One can prove that under mild assumptions on the general fit between the kernel and the learning problem, the information about the labels is always contained in the (typically small) subspace also containing most of the variance about the object features. While this borders on the trivial for the asymptotic setting, we could show that the same also holds true for a concrete finite data set, even at small sample sizes.

Our findings clarify the role of complexity control in feature space. The complexity control is not sufficient for effective learning in the feature space, but necessary. In conjunction with a sensible embedding provided by a suitable choice of the kernel function, it ensures that learning focuses on the relevant information and prevents overfitting. Interestingly, RKHS type penalty terms automatically ensure that the learned function focuses on directions in which the data has large variance, automatically leading to a concentration on the leading kernel PCA components.

6.2 RDE as a Diagnosis Tool

As discussed in Section 4.4, performance measures like the test error are very useful to compare different kernels, but fail to provide evidence if the performance is not as good as desired on whether the right kernel has not been found yet or the problem is intrinsically noisy.

Now, the RDE based estimates proposed in this paper offer a possible new approach to solve this problem. The relevant dimensionality estimate and the noise level estimate allow us to directly address the complexity vs. randomness issue, at least for a given kernel. Of course, our approach only provides a partial answer. However, using a generic kernel like an rbf-kernel for different widths results in an analysis of the data set on a whole range of scale resolutions. If the data set

appears to be low-dimensional and noisy at every scale, there is a strong indication that the noise level is actually quite high.

In the data sets discussed in Section 5, we have considered kernel widths in the range 10^{-2} to 10^4. The data sets *breast-cancer*, *diabetes*, *flare-solar*, *german*, *heart*, and *titanic*, which all have prediction errors larger than 15%, turn out to be fairly low-dimensional over the whole range.

On the other hand, the splice data set seemed to be quite complex, but not very noisy. Using domain knowledge, we improved the encoding, and finally chose a different kernel, which further reduced the complexity and noise (see Section C for further details).

In summary, using the RDE based estimates as a diagnosis tool, it is possible to obtain more detailed insights into how well a kernel is adapted to the characteristic properties of a data set and its underlying distribution than by using integrative performance measures like test errors only.

6.3 The "True" Dimensionality of the Data

We estimate the number of leading kernel PCA components necessary to capture the relevant information contained in the learning problem. This "relevant dimensionality estimate" captures only a very special kind of dimensionality notion, and we would like to compare it with two other aspects of dimensionality.

In our dimensionality estimate, the basis was fixed and given by leading kernel PCA components. One might wonder how many dimensions are necessary to capture the relevant information about the learning problem if one were also allowed to choose the basis. The answer is easy: In order to capture G, it suffices to consider the one-dimensional space spanned by G itself, which means that the minimal dimensionality of the learning problem is 1. However, note that G is not known, and estimating G amounts to solving the learning problem itself. In other words, the choice of a kernel can be interpreted as implicitly specifying an appropriate basis in feature space which is able to capture G using as few basis vector as possible, *and* also using a subspace which contains as much of the variance of the data as possible.

For most data sets, the different input variables are highly dependent, such that the data does not occupy all of the space but only a sub-manifold in the space. The dimension of this sub-manifold is a further notion of dimensionality of a data set. However, note that we consider the dimensionality of the data with respect to the information in the labels, while the sub-manifold view usually concentrates on the inputs only. Also, we are considering linear subspaces (in an RKHS), which typically require more dimensions to capture the data than a non-linear manifold would. On the other hand, since we are only looking at the subspace which is relevant for predicting the labels, the estimated dimension may also be smaller than the dimension of the data manifold in feature space.

7. Conclusion

Both in theory and on practical data sets, we have demonstrated that the relevant information in a supervised learning scenario is contained in the leading projected kernel PCA components if the kernel matches the learning problem and is sufficiently smooth. This behavior complements the common statistical learning theoretical view on kernel based learning adding insight on the intricate interplay of data and kernel: An appropriately selected kernel (a) leads to an efficient model which generalizes well, since only a comparatively low dimensional representation has to be learned for a

fixed given data size. An appropriately selected kernel (b) permits a dimension reduction step that discards some irrelevant projected kernel PCA directions and thus yields a regularized model.

We propose two algorithms for the relevant dimensionality estimate (RDE) task. These can also be used to automatically select a suitable kernel model for the data and to extract as additional side information an estimate of the effective dimension and estimated expected error for the learning problem. Compared to common cross-validation techniques one could argue that all we have achieved is to find a similar model as usual at a comparable computing time. However, we would like to emphasize that the side information extracted by our procedure contributes to a better understanding of the learning problem at hand: Is the classification result limited due to intrinsic high dimensional structure or are we facing noise and nuisance dimensions? Simulations show the usefulness of our RDE algorithms.

An interesting future direction lies in combining these results with generalization bounds which are also based on the notion of an effective dimension, this time, however, with respect to some regularized hypothesis class (see, for example, Zhang, 2005). Linking the effective dimension of a data set with the "dimension" of a learning algorithm, one could obtain data dependent bounds in a natural way with the potential to be tighter than bounds which are based on the abstract capacity of a hypothesis class.

Acknowledgments

Parts of this work have been performed while MLB was with the Intelligent Data Analysis Group at the Fraunhofer Institute FIRST. The authors would like to thank Volker Roth, Tilman Lange, Gilles Blanchard, Stefan Harmeling, Motoaki Kawanabe, Claudia Sannelli, Jan Müller, and Nicole Krämer for fruitful discussions. The authors would also like to thank the anonymous referees whose comments have helped to improve the paper further, and in particular Peter Bartlett for his valuable comments. This work was supported in part by the BMBF FaSor project, 16SV2234, and by the FP7-ICT Programme of the European Community, under the PASCAL2 Network of Excellence, ICT-216886.

Appendix A. Data Sets and Kernel Functions

In this section, we introduce some data sets and define the Gaussian kernel, since there exists some variability with respect to its parameterization.

A.1 Gaussian kernel

The Gaussian kernel, or rbf-kernel, used in this paper are parameterized as follows: The Gaussian with width w is

$$k(x,y) = \exp\left(-\frac{\|x-y\|^2}{2w}\right).$$

A.2 Classification Data Sets

For classification, we use the data sets from Rätsch et al. (2001). This benchmark data set consists of 13 classification data sets, which are partly synthetic, and partly derived from real-world data. The data sets are pre-arranged into different resamples of training and test data sets. The number

of resamples is 100 with the exception of the "image" and "splice" data sets which have only 20 resamples (because these data sets are fairly large). For visualization purposes, we often take the first resample of the "banana" data set, which is a two-dimensional classification problem (see Figure 1(a)).

A.3 Regression Data Sets

The "noisy sinc function" data set is defined as follows:

$$\begin{aligned} X_i &\sim \text{uniformly from } [-\pi,\pi], \\ Y_i &= \operatorname{sinc}(X_i) + \varepsilon_i, \\ \varepsilon_i &\sim \mathcal{N}(0,\sigma_\varepsilon^2). \end{aligned}$$

There are different alternatives for defining the sinc function, we choose $\operatorname{sinc}(x) = \sin(\pi x)/\pi x$, $\operatorname{sinc}(0) = 1$.

For regression, we sometimes measure the error using the "normalized mean squared error." If the original labels are given by Y_i, $1 \le i \le n$, and the predicted ones are $\hat{Y}_i$, then this error is defined as

$$\text{nmse} = \frac{\sum_{i=1}^n (Y_i - \hat{Y}_i)^2}{\sum_{i=1}^n (Y_i - \frac{1}{n}\sum_{j=1}^n Y_j)^2}.$$

Appendix B. Proof of the Main Theorem

In this section, the main theorem of the paper is stated and proven. We start with some definitions, then introduce and discuss the assumptions of the main result. Next we define a few quantities on which the bound depends. The bound itself is split into two theorems. First the general bound is derived and then the asymptotic rates of these quantities are studied.

B.1 Preliminaries

Using the probability measure P_X which generates the Xs, we can define a scalar product via $\langle f,g\rangle = \int_X f(x)g(x)\mathrm{P}_X(dx)$ which induces the Hilbert space $\mathcal{L}^2(\mathcal{X},\mathrm{P}_X)$. Unless indicated otherwise, $\|f\|$ will denote the norm with respect to this scalar product. Let $k(x,y) = \sum_{\ell=1}^\infty \lambda_\ell \psi_\ell(x)\psi_\ell(y)$ be a kernel function (such that $\lambda_\ell \ge 0$). The ψ_ℓ form an orthogonal family of functions on the Hilbert space $\mathcal{L}^2(\mathcal{X},\mathrm{P}_X)$. Given an n-sample $X_1,\ldots,X_n$ from P_X, the sample vector of a function g is the vector $g(\mathbf{X}) = (g(X_1),\ldots,g(X_n))$. The kernel matrix given a kernel function k and an n-sample $X_1,\ldots,X_n$ is the $n\times n$ matrix $\mathbf{K}$ with entries $k(X_i,X_j)/n$.

Let $g(x) = \sum_{\ell=1}^\infty \alpha_\ell \lambda_\ell \psi_\ell(x)$ with $(\alpha_\ell) \in \ell^2$, the set of all square-summable sequences. The expansion of g in terms of $\lambda_\ell\psi_\ell$ amounts to assuming that g lies in the range of the integral operator T_k defined by $T_k f = \int_\mathcal{X} k(\cdot,x) f(x)\mathrm{P}_X(dx)$. Then, $g = T_k h$ with $h = \sum_{\ell=1}^\infty \alpha_\ell\psi_\ell$.

The act of truncating an object with an infinite expansion to its first r coefficients is so ubiquitous in the following that we introduce a generic notation. If k is a kernel function, $\tilde{k}$ is the kernel function whose expansion has been reduced to the first r terms. Likewise, $\tilde{\mathbf{K}}$ is the kernel matrix induced by $\tilde{k}$. For a sequence $(\alpha_\ell) \in \ell^2$, $\tilde{\alpha}$ is the tuple consisting of the first r elements of the sequence. The sample vector matrices $\tilde{\Psi}$ is formed by the sample vector of the first r eigenvectors, that is, $\tilde{\Psi}_{ij} = \psi_j(X_i)/\sqrt{n}$, and $\tilde{\Lambda}$ is the diagonal matrix formed from the first r eigenvalues, such that $\tilde{\mathbf{K}} = \tilde{\Psi}\tilde{\Lambda}\tilde{\Psi}^\top$. Finally, $\tilde{g}$ is obtained from g by truncating the expansion to the first r eigenfunctions.

The eigen-decompositions of the kernel matrix and the truncated kernel matrix (kernel matrix for the truncated kernel function) are

$$\mathbf{K} = \mathbf{U}\mathbf{L}\mathbf{U}^\top, \qquad \tilde{\mathbf{K}} = \tilde{\mathbf{U}}\tilde{\mathbf{L}}\tilde{\mathbf{U}}^\top,$$

where $\mathbf{U}$, $\tilde{\mathbf{U}}$ are orthogonal matrices with columns u_i, $\tilde{u}_j$, and $\mathbf{L}$, $\tilde{\mathbf{L}}$ are diagonal matrices with entries l_i, $\tilde{l}_j$, such that the eigenpairs of $\mathbf{K}$ are (l_i, u_i), and those of $\tilde{\mathbf{K}}$ are $(\tilde{l}_j, \tilde{u}_j)$. We stick to the general convention that eigenvalues are always sorted in decreasing order.

Tail-sums of eigenvalues are denoted by

$$\Lambda_{>r} = \sum_{i=r+1}^{\infty} \lambda_i, \qquad \Lambda_{\geq r} = \sum_{i=r}^{\infty} \lambda_i.$$

We will refer to the following result relating decay rates of the eigenvalues to the tail-sums. For proofs, see, for example, Braun (2006). It holds that if $\lambda_r = r^{-d}$ with $d \geq 1$, then $\Lambda_{>r} = O(r^{1-d})$. If $\lambda_r = \exp(-cr)$ with $c > 0$, then $\Lambda_{>r} = O(\exp(-cr))$. The same rates hold for $\Lambda_{\geq r}$.

Furthermore, we will often make use of the fact that $\sqrt{a+b} \leq \sqrt{a} + \sqrt{b}$ if $a, b \geq 0$.

B.2 Assumptions

The overall goal is to derive a meaningful upper bound on $\frac{1}{\sqrt{n}}|u_i^\top g(\mathbf{X})|$. In particular, the bound should scale with the corresponding eigenvalue l_i. We proceed as follows: First, we derive the actual bound which depends on a number of quantities. In the next step, we estimate the worst case asymptotic rates of these quantities. The actual bound depends on assumptions which are discussed in the following.

(A1) We assume that the kernel is uniformly bounded, that is,

$$\sup_{x,y \in \mathcal{X} \times \mathcal{X}} |k(x,y)| = K < \infty.$$

(A2) We assume that $n \geq r$ large enough such that $\tilde{\Psi}^\top \tilde{\Psi}$ is invertible.

(A3) We assume that $\lambda_i = O(i^{-5/2-\varepsilon})$ for some $\varepsilon > 0$.

Assumption (A1) is true for radial basis functions like the Gaussian kernel, but also if the underlying space $\mathcal{X}$ is compact and the kernel is continuous. From (A1), it follows easily that g is bounded as well since

$$|g(x)| \leq K\|h\|.$$

Furthermore, since the ψ_i are orthogonal, it follows that $\|h - \tilde{h}\| \leq \|h\|$, and therefore

$$|g(x) - \tilde{g}(x)| \leq K\|h\|$$

since $g - \tilde{g} = T_k(h - \tilde{h})$, and therefore $|g(x) - \tilde{g}(x)| \leq K\|h - \tilde{h}\| \leq K\|h\|$. These inequalities play an important role for bounding the truncation error $g - \tilde{g}$ in a finite sample setting.

Since the sample vectors $\psi_\ell(\mathbf{X})$ are asymptotically pairwise orthogonal, $\tilde{\Psi}^\top \tilde{\Psi}$ converges to $\mathbf{I}$, and for large enough n, assumption (A2) is met. See also Lemma 2 below.

Assumption (A3) ensures that the term $r(\sum_{i=1}^{r}|\alpha_i|)\Lambda_{\geq r}$ occurring in the bound vanishes as $r \to \infty$. Note that since the sequence of α_i is square-summable,

$$\sum_{i=1}^{r}|\alpha_i| \leq \sqrt{r\sum_{i=1}^{r}\alpha_i^2} \leq \sqrt{r}\|\alpha\|_{\ell^2} = O(\sqrt{r}).$$

Therefore, $r\sum_{i=1}^{r}|\alpha_i| = O(r^{3/2})$. Also, $\Lambda_{\geq r} = O(r^{-3/2-\varepsilon})$, such that $r(\sum_{i=1}^{r}|\alpha_i|)\Lambda_{\geq r} = O(r^{-\varepsilon})$. Note that (A3) is quite modest and eigenvalues often decay much faster, even at exponential rates.

B.3 The Main Result

The following five quantities occur in the bound:

- $c_i = |\{1 \leq j \leq r \mid l_i/2 \leq \tilde{l}_j \leq 2l_i\}|$ is the number of eigenvalues of the truncated kernel matrix which are close to the eigenvalues of the normal kernel matrix. This is a measure for the approximate degeneracy of eigenvalues.
- $\tilde{a} = \|\tilde{\alpha}\|_1$, is a measure for the size of the first r coefficients which define g.
- $\tilde{\mathbf{E}} = \mathbf{K} - \tilde{\mathbf{K}}$ is the truncation error for the kernel matrix.
- $\tilde{T} = \|g - \tilde{g}\| = \sqrt{\sum_{j=r+1}^{\infty}\alpha_j^2\lambda_j^2}$ is the asymptotic truncation error for the function g.
- $F = \|g\|_\infty < \infty$, an upper bound on g.

We study these quantities in more detail after proving the actual bound, which follows next.

Theorem 1 *With the definitions introduced so far, it holds that with probability larger that* $1-\delta$, *for all* $1 \leq i \leq n$,

$$\frac{1}{\sqrt{n}}|u_i^\top g(\mathbf{X})| < \min_{1\leq r\leq n}\left[l_i c_i D(r,n) + E(r,n) + T(r,n)\right]$$

where the three terms are given by

$$D(r,n) = 2\tilde{a}\|\tilde{\Psi}^+\|, \qquad E(r,n) = 2r\tilde{a}\|\tilde{\Psi}^+\|\|\tilde{\mathbf{E}}\|, \qquad T(r,n) = \tilde{T} + \sqrt{F\tilde{T}}\sqrt[4]{\frac{1}{n\delta}}.$$

Proof First, we replace $g = \tilde{g} + (g - \tilde{g})$ and obtain

$$\frac{1}{\sqrt{n}}|u_i^\top g(\mathbf{X})| \leq \frac{1}{\sqrt{n}}|u_i^\top \tilde{g}(\mathbf{X})| + \frac{1}{\sqrt{n}}\|g(\mathbf{X}) - \tilde{g}(\mathbf{X})\| =: \text{(I)},$$

using the Cauchy-Schwarz-inequality and the fact that $\|u_i\| = 1$ for the second term.

Next, we re-express $\tilde{g}(\mathbf{X}) = \sum_{\ell=1}^{r}\lambda_\ell\alpha_\ell\psi_\ell(\mathbf{X})$ as follows. By definition, $\tilde{g}(\mathbf{X})$ lies in the image of $\tilde{\mathbf{K}}$, therefore, $\tilde{g}(\mathbf{X}) = \sum_{j=1}^{r}\tilde{u}_j\tilde{u}_j^\top\tilde{g}(\mathbf{X})$. Using both these equations, we obtain

$$\frac{1}{\sqrt{n}}|u_i^\top\tilde{g}(\mathbf{X})| \leq \sum_{\ell=1}^{r}|\alpha_\ell|\sum_{j=1}^{r}(u_i^\top\tilde{u}_j)\left[\frac{1}{\sqrt{n}}\lambda_\ell\psi_\ell(\mathbf{X})^\top\tilde{u}_j\right] =: \text{(II)}$$

The term $u_i^\top \tilde{u}_j$ measures the angle between the eigenvectors of $\mathbf{K}$ and $\tilde{\mathbf{K}}$. Note that $\mathbf{K}$ can be considered an additive perturbation of $\tilde{\mathbf{K}}$ by $\tilde{\mathbf{E}} = \mathbf{K} - \tilde{\mathbf{K}}$. Such perturbations are studied by the so-called *sin-theta-theorems*. Specializing Theorem 6.2 of Davis and Kahan (1970) (see Section D) to two single eigenvectors, we obtain that

$$|u_i^\top \tilde{u}_j| \leq \min\left(\frac{\|\tilde{\mathbf{E}}\|}{|l_i - \tilde{l}_j|}, 1\right).$$

The term $\lambda_\ell \psi_\ell(\mathbf{X})^\top \tilde{u}_j/\sqrt{n}$ is bounded by $\tilde{l}_j \|\tilde{\Psi}^+\|$ (where Ψ^+ denotes the pseudo-inverse of Ψ), since

$$\tilde{l}_j \tilde{u}_j = \tilde{\mathbf{K}}\tilde{u}_j = \tilde{\Psi}\tilde{\Lambda}\tilde{\Psi}^\top \tilde{u}_j \qquad \Rightarrow \qquad \tilde{l}_j \tilde{\Psi}^+ \tilde{u}_j = \tilde{\Lambda}\tilde{\Psi}^\top \tilde{u}_j.$$

Taking norms, we obtain $\|\tilde{\Lambda}\tilde{\Psi}^\top \tilde{u}_j\| \leq \tilde{l}_j \|\tilde{\Psi}^+\|$, from which the claimed inequality follows for each individual coordinate of the vector on the left-hand side.

Combining the bounds for the two terms $u_i^\top \tilde{u}_j$ and $\lambda_\ell \psi_\ell(\mathbf{X})^\top \tilde{u}_j/\sqrt{n}$, we obtain

$$(u_i^\top \tilde{u}_j)\left[\frac{1}{\sqrt{n}}\lambda_\ell \psi_\ell(\mathbf{X})^\top \tilde{u}_j\right] \leq \|\tilde{\Psi}^+\| \min\left(\frac{\|\tilde{\mathbf{E}}\|}{|l_i - \tilde{l}_j|}, 1\right)\tilde{l}_j =: \|\tilde{\Psi}^+\| c_{ij}.$$

For $j \notin J(l_i) = \{1 \leq j \leq r \mid \frac{1}{2} l_i \leq \tilde{l}_j \leq 2l_i\}$, it holds that $\|\tilde{\mathbf{E}}\|\tilde{l}_j/|l_i - \tilde{l}_j| \leq 2\|\tilde{\mathbf{E}}\|$, therefore,

$$\sum_{j=1}^{r} c_{ij} = \sum_{j \in J(l_i)} c_{ij} + \sum_{j \notin J(l_i)} c_{ij} \leq 2|J(l_i)|l_i + 2r\|\tilde{\mathbf{E}}\|.$$

We have just shown that

$$\text{(II)} \leq \|\tilde{\Psi}^+\| \sum_{\ell=1}^{r} |\alpha_\ell| \left(2|J(l_i)|l_i + 2r\|\tilde{\mathbf{E}}\|\right). \tag{7}$$

Now concerning the other term in (I), note that by the strong law of large numbers,

$$\frac{1}{n}\|g(\mathbf{X}) - \tilde{g}(\mathbf{X})\|_{\mathbb{R}^n}^2 \to \|g - \tilde{g}\|_{L^2(X, \mathrm{P}_X)}^2 = \sum_{j=r+1}^{\infty} \alpha_j^2 \lambda_j^2 =: \tilde{T}^2.$$

Since g is bounded, $\|g\|_\infty = F < \infty$, we can bound the variance of $g - \tilde{g}$:

$$\mathrm{Var}_{\mathrm{P}_X}((g - \tilde{g})^2) \leq \|g - \tilde{g}\|_\infty^2 \|g - \tilde{g}\|^2 = F^2 \tilde{T}^2.$$

We can thus bound the probability of a large deviation using the Chebychev-inequality. Taking the square roots, we obtain that with probability larger than $1 - \delta$,

$$\frac{1}{\sqrt{n}}\|g(\mathbf{X}) - \tilde{g}(\mathbf{X})\| \leq \tilde{T} + \sqrt{F\tilde{T}}(n\delta)^{-\frac{1}{4}}. \tag{8}$$

Combining bound (7) and (8), we obtain that

$$\frac{1}{\sqrt{n}}|u_i^\top g(\mathbf{X})| \leq 2l_i|J(l_i)|\|\tilde{\alpha}\|_1\|\tilde{\Psi}^+\| + 2r\|\tilde{\mathbf{E}}\|\|\tilde{\alpha}\|_1\|\tilde{\Psi}^+\| + \tilde{T} + \sqrt{F\tilde{T}}(n\delta)^{-\frac{1}{4}}.$$

This proves the upper bound on the coefficients. ■

B.4 Worst Case Asymptotic Rates of the Error Matrices

The bound depends on a number of error terms, whose worst case asymptotic rates and their dependency on r are studied next.

The norm of the pseudo-inverse of $\tilde{\Psi}$ can be related to the matrix $\tilde{\mathbf{C}} = \tilde{\Psi}^\top\tilde{\Psi} - \mathbf{I}$, which measures the deviation from orthonormality of the sample vectors of the first r eigenfunctions of T_k. Since the eigenfunctions are asymptotically orthonormal, it is guaranteed that $\|\tilde{\mathbf{C}}\| \to 0$ as $n \to \infty$.

Lemma 2 *Let* $\tilde{\mathbf{C}} = \tilde{\Psi}^\top\tilde{\Psi} - \mathbf{I}$. *If* $\|\tilde{\mathbf{C}}\| < 1$, *then*

$$\|\tilde{\Psi}^+\| \leq (1 - \|\tilde{\mathbf{C}}\|)^{-1/2} = 1 + O(\sqrt{\|\tilde{\mathbf{C}}\|}).$$

Proof Recall that $\|\tilde{\Psi}^+\| = 1/\sigma_r(\tilde{\Psi})$, where $\sigma_r(\tilde{\Psi})$ is the rth singular value of $\tilde{\Psi}$ in descending order. The singular values are the square roots of the eigenvalues of $\tilde{\Psi}^\top\tilde{\Psi}$, and

$$1 - \lambda_r(\tilde{\Psi}^\top\tilde{\Psi}) \leq \max_{1\leq i\leq r} |\lambda_i(\tilde{\Psi}^\top\tilde{\Psi}) - 1| \leq \|\tilde{\Psi}^\top\tilde{\Psi} - \mathbf{I}\|,$$

and therefore $\sigma_r(\tilde{\Psi}) = (\lambda_r(\tilde{\Psi}^\top\tilde{\Psi}))^{1/2} \geq (1 - \|\tilde{\Psi}^\top\tilde{\Psi} - \mathbf{I}\|)^{1/2}$, which proves the inequality.

For the asymptotic rate, observe that

$$\|\tilde{\Psi}^+\| \leq \sqrt{\frac{1}{1 - \|\tilde{\mathbf{C}}\|}} = \sqrt{\frac{\|\tilde{\mathbf{C}}\|^{-1}}{\|\tilde{\mathbf{C}}\|^{-1} - 1}} = \sqrt{1 + \frac{1}{\|\tilde{\mathbf{C}}\|^{-1} - 1}} \leq 1 + \sqrt{\frac{1}{\|\tilde{\mathbf{C}}\|^{-1} - 1}}.$$

Now, $1/(x-1) = O(1/x)$ for $x \to \infty$, which proves the asymptotic rate. ■

The two error matrices $\tilde{\mathbf{C}}$ and $\tilde{\mathbf{E}}$ were discussed in depth by Braun (2006). However, note that these asymptotic rates are worst case rates over certain families of kernel functions. This means that the results on the asymptotic rates do not describe typical behavior but rather worst case behavior, and their main purpose of these rates is to ensure that the error terms cannot diverge rather than giving realistic estimates.

The following result is Theorem 4 from Braun (2006).

Lemma 3 *For* $1 \leq r \leq n$, *with probability larger than* $1 - \delta$,

$$\|\tilde{\mathbf{C}}\| < r\sqrt{\frac{r(r+1)K}{\lambda_r n\delta}}, \qquad \|\tilde{\mathbf{E}}\| < \lambda_r + \Lambda_{>r} + \sqrt{\frac{2K\Lambda_{>r}}{n\delta}}.$$

¿From Lemma 3, it follows that

$$\|\tilde{\Psi}^+\| = 1 + O(r\lambda_r^{-1/4} n^{-1/4}),$$
$$\|\tilde{\mathbf{E}}\| = \Lambda_{\geq r} + O(\sqrt{\Lambda_{>r}}\, n^{-1/2}).$$

If we plug these rates into the bound from Theorem 1 and suppress all parts which converge to zero, the bound becomes

$$\frac{1}{\sqrt{n}} |u_i^\top g(\mathbf{X})| \leq 2c_i\tilde{a}l_i + 2r\tilde{a}\Lambda_{\geq r} + \tilde{T} + \text{terms which vanish as } n \to \infty.$$

We see that the general structure of the bound consists a part which scales with the eigenvalue under consideration and an additive part which is independent of i. The factor of the scaling part increases with r since $\tilde{a} = O(\sqrt{r})$ in the worst case. At the same time, the truncation error $\tilde{T}$ arising from the truncation of g becomes smaller as r is increased, and by assumption (A3), it is ensured that the second term actually converges to zero as $r \to \infty$. The two parts therefore form a trade-off and by choosing r, one can balance these two terms.

Now, in particular the convergence of $\|\tilde{\Psi}^+\| \to 1$ can be quite slow in the worst case, if the eigenvalues of the kernel matrix decay quickly (see the paper by Braun, 2006, for a more thorough discussion including an artificial example of a kernel function which achieves the described rate). However, note that $\|\tilde{\Psi}^+\|$ only occurs in conjunction with terms involving eigenvalues, such that the overall bound still converges. For example, one can prove that a decay rate of λ_r faster than $O(r^{-12})$ ensures that $E(r,n) = 2r\tilde{a}\|\tilde{\Psi}^+\|\|\tilde{\mathbf{E}}\| \to 0$ for $r \to \infty$ independently of n: It holds that

$$E(r,n) = 2r\tilde{a}\|\tilde{\Psi}^+\|\|\tilde{\mathbf{E}}\| = 2r\tilde{a}\left(1 + O(r\lambda_r^{-1/4}n^{-1/4})\right)\left(\Lambda_{\geq r} + O(\sqrt{\Lambda_{>r}}n^{-1/2})\right).$$

If one expands the product, the term which decays slowest with respect to r is (recall that $\tilde{a} = O(\sqrt{r})$)

$$2r\tilde{a}O(r\lambda_r^{-1/4})O(\sqrt{\Lambda_{>r}}) = O(r^{5/2}\lambda_r^{-1/4}\Lambda_{>r}^{1/2}).$$

Now if $\lambda_r = r^{-d}$, then $\Lambda_{>r} = O(r^{1-d})$, and

$$O(r^{5/2}\lambda_r^{-1/4}\Lambda_{>r}^{1/2}) = O(r^{5/2}r^{d/4}r^{(1-d)/2}) = O(r^{3-d/4}).$$

We require that the exponent is smaller than 0 which is true if $d > 12$. Again, since these are worst case considerations, and usually r and n will be coupled in some way, the additive terms will be controlled even for slower decay rates.

An interesting feature of the bound is that it is uniform in i, which means that the bound holds simultaneously for all eigenvectors. Therefore, the individual bounds can be combined, for example, to sums of scalar products without a decrease in the probability with which the bound holds.

In principle, it is possible to further relate the decay rate of the eigenvalues of the kernel matrix l_i to the asymptotic eigenvalue λ_i, for example using bounds for individual eigenvalues (Braun, 2006), or tail-sums of eigenvalues (Blanchard et al., 2007; Shawe-Taylor et al., 2005) if we wish to explicitly control the component of the relevant information vector which is not contained in the leading kernel PCA directions.

Appendix C. A Worked Through Example

In this section, we work through the "splice" data set to show how one would perform a kernel fitness analysis using the methods presented here. The computations of the estimates proposed in Section 4 are summarized in Algorithm 1.

We start out with the splice data set. As explained in the main section, each data points encodes sequence of aminoacids. In the positive examples, there exists a so-called splice site in the center of the encoded DNA signal. The task requires to predict splice sites in these short DNA sequences.

Usually, one would start with some specific kernel, for example an rbf-kernel, train some kernel learning algorithm using this kernel, evaluate the kernel on some test data set, and start to select different parameters. There are two potential drawbacks following this approach: (1) there exists

Algorithm 1 Computing the estimates from Section 4

Input: Kernel matrix $\mathbf{K}$, label vector Y, loss function L
Output: kernel PCA coefficients z, dimensionality $\hat{d}$,
negative log-likelihood $\hat{\ell}$, denoised labels $\hat{Y}$,
noise-level $\hat{\text{err}}$

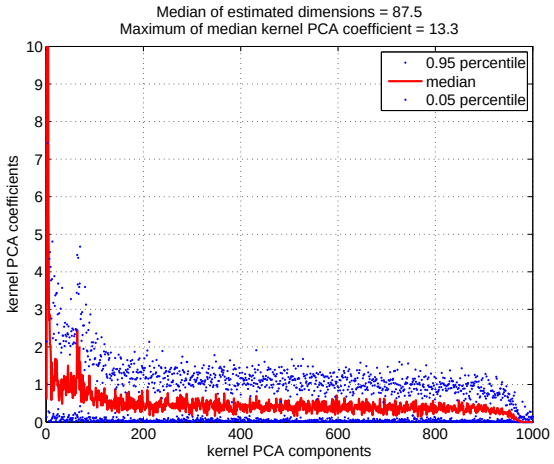
1: {*Compute kernel PCA coefficients*}
2: Compute eigendecomposition $\mathbf{KU} = \mathbf{UD}$
3: $z \leftarrow \mathbf{U}^\top Y$
4: {*Estimate dimensionality $\hat{d}$ (Eq. 4)*}
5: $c \leftarrow 0$; $C \leftarrow \|z\|^2$ {here, it is shown in detail how to achieve linear run-time}
6: **for** $d = 1$ to $n/2$ **do**
7: $\quad c \leftarrow c + z_i^2$
8: $\quad s_1 \leftarrow c/d$
9: $\quad s_2 \leftarrow (C-c)/(n-d)$
10: $\quad l_d \leftarrow d \log s_1 + (n-d)\log s_2$
11: **end for**
12: $\hat{d} \leftarrow \operatorname{argmin}_{1 \le d \le n/2} l_d$
13: $\hat{\ell} \leftarrow l_{\hat{d}}$.
14: {*Compute denoised labels (Eq. 5)*}
15: Extract first $\hat{d}$ eigenvectors $\mathbf{T} \leftarrow \mathbf{U}_{:,1:\hat{d}}$
16: $\hat{Y} \leftarrow \mathbf{TT}^\top Y$
17: {*Estimate noise-level (Eq. 6)*}
18: $\hat{err} = \frac{1}{n}\sum_{i=1}^n L(Y, \hat{Y})$

no absolute measure of the goodness of a certain kernel choice, only comparisons to other kernels, (2) there exists some dependency on the kernel learning method employed. Using the methods developed in this paper, it is possible to explore the relationship between the kernel and the data set in an algorithm independent way. Furthermore, in the case of poor performance, it is possible to distinguish between very complex cases (which require more input data), and cases where the data set appears to be very noisy (either requiring better data quality, or a kernel which can capture more information about the learning problem).

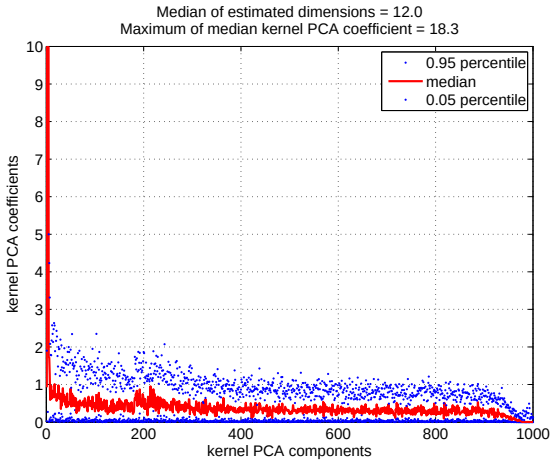
The splice data set consists of 20 resamples. We first try an rbf-kernel with width $w = 50$ (see Section A). We start by computing and plotting the kernel PCA coefficients. The resulting coefficients are plotted in Figure 9(a). We see that the data set appears to be rather high-dimensional, and the noise level is also quite high. The estimated median estimated dimension is 87.5, but it seems that roughly up to dimension 200, relevant information might be contained.

As explained in the main text, the encoding used by the rbf-kernel is not fit for this example. The four aminoacids A, C, G, and T have just been mapped to the numbers 1–4. We re-encode the object features by mapping A, C, G, and T to the four vectors $(1,0,0,0)$, $(0,1,0,0)$, and so on. The resulting kernel PCA coefficients are plotted in Figure 9(b). The encoding has obviously resulted in a large improvement, as the dimension is much smaller now, while the amount of noise has also been reduced.

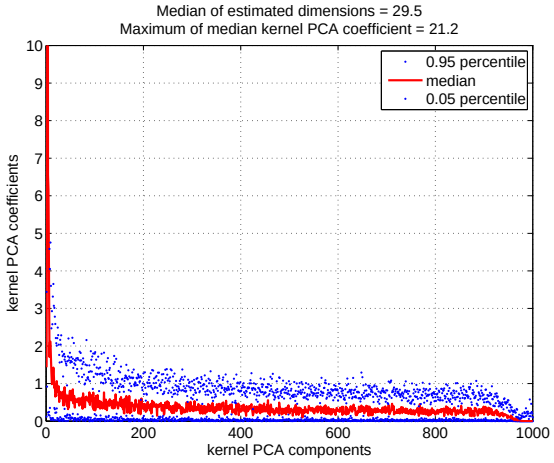
Finally, we consider using a weighted-degree-kernel (Sonnenburg et al., 2005). The resulting kernel PCA coefficients are plotted in Figure 9(c). While the estimated dimension is larger than



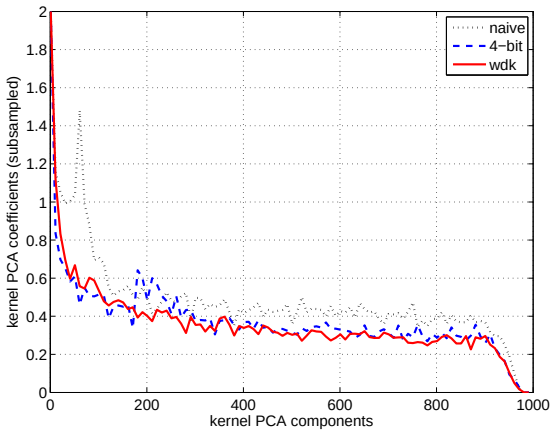
(a) Rbf-kernel on the original data.



(b) Encoding the aminoacids using four bits.



(c) Using a weighted-degree kernel.



(d) The mean kernel PCA coefficients of all three kernels compared (coefficients clipped to the interval from 0 to 2).

Figure 9: Figures (a)-(c) show 0.05, 0.5, and 0.95 percentiles of the kernel PCA coefficients over the 20 resamples of the *splice* data set using the indicated kernels. Coefficients have been truncated to the range $[0, 10]$ for better visibility. Figure (d) plots all three medians for comparison (subsampled by combining ten consecutive points into their mean for better visibility). Coefficients are sorted by decreasing corresponding eigenvalue.

in the previous case, the amount of noise was dramatically reduced, which is also reflected in the classification results shown in Table 5.

In summary, using the estimates here, one can get a much more fine-grained assessment of how well a kernel is adapted to the data. Figure 9(d) compares the mean kernel PCA coefficients over the resamples for the three kernels. Initially, the splice data set appears to be rather high-dimensional, indicating that more data would be needed. Incorporating domain knowledge in the encoding and finally switching to a special-purpose kernel shows that the true dimensionality of the data is in fact

smaller, and that the noise level, which was initially quite high, could also be lowered significantly. Using the weighted-degree-kernel the data quality and the amount of data seem to be suited for predicting with high accuracy.

Appendix D. A Sin-Theta-Theorem

The following theorem is a special case of Theorem 6.2 in the book by Davis and Kahan (1970).

Theorem 2 *Let* $\mathbf{A}$ *be a symmetric* $n \times n$*-matrix with eigendecomposition* $\mathbf{A} = \mathbf{U}\mathbf{L}\mathbf{U}^\top$*. Let* $\mathbf{U}$ *and* $\mathbf{L}$ *be partitioned as follows:*

$$\mathbf{U} = [\mathbf{U}_1\, \mathbf{U}_2], \qquad \mathbf{L} = \begin{bmatrix} \mathbf{L}_1 & 0 \\ 0 & \mathbf{L}_2 \end{bmatrix},$$

where $\mathbf{U}_1$ *is an* $n \times k$*-matrix,* $\mathbf{L}_1$ *is a* $k \times k$*-matrix,* $\mathbf{U}_2$ *is an* $n \times n-k$*-matrix, and* $\mathbf{L}_2$ *is an* $n-k \times n-k$*-matrix. Furthermore, let* $\mathbf{E}$ *be another symmetric* $n \times n$*-matrix, and* $\tilde{\mathbf{A}} = \mathbf{A} + \mathbf{E}$*. Let* $\tilde{l}$ *be an eigenvalue of* $\tilde{\mathbf{A}}$ *and* $\tilde{x}$ *an associated unit-length eigenvector. Then,*

$$\|\mathbf{U}_2^\top \tilde{x}\| \leq \frac{\|\mathbf{E}\|}{\min\limits_{n-k \leq i \leq n} |\tilde{l} - l_i|}.$$

The proof of this theorem can also be found in the thesis of Braun (2005), Lemma 4.50, p. 70.

Abstract

We analyze the performance of a class of manifold-learning algorithms that find their output by minimizing a quadratic form under some normalization constraints. This class consists of Locally Linear Embedding (LLE), Laplacian Eigenmap, Local Tangent Space Alignment (LTSA), Hessian Eigenmaps (HLLE), and Diffusion maps. We present and prove conditions on the manifold that are necessary for the success of the algorithms. Both the finite sample case and the limit case are analyzed. We show that there are simple manifolds in which the necessary conditions are violated, and hence the algorithms cannot recover the underlying manifolds. Finally, we present numerical results that demonstrate our claims.

Keywords: dimensionality reduction, manifold learning, Laplacian eigenmap, diffusion maps, locally linear embedding, local tangent space alignment, Hessian eigenmap

1. Introduction

Many seemingly complex systems described by high-dimensional data sets are in fact governed by a surprisingly low number of parameters. Revealing the low-dimensional representation of such high-dimensional data sets not only leads to a more compact description of the data, but also enhances our understanding of the system. Dimension-reducing algorithms attempt to simplify the system's representation without losing significant structural information. Various dimension-reduction algorithms were developed recently to perform embeddings for manifold-based data sets. These include the following algorithms: Locally Linear Embedding (LLE, Roweis and Saul, 2000), Isomap (Tenenbaum et al., 2000), Laplacian Eigenmaps (LEM, Belkin and Niyogi, 2003), Local Tangent Space Alignment (LTSA, Zhang and Zha, 2004), Hessian Eigenmap (HLLE, Donoho and Grimes,

2004), Semi-definite Embedding (SDE, Weinberger and Saul, 2006) and Diffusion Maps (DFM, Coifman and Lafon, 2006).

These manifold-learning algorithms compute an embedding for some given input. It is assumed that this input lies on a low-dimensional manifold, embedded in some high-dimensional space. Here a manifold is defined as a topological space that is locally equivalent to a Euclidean space. It is further assumed that the manifold is the image of a low-dimensional domain. In particular, the input points are the image of a sample taken from the domain. The goal of the manifold-learning algorithms is to recover the original domain structure, up to some scaling and rotation. The non-linearity of these algorithms allows them to reveal the domain structure even when the manifold is not linearly embedded.

The central question that arises when considering the output of a manifold-learning algorithm is, whether the algorithm reveals the underlying low-dimensional structure of the manifold. The answer to this question is not simple. First, one should define what "revealing the underlying lower-dimensional description of the manifold" actually means. Ideally, one could measure the degree of similarity between the output and the original sample. However, the original low-dimensional data representation is usually unknown. Nevertheless, if the low-dimensional structure of the data is known in advance, one would expect it to be approximated by the dimension-reducing algorithm, at least up to some rotation, translation, and global scaling factor. Furthermore, it would be reasonable to expect the algorithm to succeed in recovering the original sample's structure asymptotically, namely, when the number of input points tends to infinity. Finally, one would hope that the algorithm would be robust in the presence of noise.

Previous papers have addressed the central question posed earlier. Zhang and Zha (2004) presented some bounds on the local-neighborhoods' error-estimation for LTSA. However, their analysis says nothing about the global embedding. Huo and Smith (2006) proved that, asymptotically, LTSA recovers the original sample up to an affine transformation. They assume in their analysis that the level of noise tends to zero when the number of input points tends to infinity. Bernstein et al. (2000.) proved that, asymptotically, the embedding given by the Isomap algorithm (Tenenbaum et al., 2000) recovers the geodesic distances between points on the manifold.

In this paper we develop theoretical results regarding the performance of a class of manifold-learning algorithms, which includes the following five algorithms: Locally Linear Embedding (LLE), Laplacian Eigenmap (LEM), Local Tangent Space Alignment (LTSA), Hessian Eigenmaps (HLLE), and Diffusion maps (DFM).

We refer to this class of algorithms as the normalized-output algorithms. The normalized-output algorithms share a common scheme for recovering the domain structure of the input data set. This scheme is constructed in three steps. In the first step, the local neighborhood of each point is found. In the second step, a description of these neighborhoods is computed. In the third step, a low-dimensional output is computed by solving some convex optimization problem under some normalization constraints. A detailed description of the algorithms is given in Section 2.

In Section 3 we discuss informally the criteria for determining the success of manifold-learning algorithms. We show that one should not expect the normalized-output algorithms to recover geodesic distances or local structures. A more reasonable criterion for success is a high degree of similarity between the output of the algorithms and the original sample, up to some affine transformation; the definition of similarity will be discussed later. We demonstrate that under certain circumstances, this high degree of similarity does not occur. In Section 4 we find necessary conditions for the successful performance of LEM and DFM on the two-dimensional grid. This section serves

as an explanatory introduction to the more general analysis that appears in Section 5. Some of the ideas that form the basis of the analysis in Section 4 were discussed independently by both Gerber et al. (2007) and ourselves (Goldberg et al., 2007). Section 5 finds necessary conditions for the successful performance of all the normalized-output algorithms on general two-dimensional manifolds. It should be noted that the necessary conditions are hard to verify in practice. However, they serve as an analytic tool to prove that there are general classes of manifolds on which the normalized-output algorithms fail. Moreover, the numerical examples in this section show that the class of manifolds on which the normalized-output algorithms fail is wide and includes non-isometrically manifolds and real-world data. In Section 6 we discuss the performance of the algorithms in the asymptotic case. Concluding remarks appear in Section 7. The detailed proofs appear in the Appendix.

Our paper has two main results. First, we give well-defined necessary conditions for the successful performance of the normalized-output algorithms. Second, we show that there exist simple manifolds that do not fulfill the necessary conditions for the success of the algorithms. For these manifolds, the normalized-output algorithms fail to generate output that recovers the structure of the original sample. We show that these results hold asymptotically for LEM and DFM. Moreover, when noise, even of small variance, is introduced, LLE, LTSA, and HLLE will fail asymptotically on some manifolds. Throughout the paper, we present numerical results that demonstrate our claims.

2. Description of Output-normalized Algorithms

In this section we describe in short the normalized-output algorithms. The presentation of these algorithms is not in the form presented by the respective authors. The form used in this paper emphasizes the similarities between the algorithms and is better-suited for further derivations. In Appendix A.1 we show the equivalence of our representation of the algorithms and the representations that appear in the original papers.

Let $X = [x_1, \ldots, x_N]'$, $x_i \in \mathbb{R}^{\mathcal{D}}$ be the input data where $\mathcal{D}$ is the dimension of the ambient space and N is the size of the sample. The normalized-output algorithms attempt to recover the underlying structure of the input data X in three steps.

In the first step, the normalized-output algorithms assign neighbors to each input point x_i based on the Euclidean distances in the high-dimensional space.[1] This can be done, for example, by choosing all the input points in an r-ball around x_i or alternatively by choosing x_i's K-nearest-neighbors. The neighborhood of x_i is given by the matrix $X_i = [x_i, x_{i,1}, \ldots, x_{i,K}]'$ where $x_{i,j} : j = 1, \ldots, K$ are the neighbors of x_i. Note that $K = K(i)$ can be a function of i, the index of the neighborhood, yet we omit this index to simplify the notation. For each neighborhood, we define the radius of the neighborhood as

$$r(i) = \max_{j,k \in \{0,\ldots,K\}} \left\| x_{i,j} - x_{i,k} \right\|$$

where we define $x_{i,0} = x_i$. Finally, we assume throughout this paper that the neighborhood graph is connected.

In the second step, the normalized-output algorithms compute a description of the local neighborhoods that were found in the previous step. The description of the i-th neighborhood is given by some weight matrix W_i. The matrices W_i for the different algorithms are presented.

1. The neighborhoods are not mentioned explicitly by Coifman and Lafon (2006). However, since a sparse optimization problem is considered, it is assumed implicitly that neighborhoods are defined (see Sec. 2.7 therein).

- LEM and DFM: W_i is a $K \times (K+1)$ matrix,

$$W_i = \begin{pmatrix} w_{i,1}^{1/2} & -w_{i,1}^{1/2} & 0 & \cdots & 0 \\ w_{i,2}^{1/2} & 0 & -w_{i,2}^{1/2} & \ddots & \vdots \\ \vdots & \vdots & \ddots & \ddots & 0 \\ w_{i,K}^{1/2} & 0 & \cdots & 0 & -w_{i,K}^{1/2} \end{pmatrix}.$$

  For LEM $w_{i,j} = 1$ is a natural choice, yet it is also possible to define the weights as $\tilde{w}_{i,j} = e^{-\left\|x_i - x_{i,j}\right\|^2/\varepsilon}$, where ε is the width parameter of the kernel. For the case of DFM,

$$w_{i,j} = \frac{k_\varepsilon(x_i, x_{i,j})}{q_\varepsilon(x_i)^\alpha q_\varepsilon(x_{i,j})^\alpha}, \tag{1}$$

  where k_ε is some rotation-invariant kernel, $q_\varepsilon(x_i) = \sum_j k_\varepsilon(x_i, x_{i,j})$ and ε is again a width parameter. We will use $\alpha = 1$ in the normalization of the diffusion kernel, yet other values of α can be considered (see details in Coifman and Lafon, 2006). For both LEM and DFM, we define the matrix D to be a diagonal matrix where $d_{ii} = \sum_j w_{i,j}$.

- LLE: W_i is a $1 \times (K+1)$ matrix,

$$W_i = \begin{pmatrix} 1 & -w_{i,1} & \cdots & -w_{i,K} \end{pmatrix}.$$

  The weights $w_{i,j}$ are chosen so that x_i can be best linearly reconstructed from its neighbors. The weights minimize the reconstruction error function

$$\Delta^i(w_{i,1}, \ldots, w_{i,K}) = \|x_i - \sum_j w_{i,j} x_{i,j}\|^2$$

  under the constraint $\sum_j w_{i,j} = 1$. In the case where there is more than one solution that minimizes Δ^i, regularization is applied to force a unique solution (for details, see Saul and Roweis, 2003).

- LTSA: W_i is a $(K+1) \times (K+1)$ matrix,

$$W_i = (I - P_i P_i')H.$$

  Let $U_i L_i V_i'$ be the SVD of $X_i - \mathbf{1}\bar{x_i}'$ where $\bar{x_i}$ is the sample mean of X_i and $\mathbf{1}$ is a vector of ones (for details about SVD, see, for example, Golub and Loan, 1983). Let $P_i = [u_{(1)}, \ldots, u_{(d)}]$ be the matrix that holds the first d columns of U_i where d is the output dimension. The matrix $H = I - \frac{1}{K}\mathbf{1}\mathbf{1}'$ is the centering matrix. See also Huo and Smith (2006) regarding this representation of the algorithm.

- HLLE: W_i is a $d(d+1)/2 \times (K+1)$ matrix,

$$W_i = (\mathbf{0}, H^i)$$

  where $\mathbf{0}$ is a vector of zeros and H^i is the $\frac{d(d+1)}{2} \times K$ Hessian estimator.
  The estimator can be calculated as follows. Let $U_i L_i V_i'$ be the SVD of $X_i - \mathbf{1}\bar{x_i}'$. Let

$$M_i = [\mathbf{1}, U_i^{(1)}, \ldots, U_i^{(d)}, \mathrm{diag}(U_i^{(1)} U_i^{(1)\prime}), \mathrm{diag}(U_i^{(1)} U_i^{(2)\prime}), \ldots, \mathrm{diag}(U_i^{(d)} U_i^{(d)\prime})],$$

where the operator diag returns a column vector formed from the diagonal elements of the matrix. Let $\widetilde{M}_i$ be the result of the Gram-Schmidt orthonormalization on M_i. Then H^i is defined as the transpose of the last $d(d+1)/2$ columns of $\widetilde{M}_i$.

The third step of the normalized-output algorithms is to find a set of points $Y = [y_1, \ldots, y_N]', y_i \in \mathbb{R}^d$ where $d \leq \mathcal{D}$ is the dimension of the manifold. Y is found by minimizing a convex function under some normalization constraints, as follows. Let Y be any $N \times d$ matrix. We define the i-th neighborhood matrix $Y_i = [y_i, y_{i,1}, \ldots, y_{i,K}]'$ using the same pairs of indices i, j as in X_i. The cost function for all of the normalized-output algorithms is given by

$$\Phi(Y) = \sum_{i=1}^{N} \phi(Y_i) = \sum_{i=1}^{N} \|W_i Y_i\|_F^2 \,, \tag{2}$$

under the normalization constraints

$$\begin{cases} Y'DY = I \\ Y'D\mathbf{1} = \mathbf{0} \end{cases} \text{for LEM and DFM,} \quad \begin{cases} \mathrm{Cov}(Y) = I \\ Y'\mathbf{1} = \mathbf{0} \end{cases} \text{for LLE, LTSA and HLLE,} \tag{3}$$

where $\| \|_F$ stands for the Frobenius norm, and W_i is algorithm-dependent.

Define the output matrix Y to be the matrix that achieves the minimum of Φ under the normalization constraints of Eq. 3 (Y is defined up to rotation). Then we have the following: the embeddings of LEM and LLE are given by the according output matrices Y; the embeddings of LTSA and HLLE are given by the according output matrices $\frac{1}{\sqrt{N}}Y$; and the embedding of DFM is given by a linear transformation of Y as discussed in Appendix A.1. The discussion of the algorithms' output in this paper holds for any affine transformation of the output (see Section 3). Thus, without loss of generality, we prefer to discuss the output matrix Y directly, rather than the different embeddings. This allows a unified framework for all five normalized-output algorithms.

3. Embedding Quality

In this section we discuss possible definitions of "successful performance" of manifold-learning algorithms. To open our discussion, we present a numerical example. We chose to work with LTSA rather arbitrarily. Similar results can be obtained using the other algorithms.

The example we consider is a uniform sample from a two-dimensional strip, shown in Fig. 1A. Note that in this example, $\mathcal{D} = d$; that is, the input data is identical to the original data. Fig. 1B presents the output of LTSA on the input in Fig. 1A. The most obvious difference between input and output is that while the input is a strip, the output is roughly square. While this may seem to be of no importance, note that it means that the algorithm, like all the normalized-output algorithms, does not preserve geodesic distances even up to a scaling factor. By definition, the geodesic distance between two points on a manifold is the length of the shortest path on the manifold between the two points. Preservation of geodesic distances is particularly relevant when the manifold is isometrically embedded. In this case, assuming the domain is convex, the geodesic distance between any two points on the manifold is equal to the Euclidean distance between the corresponding domain points. Geodesic distances are conserved, for example, by the Isomap algorithm (Tenenbaum et al., 2000).

Figs. 1E and 1F present closeups of Figs. 1A and 1B, respectively. Here, a less obvious phenomenon is revealed: the structure of the local neighborhood is not preserved by LTSA. By local structure we refer to the angles and distances (at least up to a scale) between all points within each

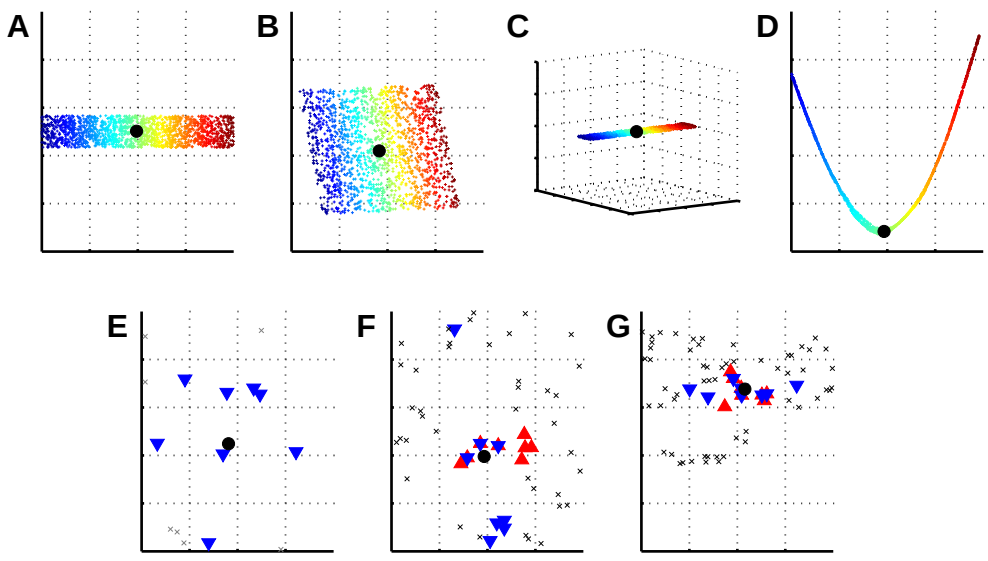

Figure 1: The output of LTSA (B) for the (two-dimensional) input shown in (A), where the input is a uniform sample from the strip $[0,1] \times [0,6]$. Ideally one would expect the two to be identical. The normalization constraint shortens the horizontal distances and lengthens the vertical distances, leading to the distortion of geodesic distances. (E) and (F) focus on the points shown in black in (A) and (B), respectively. The (blue) triangles pointing downwards in (E) and (F) are the 8-nearest-neighborhood of the point denoted by the full black circle. The (red) triangles pointing upwards in (F) indicate the neighborhood computed for the corresponding point (full black circle) in the output space. Note that less than half of the original neighbors of the point remain neighbors in the output space. The input (A) with the addition of Gaussian noise normal to the manifold and of variance 10^{-4} is shown in (C). The output of LTSA for the noisy input is shown in (D). (G) shows a closeup of the neighborhood of the point indicated by the black circle in (D).

local neighborhood. Mappings that preserve local structures up to a scale are called conformal mappings (see for example de Silva and Tenenbaum, 2003; Sha and Saul, 2005). In addition to the distortion of angles and distances, the K-nearest-neighbors of a given point on the manifold do not necessarily correspond to the K-nearest-neighbors of the respective output point, as shown in Figs. 1E and 1F. Accordingly, we conclude that the original structure of the local neighborhoods is not necessarily preserved by the normalized-output algorithms.

The above discussion highlights the fact that one cannot expect the normalized-output algorithms to preserve geodesic distances or local neighborhood structure. However, it seems reasonable to demand that the output of the normalized-output algorithms resemble an affine transformation of the original sample. In fact, the output presented in Fig. 1B is an affine transformation of the input, which is the original sample, presented in Fig. 1A. A formal similarity criterion based on affine transformations is given by Huo and Smith (2006). In the following, we will claim that a

normalized-output algorithm succeeds (or fails) based on the existence (or lack thereof) of resemblance between the output and the original sample, up to an affine transformation.

Fig. 1D presents the output of LTSA on a noisy version of the input, shown in Fig. 1C. In this case, the algorithm prefers an output that is roughly a one-dimensional curve embedded in $\mathbb{R}^2$. While this result may seem incidental, the results of all the other normalized-output algorithms for this example are essentially the same.

Using the affine transformation criterion, we can state that LTSA succeeds in recovering the underlying structure of the strip shown in Fig. 1A. However, in the case of the noisy strip shown in Fig. 1C, LTSA fails to recover the structure of the input. We note that all the other normalized-output algorithms perform similarly.

For practical purposes, we will now generalize the definition of failure of the normalized-output algorithms. This definition is more useful when it is necessary to decide whether an algorithm has failed, without actually computing the output. This is useful, for example, when considering the outputs of an algorithm for a class of manifolds.

We now present the generalized definition of failure of the algorithms. Let $X = X_{N\times d}$ be the original sample. Assume that the input is given by $\psi(X) \subset \mathbb{R}^{\mathcal{D}}$, where $\psi : \mathbb{R}^d \to \mathbb{R}^{\mathcal{D}}$ is some smooth function, and $\mathcal{D} \geq d$ is the dimension of the input. Let $Y = Y_{N\times d}$ be an affine transformation of the original sample X, such that the normalization constraints of Eq. 3 hold. Note that Y is algorithm-dependent, and that for each algorithm, Y is unique up to rotation and translation. When the algorithm succeeds it is expected that the output will be similar to a normalized version of X, namely to Y. Let $Z = Z_{N\times d}$ be any matrix that satisfies the same normalization constraints. We say that the algorithm has failed if $\Phi(Y) > \Phi(Z)$, and Z is substantially different from Y, and hence also from X. In other words, we say that the algorithm has failed when a substantially different embedding Z has a lower cost than the most appropriate embedding Y. A precise definition of "substantially different" is not necessary for the purposes of this paper. It is enough to consider Z substantially different from Y when Z is of lower dimension than Y, as in Fig. 1D.

We emphasize that the matrix Z is not necessarily similar to the output of the algorithm in question. It is a mathematical construction that shows when the output of the algorithm is not likely to be similar to Y, the normalized version of the true manifold structure. The following lemma shows that if $\Phi(Y) > \Phi(Z)$, the inequality is also true for a small perturbation of Y. Hence, it is not likely that an output that resembles Y will occur when $\Phi(Y) > \Phi(Z)$ and Z is substantially different from Y.

Lemma 3.1 *Let Y be an $N \times d$ matrix. Let $\widetilde{Y} = Y + \varepsilon E$ be a perturbation of Y, where E is an $N \times d$ matrix such that $\|E\|_F = 1$ and where $\varepsilon > 0$. Let S be the maximum number of neighborhoods to which a single input point belongs. Then for LLE with positive weights $w_{i,j}$, LEM, DFM, LTSA, and HLLE, we have*

$$\Phi(\widetilde{Y}) > (1-\varepsilon)\Phi(Y) - \varepsilon C_a S,$$

where C_a is a constant that depends on the algorithm.

The use of positive weights in LLE is discussed in Saul and Roweis (2003, Section 5); a similar result for LLE with general weights can be obtained if one allows a bound on the values of $w_{i,j}$. The proof of Lemma 3.1 is given in Appendix A.2.

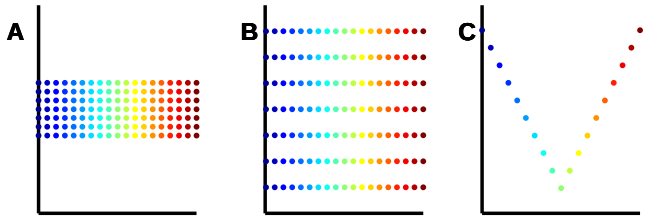

Figure 2: (A) The input grid. (B) Embedding Y, the normalized grid. (C) Embedding Z, a curve that satisfies $\mathrm{Cov}(Z) = I$.

4. Analysis of the Two-Dimensional Grid

In this section we analyze the performance of LEM on the two-dimensional grid. In particular, we argue that LEM cannot recover the structure of a two-dimensional grid in the case where the aspect ratio of the grid is greater than 2. Instead, LEM prefers a one-dimensional curve in $\mathbb{R}^2$. Implications also follow for DFM, as explained in Section 4.3, followed by a discussion of the other normalized-output algorithms. Finally, we present empirical results that demonstrate our claims.

In Section 5 we prove a more general statement regarding any two-dimensional manifold. Necessary conditions for successful performance of the normalized-output algorithms on such manifolds are presented. However, the analysis in this section is important in itself for two reasons. First, the conditions for the success of LEM on the two-dimensional grid are more limiting. Second, the analysis is simpler and points out the reasons for the failure of all the normalized-output algorithms when the necessary conditions do not hold.

4.1 Possible Embeddings of a Two-Dimensional Grid

We consider the input data set X to be the two-dimensional grid $[-m,\ldots,m]\times[-q,\ldots,q]$, where $m \geq q$. We denote $x_{ij} = (i, j)$. For convenience, we regard $X = (X^{(1)}, X^{(2)})$ as an $N \times 2$ matrix, where $N = (2m+1)(2q+1)$ is the number of points in the grid. Note that in this specific case, the original sample and the input are the same.

In the following we present two different embeddings, Y and Z. Embedding Y is the grid itself, normalized so that $\mathrm{Cov}(Y) = I$. Embedding Z collapses each column to a point and positions the resulting points in the two-dimensional plane in a way that satisfies the constraint $\mathrm{Cov}(Z) = I$ (see Fig. 2 for both). The embedding Z is a curve in $\mathbb{R}^2$ and clearly does not preserve the original structure of the grid.

We first define the embeddings more formally. We start by defining $\widehat{Y} = X(X'DX)^{-1/2}$. Note that this is the only linear transformation of X (up to rotation) that satisfies the conditions $\widehat{Y}'D\mathbf{1} = \mathbf{0}$ and $\widehat{Y}'D\widehat{Y} = I$, which are the normalization constraints for LEM (see Eq. 3). However, the embedding $\widehat{Y}$ depends on the matrix D, which in turn depends on the choice of neighborhoods. Recall that the matrix D is a diagonal matrix, where d_{ii} equals the number of neighbors of the i-th point. Choose r to be the radius of the neighborhoods. Then, for all inner points x_{ij}, the number of neighbors $K(i, j)$ is a constant, which we denote as K. We shall call all points with less than K neighbors *boundary*

points. Note that the definition of boundary points depends on the choice of r. For inner points of the grid we have $d_{ii} \equiv K$. Thus, when $K \ll N$ we have $X'DX \approx KX'X$.

We define $Y = X\mathrm{Cov}(X)^{-1/2}$. Note that $Y'\mathbf{1} = 0$, $\mathrm{Cov}(Y) = I$ and for $K \ll N$, $Y \approx \sqrt{KN}\widehat{Y}$. In this section we analyze the embedding Y instead of $\widehat{Y}$, thereby avoiding the dependence on the matrix D and hence simplifying the notation. This simplification does not significantly change the problem and does not affect the results we present. Similar results are obtained in the next section for general two-dimensional manifolds, using the exact normalization constraints (see Section 5.2).

Note that Y can be described as the set of points $[-m/\sigma,\ldots,m/\sigma]\times[-q/\tau,\ldots,q/\tau]$, where $y_{ij} = (i/\sigma, j/\tau)$. The constants $\sigma^2 = \mathrm{Var}(X^{(1)})$ and $\tau^2 = \mathrm{Var}(X^{(2)})$ ensure that the normalization constraint $\mathrm{Cov}(Y) = I$ holds. Straightforward computation (see Appendix A.3) shows that

$$\sigma^2 = \frac{(m+1)m}{3};\ \tau^2 = \frac{(q+1)q}{3}. \tag{4}$$

The definition of the embedding Z is as follows:

$$z_{ij} = \begin{cases} \left(\frac{i}{\sigma}, \frac{-2i}{\rho} - \overline{z}^{(2)}\right) & i \le 0 \\ \\ \left(\frac{i}{\sigma}, \frac{2i}{\rho} - \overline{z}^{(2)}\right) & i \ge 0 \end{cases},$$

where $\overline{z}^{(2)} = \frac{(2q+1)2}{N\rho}\sum_{i=1}^{m}(2i)$ ensures that $Z'\mathbf{1} = \mathbf{0}$, and σ (the same σ as before; see below) and ρ are chosen so that sample variance of $Z^{(1)}$ and $Z^{(2)}$ is equal to one. The symmetry of $Z^{(1)}$ about the origin implies that $\mathrm{Cov}(Z^{(1)}, Z^{(2)}) = 0$, hence the normalization constraint $\mathrm{Cov}(Z) = I$ holds. σ is as defined in Eq. 4, since $Z^{(1)} = Y^{(1)}$ (with both defined similarly to $X^{(1)}$). Finally, note that the definition of z_{ij} does not depend on j.

4.2 Main Result for LEM on the Two-Dimensional Grid

We estimate $\Phi(Y)$ by $N\phi(Y_{ij})$ (see Eq. 2), where y_{ij} is an inner point of the grid and Y_{ij} is the neighborhood of y_{ij}; likewise, we estimate $\Phi(Z)$ by $N\phi(Z_{ij})$ for an inner point z_{ij}. For all inner points, the value of $\phi(Y_{ij})$ is equal to some value ϕ. For boundary points, $\phi(Y_{ij})$ is bounded by ϕ multiplied by some constant that depends only on the number of neighbors. Hence, for large m and q, the difference between $\Phi(Y)$ and $N\phi(Y_{ij})$ is negligible.

The main result of this section states:

Theorem 4.1 *Let y_{ij} be an inner point and let the ratio $\frac{m}{q}$ be greater than* 2. *Then*

$$\phi(Y_{ij}) > \phi(Z_{ij})$$

for neighborhood-radius r that satisfies $1 \le r \le 3$, or similarly, for K-nearest neighborhoods where $K = 4, 8, 12$.

This indicates that for aspect ratios $\frac{m}{q}$ that are greater than 2 and above, mapping Z, which is essentially one-dimensional, is preferred to Y, which is a linear transformation of the grid. The case of general r-ball neighborhoods is discussed in Appendix A.4 and indicates that similar results should be expected.

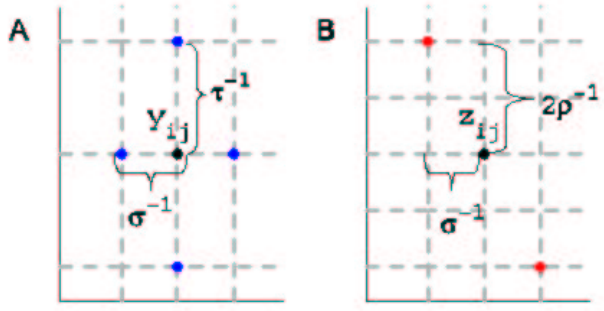

Figure 3: (A) The normalized grid at an inner point y_{ij}. The 4-nearest-neighbors of y_{ij} are marked in blue. Note that the neighbors from the left and from the right are at a distance of $1/\sigma$, while the neighbors from above and below are at a distance of $1/\tau$. The value of $\phi(Y_{ij})$ is equal to the sum of squared distances of y_{ij} to its neighbors. Hence, we obtain that $\phi(Y_{ij}) = 2/\sigma^2 + 2/\tau^2$ when $K = 4$ and $\phi(Y_{ij}) = 2/\sigma^2 + 2/\tau^2 + 4(1/\sigma^2 + 1/\tau^2)$ when $K = 8$. (B) The curve embedding at an inner point z_{ij}. The neighbors of z_{ij} from the left and from the right are marked in red. The neighbors from above and below are embedded to the same point as z_{ij}. Note that the squared distance between z_{ij} and $z_{(i\pm1)j}$ equals $1/\sigma^2 + 4/\rho^2$. Hence, $\phi(Z_{ij}) = 2(1/\sigma^2 + 4/\rho^2)$ when $K = 4$, and $\phi(Z_{ij}) = 6(1/\sigma^2 + 4/\rho^2)$ when $K = 8$.

The proof of the theorem is as follows. It can be shown analytically (see Fig. 3) that

$$\phi(Y_{ij}) = F(K)\left(\frac{1}{\sigma^2} + \frac{1}{\tau^2}\right), \tag{5}$$

where

$$F(4) = 2;\ F(8) = 6;\ F(12) = 14.$$

For higher K, $F(K)$ can be approximated for any r-ball neighborhood of y_{ij} (see Appendix A.4).

It can be shown (see Fig. 3) that

$$\phi(Z_{ij}) = \widetilde{F}(K)\left(\frac{1}{\sigma^2} + \frac{4}{\rho^2}\right), \tag{6}$$

where $\widetilde{F}(K) = F(K)$ for $K = 4, 8, 12$. For higher K, it can be shown (see Appendix A.4) that $\widetilde{F}(K) \approx F(K)$ for any r-ball neighborhood.

A careful computation (see Appendix A.5) shows that

$$\rho > \sigma, \tag{7}$$

and therefore

$$\phi(Z_{ij}) < \frac{5F(K)}{\sigma^2}. \tag{8}$$

Assume that $\frac{m}{q} > 2$. Since both m and q are integers, we have that $m+1 \geq 2(q+1)$. Hence, using Eq. 4 we have

$$\sigma^2 = \frac{m(m+1)}{3} > \frac{4q(q+1)}{3} = 4\tau^2 .$$

Combining this result with Eqs. 5 and 8 we have

$$\frac{m}{q} > 2 \Rightarrow \phi(Y_{ij}) > \phi(Z_{ij})$$

which proves Theorem 4.1.

4.3 Implications to Other Algorithms

We start with implications regarding DFM. There are two main differences between LEM and DFM. The first difference is the choice of the kernel. LEM chooses $w_{i,j} = 1$, which can be referred to as the "window" kernel (a Gaussian weight function was also considered by Belkin and Niyogi, 2003). DFM allows a more general rotation-invariant kernel, which includes the "window" kernel of LEM. The second difference is that DFM renormalizes the weights $k_\varepsilon(x_i, x_{i,j})$ (see Eq. 1). However, for all the inner points of the grid with neighbors that are also inner points, the renormalization factor $(q_\varepsilon(x_i)^{-1} q_\varepsilon(x_{i,j})^{-1})$ is a constant. Therefore, if DFM chooses the "window" kernel, it is expected to fail, like LEM. In other words, when DFM using the "window" kernel is applied to a grid with aspect ratio slightly greater than 2 or above, DFM will prefer the embedding Z over the embedding Y (see Fig 2). For a more general choice of kernel, the discussion in Appendix A.4 indicates that a similar failure should occur. This is because the relation between the estimations of $\Phi(Y)$ and $\Phi(Z)$ presented in Eqs. 5 and 6 holds for any rotation-invariant kernel (see Appendix A.4). This observation is also evident in numerical examples, as shown in Figs. 4 and 5.

In the cases of LLE with no regularization, LTSA, and HLLE, it can be shown that $\Phi(Y) \equiv 0$. Indeed, for LTSA and HLLE, the weight matrix W_i projects on a space that is perpendicular to the SVD of the neighborhood X_i, thus $\|W_i X_i\|_F^2 = 0$. Since $Y_i = X_i \mathrm{Cov}(X)^{-1/2}$, we have $\|W_i Y_i\|_F^2 = 0$, and, therefore, $\Phi(Y) \equiv 0$. For the case of LLE with no regularization, when $K \geq 3$, each point can be reconstructed perfectly from its neighbors, and the result follows. Hence, a linear transformation of the original data should be the preferred output. However, the fact that $\Phi(Y) \equiv 0$ relies heavily on the assumption that both the input X and the output Y are of the same dimension (see Theorem 5.1 for manifolds embedded in higher dimensions), which is typically not the case in dimension-reducing applications.

4.4 Numerical Results

For the following numerical results, we used the Matlab implementation written by the respective algorithms' authors as provided by Wittman (retrieved Jan. 2007) (a minor correction was applied to the code of HLLE).

We ran the LEM algorithm on data sets with aspect ratios above and below 2. We present results for both a grid and a uniformly sampled strip. The neighborhoods were chosen using K-nearest neighbors with $K = 4, 8, 16$, and 64. We present the results for $K = 8$; the results for $K = 4, 16$, and 64 are similar. The results for the grid and the random sample are presented in Figs. 4 and 5, respectively.

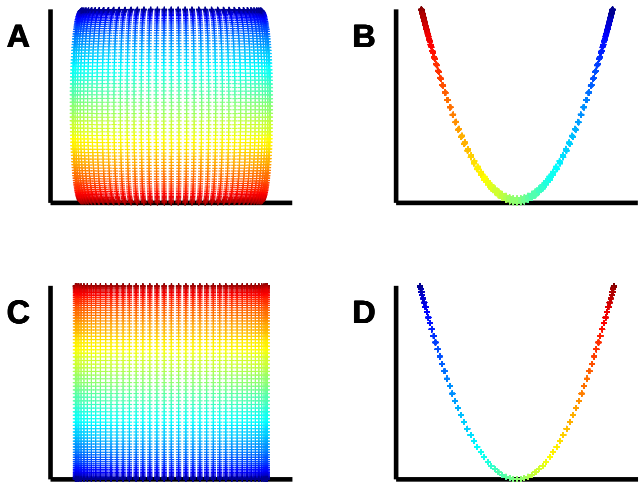

Figure 4: The output of LEM on a grid of dimensions 81×41 is presented in (A). The result of LEM for the grid of dimensions 81×39 is presented in (B). The number of neighbors in both computations is 8. The output for DFM on the same data sets using $\sigma = 2$ appears in (C) and (D), respectively.

We ran the DFM algorithm on the same data sets. We used the normalization constant $\alpha = 1$ and the kernel width $\sigma = 2$; the results for $\sigma = 1, 4$, and 8 are similar. The results for the grid and the random sample are presented in Figures 4 and 5, respectively.

Both examples clearly demonstrate that for aspect ratios sufficiently greater than 2, both LEM and DFM prefer a solution that collapses the input data to a nearly one-dimensional output, normalized in $\mathbb{R}^2$. This is exactly as expected, based on our theoretical arguments.

Finally, we ran LLE, HLLE, and LTSA on the same data sets. In the case of the grid, both LLE and LTSA (roughly) recovered the grid shape for $K = 4, 8, 16$, and 64, while HLLE failed to produce any output due to large memory requirements. In the case of the random sample, both LLE and HLLE succeeded for $K = 16, 64$ but failed for $K = 4, 8$. LTSA succeeded for $K = 8, 16$, and 64 but failed for $K = 4$. The reasons for the failure for lower values of K are not clear, but may be due to roundoff errors. In the case of LLE, the failure may also be related to the use of regularization in LLE's second step.

5. Analysis for General Two-Dimensional Manifolds

The aim of this section is to present necessary conditions for the success of the normalized-output algorithms on general two-dimensional manifolds embedded in high-dimensional space. We show how this result can be further generalized to manifolds of higher dimension. We demonstrate the theoretical results using numerical examples.

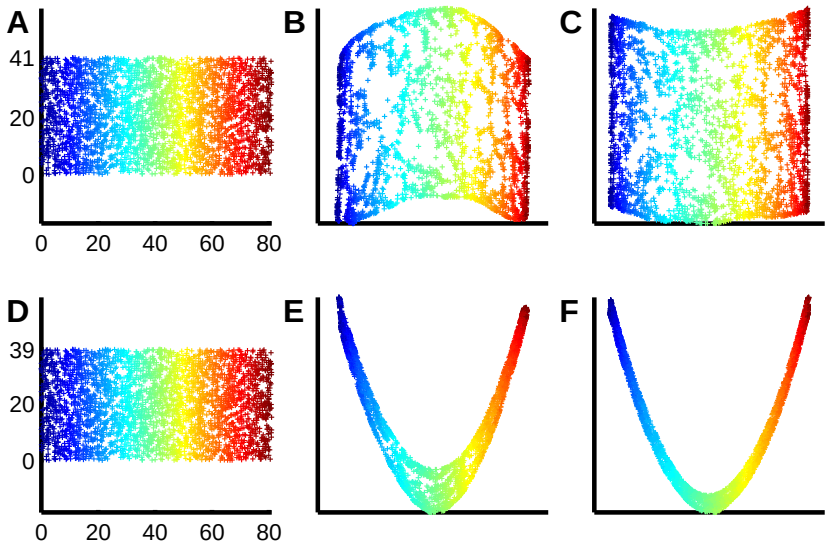

Figure 5: (A) and (D) show the same 3000 points, uniformly-sampled from the unit square, scaled to the areas $[0,81]\times[0,41]$ and $[0,81]\times[0,39]$, respectively. (B) and (E) show the outputs of LEM for inputs (A) and (D), respectively. The number of neighbors in both computations is 8. (C) and (F) show the output for DFM on the same data sets using $\sigma = 2$. Note the sharp change in output structure for extremely similar inputs.

5.1 Two Different Embeddings for a Two-Dimensional Manifold

We start with some definitions. Let $X = [x_1,\ldots,x_N]'$, $x_i \in \mathbb{R}^2$ be the original sample. Without loss of generality, we assume that

$$\bar{x} = \mathbf{0}; \quad \mathrm{Cov}(X) \equiv \Sigma = \begin{pmatrix} \sigma^2 & 0 \\ 0 & \tau^2 \end{pmatrix}.$$

As in Section 4, we assume that $\sigma > \tau$. Assume that the input for the normalized-output algorithms is given by $\psi(X) \subset \mathbb{R}^{\mathcal{D}}$ where $\psi : \mathbb{R}^2 \to \mathbb{R}^{\mathcal{D}}$ is a smooth function and $\mathcal{D} \geq 2$ is the dimension of the input. When the mapping ψ is an isometry, we expect $\Phi(X)$ to be small. We now take a close look at $\Phi(X)$.

$$\Phi(X) = \sum_{i=1}^{N} \|W_i X_i\|_F^2 = \sum_{i=1}^{N} \left\|W_i X_i^{(1)}\right\|^2 + \sum_{i=1}^{N} \left\|W_i X_i^{(2)}\right\|^2,$$

where $X_i^{(j)}$ is the j-th column of the neighborhood X_i. Define $e_i^{(j)} = \left\|W_i X_i^{(j)}\right\|^2$, and note that $e_i^{(j)}$ depends on the different algorithms through the definition of the matrices W_i. The quantity $e_i^{(j)}$ is the portion of error obtained by using the j-th column of the i-th neighborhood when using the original sample as output. Denote $\bar{e}^{(j)} = \frac{1}{N}\sum_i e_i^{(j)}$, the average error originating from the j-th column.

We define two different embeddings for $\psi(X)$, following the logic of Sec. 4.1. Let

$$Y = X\Sigma^{-1/2} \tag{9}$$

be the first embedding. Note that Y is just the original sample up to a linear transformation that ensures that the normalization constraints $\mathrm{Cov}(Y) = I$ and $Y'\mathbf{1} = \mathbf{0}$ hold. Moreover, Y is the only transformation of X that satisfies these conditions, which are the normalization constraints for LLE, HLLE, and LTSA. In Section 5.2 we discuss the modified embeddings for LEM and DFM.

The second embedding, Z, is given by

$$z_i = \begin{cases} \left(\frac{x_i^{(1)}}{\sigma}, \frac{-x_i^{(1)}}{\rho} - \bar{z}^{(2)}\right) & x_i^{(1)} < 0 \\ \left(\frac{x_i^{(1)}}{\sigma}, \frac{\kappa x_i^{(1)}}{\rho} - \bar{z}^{(2)}\right) & x_i^{(1)} \geq 0 \end{cases}. \tag{10}$$

Here

$$\kappa = \Big(\sum_{i:x_i^{(1)}<0} \left(x_i^{(1)}\right)^2\Big)^{1/2} \Big(\sum_{i:x_i^{(1)}\geq 0} \left(x_i^{(1)}\right)^2\Big)^{-1/2} \tag{11}$$

ensures that $\mathrm{Cov}(Z^{(1)}, Z^{(2)}) = 0$, and $\bar{z}^{(2)} = \frac{1}{N}(\sum_{x_i^{(1)}\geq 0} \frac{\kappa x_i^{(1)}}{\rho} + \sum_{x_i^{(1)}<0} \frac{-x_i^{(1)}}{\rho})$ and ρ are chosen so that the sample mean and variance of $Z^{(2)}$ are equal to zero and one, respectively. We assume without loss of generality that $\kappa \geq 1$.

Note that Z depends only on the first column of X. Moreover, each point z_i is just a linear transformation of $x_i^{(1)}$. In the case of neighborhoods Z_i, the situation can be different. If the first column of X_i is either non-negative or non-positive, then Z_i is indeed a linear transformation of $X_i^{(1)}$. However, if $X_i^{(1)}$ is located on both sides of zero, Z_i is not a linear transformation of $X_i^{(1)}$. Denote by N_0 the set of indices i of neighborhoods Z_i that are not linear transformations of $X_i^{(1)}$. The number $|N_0|$ depends on the number of nearest neighbors K. Recall that for each neighborhood, we defined the radius $r(i) = \max_{j,k\in\{0,\ldots,K\}} \left\|x_{i,j} - x_{i,k}\right\|$. Define $r_{\max} = \max_{i\in N_0} r(i)$ to be the maximum radius of neighborhoods i, such that $i \in N_0$.

5.2 The Embeddings for LEM and DFM

So far we have claimed that given the original sample X, we expect the output to resemble Y (see Eq. 9). However, Y does not satisfy the normalization constraints of Eq. 3 for the cases of LEM and DFM. Define $\hat{Y}$ to be the only affine transformation of X (up to rotation) that satisfies the normalization constraint of LEM and DFM. When the original sample is given by X, we expect the output of LEM and DFM to resemble $\hat{Y}$. We note that unlike the matrix Y that was defined in terms of the matrix X only, $\hat{Y}$ depends also on the choice of neighborhoods through the matrix D that appears in the normalization constraints.

We define $\hat{Y}$ more formally. Denote $\widetilde{X} = X - \frac{1}{\mathbf{1}'D\mathbf{1}}\mathbf{1}\mathbf{1}'DX$. Note that $\widetilde{X}$ is just a translation of X that ensures that $\widetilde{X}'D\mathbf{1} = \mathbf{0}$. The matrix $\widetilde{X}'D\widetilde{X}$ is positive definite and therefore can be presented by $\Gamma\widehat{\Sigma}\Gamma'$ where Γ is a 2×2 orthogonal matrix and

$$\widehat{\Sigma} = \begin{pmatrix} \hat{\sigma}^2 & 0 \\ 0 & \hat{\tau}^2 \end{pmatrix},$$

where $\hat{\sigma} \geq \hat{\tau}$. Define $\widehat{X} = \widetilde{X}\Gamma$; then $\widehat{Y} = \widehat{X}\widehat{\Sigma}^{-1/2}$ is the only affine transformation of X that satisfies the normalization constraints of LEM and DFM; namely, we have $\widehat{Y}'D\widehat{Y} = I$ and $\widehat{Y}'D\mathbf{1} = \mathbf{0}$.

We define $\widehat{Z}$ similarly to Eq. 10,

$$\hat{z}_i = \begin{cases} \left(\frac{\hat{x}_i^{(1)}}{\hat{\sigma}}, \frac{-\hat{x}_i^{(1)}}{\hat{\rho}} - \tilde{z}^{(2)}\right) & \hat{x}_i^{(1)} < 0 \\ \\ \left(\frac{\hat{x}_i^{(1)}}{\hat{\sigma}}, \frac{\hat{\kappa}\hat{x}_i^{(1)}}{\hat{\rho}} - \tilde{z}^{(2)}\right) & \hat{x}_i^{(1)} \geq 0 \end{cases},$$

where $\hat{\kappa}$ is defined by Eq. 11 with respect to $\widehat{X}$, $\tilde{z}^{(2)} = \frac{1}{N}\left(\sum_{x_i^{(1)} \geq 0} \frac{d_{ii}\hat{\kappa}x_i^{(1)}}{\rho} + \sum_{x_i^{(1)} < 0} \frac{-d_{ii}x_i^{(1)}}{\rho}\right)$ and $\hat{\rho}^2 = \kappa^2 \sum_{\hat{x}_i^{(1)} \geq 0} d_{ii}\left(\hat{x}_i^{(1)}\right)^2 + \sum_{\hat{x}_i^{(1)} \leq 0} d_{ii}\left(\hat{x}_i^{(1)}\right)^2$.

A similar analysis to that of Y and Z can be performed for $\widehat{Y}$ and $\widehat{Z}$. The same necessary conditions for success are obtained, with σ, τ, and ρ replaced by $\hat{\sigma}$, $\hat{\tau}$, and $\hat{\rho}$, respectively. In the case where the distribution of the original points is uniform, the ratio $\frac{\hat{\sigma}}{\hat{\tau}}$ is close to the ratio $\frac{\sigma}{\tau}$ and thus the necessary conditions for the success of LEM and DFM are similar to the conditions in Corollary 5.2.

5.3 Characterization of the Embeddings

The main result of this section provides necessary conditions for the success of the normalized-output algorithms. Following Section 3, we say that the algorithms fail if $\Phi(Y) > \Phi(Z)$, where Y and Z are defined in Eqs. 9 and 10, respectively. Thus, a necessary condition for the success of the normalized-output algorithms is that $\Phi(Y) \leq \Phi(Z)$.

Theorem 5.1 *Let X be a sample from a two-dimensional domain and let $\psi(X)$ be its embedding in high-dimensional space. Let Y and Z be defined as above. Then*

$$\frac{\kappa^2}{\rho^2}\left(\bar{e}^{(1)} + \frac{|N_0|}{N} c_a r_{\max}^2\right) < \frac{\bar{e}^{(2)}}{\tau^2} \quad \Longrightarrow \quad \Phi(Y) > \Phi(Z)\,, \tag{12}$$

where c_a is a constant that depends on the specific algorithm. For the algorithms LEM and DFM a more restrictive condition can be defined:

$$\frac{\kappa^2}{\rho^2}\bar{e}^{(1)} < \frac{\bar{e}^{(2)}}{\tau^2} \quad \Longrightarrow \quad \Phi(Y) > \Phi(Z)\,.$$

For the proof, see Appendix A.6.

Note that the bound in Eq. 12 depends on the radii of the neighborhoods, and when the maximum radius is large, the bound is less effective. However, there is a tradeoff between enlarging the radius and improving the description of the neighborhoods, that is, reducing $\bar{e}^{(2)}$. In other words, when the neighborhoods are large, one can expect a large average error in the description of the neighborhoods, since the Euclidian approximation of the neighborhoods is less accurate for neighborhoods of large radius.

Adding some assumptions, we can obtain a simpler criterion. First note that, in general, $\bar{e}^{(1)}$ and $\bar{e}^{(2)}$ should be of the same order, since it can be assumed that, locally, the neighborhoods are

uniformly distributed. Second, following Lemma A.2 (see Appendix A.8), when $X^{(1)}$ is a sample from a symmetric unimodal distribution it can be assumed that $\kappa \approx 1$ and $\rho^2 > \frac{\sigma^2}{8}$. Then we have the following corollary:

Corollary 5.2 *Let X,Y,Z be as in Theorem 5.1. Let $c = \sigma/\tau$ be the ratio between the variance of the first and second columns of X. Assume that $\bar{e}^{(1)} < \sqrt{2}\bar{e}^{(2)}$, $\kappa < \sqrt[4]{2}$, and $\rho^2 > \frac{\sigma^2}{8}$. Then*

$$4\left(1+\frac{|N_0|}{N}\frac{c_a r_{\max}^2}{\sqrt{2}\bar{e}^{(2)}}\right) < c \Rightarrow \Phi(Y) > \Phi(Z)\,.$$

For LEM and DFM, we can write

$$4 < c \Rightarrow \Phi(Y) > \Phi(Z)\,.$$

We emphasize that both Theorem 5.1 and Corollary 5.2 do not state that Z is the output of the normalized-output algorithms. However, when the difference between the right side and the left side of the inequalities is large, one cannot expect the output to resemble the original sample (see Lemma 3.1). In these cases we say that the algorithms fail to recover the structure of the original domain.

5.4 Generalization of the Results to Manifolds of Higher Dimensions

The discussion above introduced necessary conditions for the normalized-output algorithms' success on two-dimensional manifolds embedded in $\mathbb{R}^{\mathcal{D}}$. Necessary conditions for success on general d-dimensional manifolds, $d \geq 3$, can also be obtained. We present here a simple criterion to demonstrate the fact that there are d-dimensional manifolds that the normalized-output algorithms cannot recover.

Let $X = [X^{(1)},\ldots,X^{(d)}]$ be a $N \times d$ sample from a d-dimensional domain. Assume that the input for the normalized-output algorithms is given by $\psi(X) \subset \mathbb{R}^{\mathcal{D}}$ where $\psi : \mathbb{R}^d \to \mathbb{R}^{\mathcal{D}}$ is a smooth function and $\mathcal{D} \geq d$ is the dimension of the input. We assume without loss of generality that $X'\mathbf{1} = \mathbf{0}$ and that $\mathrm{Cov}(X)$ is a diagonal matrix. Let $Y = X\mathrm{Cov}(X)^{-1/2}$. We define the matrix $Z = [Z^{(1)},\ldots,Z^{(d)}]$ as follows. The first column of Z, $Z^{(1)}$, equals the first column of Y, namely, $Z^{(1)} = Y^{(1)}$. We define the second column $Z^{(2)}$ similarly to the definition in Eq. 10:

$$Z_i^{(2)} = \begin{cases} \frac{-x_i^{(1)}}{\rho} - \bar{z}^{(2)} & x_i^{(1)} < 0 \\ \\ \frac{\kappa x_i^{(1)}}{\rho} - \bar{z}^{(2)} & x_i^{(1)} \geq 0 \end{cases}, \tag{13}$$

where κ is defined as in Eq. 11, and $\bar{z}^{(2)}$ and ρ are chosen so that the sample mean and variance of $Z^{(2)}$ are equal to zero and one, respectively. We define the next $d-2$ columns of Z by

$$Z^{(j)} = \frac{Y^{(j)} - \sigma_{2j}Z^{(2)}}{\sqrt{1-\sigma_{2j}^2}}; \quad j = 3,\ldots,d\,,$$

where $\sigma_{2j} = Z^{(2)\prime}Y^{(j)}$. Note that $Z'\mathbf{1} = \mathbf{0}$ and $\mathrm{Cov}(Z) = I$. Denote $\sigma_{\max} = \max_{j\in\{3,\ldots,d\}}\sigma_{2j}$.

We bound $\Phi(Z)$ from above:

$$\begin{aligned}\Phi(Z) &= \Phi(Y^{(1)})+\Phi(Z^{(2)})+\sum_{i=1}^{N}\left(\frac{1}{1-\sigma_{2j}^2}\right)\sum_{j=3}^{d}\left\|W_i\left(Y_i^{(j)}-\sigma_{2j}Z_i^{(2)}\right)\right\|^2 \\ &\leq \Phi(Y^{(1)})+\Phi(Z^{(2)})+\frac{1}{1-\sigma_{\max}^2}\sum_{i=1}^{N}\sum_{j=3}^{d}\left\|W_iY_i^{(j)}\right\|^2+\frac{\sigma_{\max}^2}{1-\sigma_{\max}^2}\sum_{i=1}^{N}\sum_{j=3}^{d}\left\|W_iZ_i^{(2)}\right\|^2 \\ &= \Phi(Y^{(1)})+\frac{1+(d-3)\sigma_{\max}^2}{1-\sigma_{\max}^2}\Phi(Z^{(2)})+\frac{1}{1-\sigma_{\max}^2}\sum_{j=3}^{d}\Phi(Y^{(j)}).\end{aligned}$$

Since we may write $\Phi(Y)=\sum_{j=1}^{d}\Phi(Y^{(j)})$, we have

$$\frac{1+(d-3)\sigma_{\max}^2}{1-\sigma_{\max}^2}\Phi(Z^{(2)})<\Phi(Y^{(2)})+\frac{\sigma_{\max}^2}{1-\sigma_{\max}^2}\sum_{j=3}^{d}\Phi(Y^{(j)})\Rightarrow\Phi(Z)<\Phi(Y).$$

When the sample is taken from a symmetric distribution with respect to the axes, one can expect $\sigma_{\max}$ to be small. To see this, note that by symmetry and Eq. 13, $Z_i^{(2)}\approx|Y_i^{(1)}|$, and by assumption $\mathrm{Cov}(Y^{(1)},Y^{(j)})=0$ for $j=3,\ldots,d$. Hence, by the symmetry of $Y^{(j)}$, σ_{2j} is expected to be small. In the specific case of the d-dimensional grid, $\sigma_{\max}=0$. Indeed, $Y^{(j)}$ is symmetric around zero, and all values of $Z^{(2)}$ appear for a given value of $Y^{(j)}$. Hence, both LEM and DFM are expected to fail whenever the ratio between the length of the grid in the first and second coordinates is slightly greater than 2 or more, regardless of the length of grid in the other coordinates, similar to the result presented in Theorem 4.1. Corresponding results for the other normalized-output algorithms can also be obtained, similar to the derivation of Corollary 5.2.

5.5 Numerical Results

We ran all five normalized-output algorithms, along with Isomap, on three data sets. We used the Matlab implementations written by the algorithms' authors as provided by Wittman (retrieved Jan. 2007).

The first data set is a 1600-point sample from the swissroll as obtained from Wittman (retrieved Jan. 2007). The results for the swissroll are given in Fig. 7, A1-F1. The results for the same swissroll, after its first dimension was stretched by a factor 3, are given in Fig. 7, A2-F2. The original and stretched swissrolls are presented in Fig. 6A. The results for $K=8$ are given in Fig. 7. We also checked for $K=12,16$; but "short-circuits" occur (see Balasubramanian et al., 2002, for a definition and discussion of "short-circuits").

The second data set consists of 2400 points, uniformly sampled from a "fishbowl", where a "fishbowl" is a two-dimensional sphere minus a neighborhood of the northern pole (see Fig. 6B for both the "fishbowl" and its stretched version). The results for $K=8$ are given in Fig. 8. We also checked for $K=12,16$; the results are roughly similar. Note that the "fishbowl" is a two-dimensional manifold embedded in $\mathbb{R}^3$, which is not an isometry.

The third data set consists of 900 images of the globe, each of 100×100 pixels (see Fig. 6C). The images, provided by Hamm et al. (2005), were obtained by changing the globe's azimuthal and elevation angles. The parameters of the variations are given by a 30×30 array that contains -45 to 45 degrees of azimuth and -30 to 60 degrees of elevation. We checked the algorithms both on the

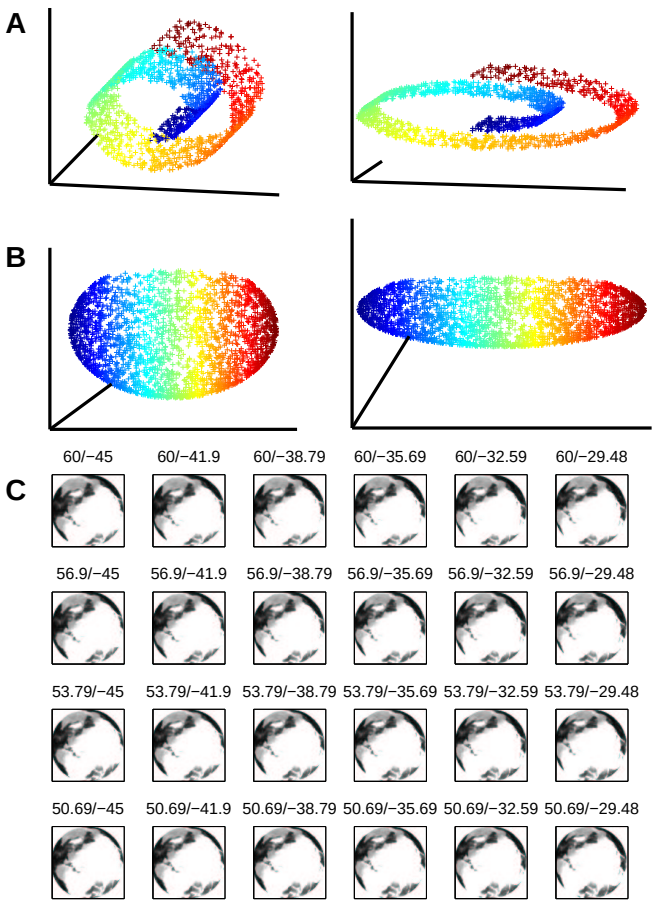

Figure 6: The data sets for the first example appear in panel A. In the left appears the 1600-point original swissroll and in the right appears the same swissroll, after its first dimension was stretched by a factor of 3. The data for the second example appear in panel B. In the left appears a 2400-point uniform sample from the "fishbowl", and in the right appears the same "fishbowl", after its first dimension was stretched by a factor of 4. In panel C appears the upper left corner of the array of 100×100 pixel images of the globe. Above each image we write the elevation and azimuth.

entire set of images and on a strip of 30×10 angular variations. The results for $K = 8$ are given in Fig. 9. We also checked for $K = 12, 16$; the results are roughly similar.

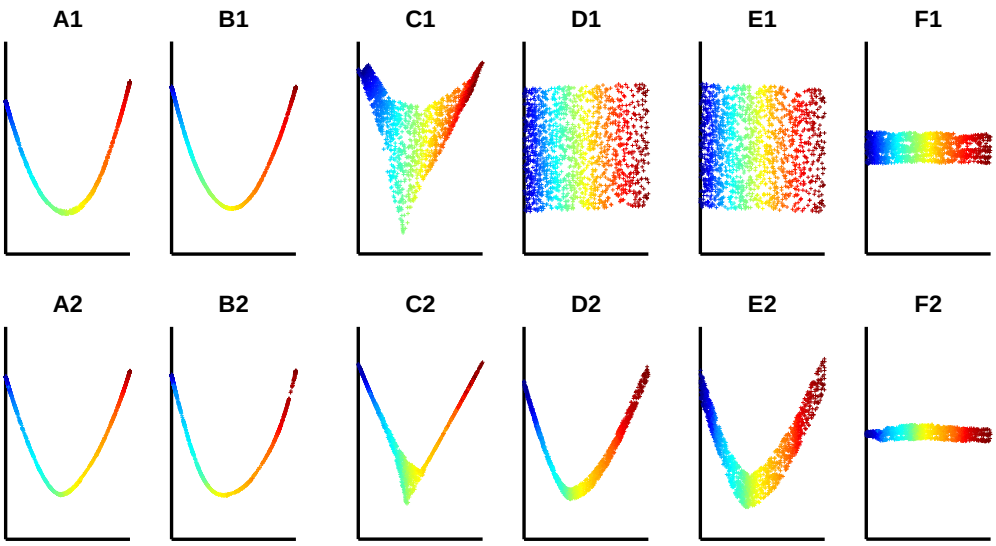

Figure 7: The output of LEM on 1600 points sampled from a swissroll is presented in A1. The output of LEM on the same swissroll after stretching its first dimension by a factor of 3 is presented in A2. Similarly, the outputs of DFM, LLE, LTSA, HLLE, and Isomap are presented in B1-2, C1-2, D1-2, E1-2, and F1-2, respectively. We used $K = 8$ for all algorithms except DFM, where we used $\sigma = 2$.

These three examples, in addition to the noisy version of the two-dimensional strip discussed in Section 3 (see Fig. 1), clearly demonstrate that when the aspect ratio is sufficiently large, all the normalized-output algorithms prefer to collapse their output.

6. Asymptotics

In the previous sections we analyzed the phenomenon of global distortion obtained by the normalized-output algorithms on a finite input sample. However, it is of great importance to explore the limit behavior of the algorithms, that is, the behavior when the number of input points tends to infinity. We consider the question of convergence in the case of input that consists of a d-dimensional manifold embedded in $\mathbb{R}^{\mathcal{D}}$, where the manifold is isometric to a convex subset of Euclidean space. By convergence we mean recovering the original subset of $\mathbb{R}^d$ up to a non-singular affine transformation.

Some previous theoretical works presented results related to the convergence issue. Huo and Smith (2006) proved convergence of LTSA under some conditions. However, to the best of our knowledge, no proof or contradiction of convergence has been given for any other of the normalized-output algorithms. In this section we discuss the various algorithms separately. We also discuss the influence of noise on the convergence. Using the results from previous sections, we show that there

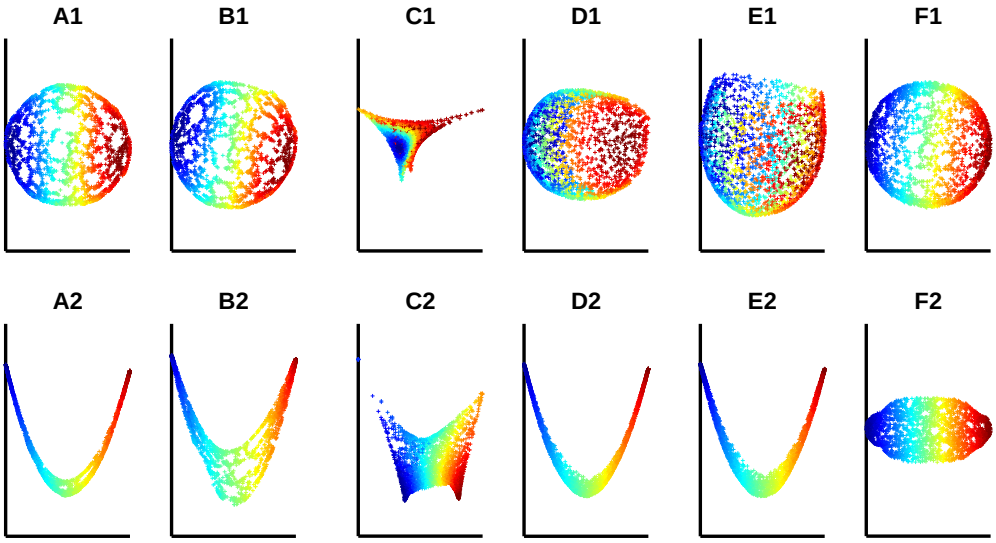

Figure 8: The output of LEM on 2400 points sampled from a "fishbowl" is presented in A1. The output of LEM on the same "fishbowl" after stretching its first dimension by a factor of 4 is presented in A2. Similarly, the outputs of DFM, LLE, LTSA, HLLE, and Isomap are presented in B1-2, C1-2, D1-2, E1-2, and F1-2, respectively. We used $K = 8$ for all algorithms except DFM, where we used $\sigma = 2$.

are classes of manifolds on which the normalized-output algorithms cannot be expected to recover the original sample, not even asymptotically.

6.1 LEM and DFM

Let $x_1, x_2, \ldots$ be a uniform sample from the two-dimensional strip $S = [0, L] \times [0, 1]$. Let $X_n = [x_1, \ldots, x_n]'$ be the sample of size n. Let $K = K(n)$ be the number of nearest neighbors. Then when $K \ll n$ there exists with probability one an N, such that for all $n > N$ the assumptions of Corollary 5.2 hold. Thus, if $L > 4$ we do not expect either LEM or DFM to recover the structure of the strip as the number of points in the sample tends to infinity. Note that this result does not depend on the number of neighbors or the width of the kernel, which can be changed as a function of the number of points n, as long as $K \ll n$. Hence, we conclude that LEM and DFM generally do not converge, regardless of the choice of parameters.

In the rest of this subsection we present further explanations regarding the failure of LEM and DFM based on the asymptotic behavior of the graph Laplacian (see Belkin and Niyogi, 2003, for details). Although it was not mentioned explicitly in this paper, it is well known that the outputs of LEM and DFM are highly related to the lower non-negative eigenvectors of the normalized graph Laplacian matrix (see Appendix A.1). It was shown by Belkin and Niyogi (2005), Hein et al. (2005), and Singer (2006) that the graph Laplacian operator converges to the continuous Laplacian

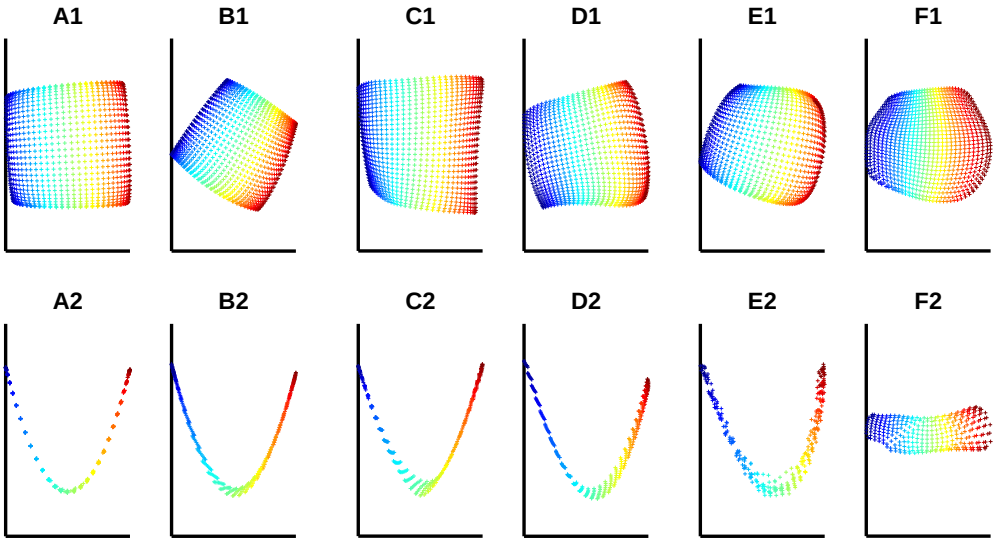

Figure 9: The output of LEM on the 30×30 array of the globe rotation images is presented in A1; the output of LEM on the array of 30×10 is presented in A2. Similarly, the outputs of DFM, LLE, LTSA, HLLE, and Isomap are presented in B1-2, C1-2, D1-2, E1-2, and F1-2 respectively. We used $K = 8$ for all algorithms except DFM, where we chose σ to be the root of the average distance between neighboring points.

operator. Thus, taking a close look at the eigenfunctions of the continuous Laplacian operator may reveal some additional insight into the behavior of both LEM and DFM.

Our working example is the two-dimensional strip $S = [0,L] \times [0,1]$, which can be considered as the continuous counterpart of the grid X defined in Section 4. Following Coifman and Lafon (2006) we impose the Neumann boundary condition (see details therein). The eigenfunctions $\varphi_{i,j}(x_1,x_2)$ and eigenvalues $\lambda_{i,j}$ on the strip S under these conditions are given by

$$\varphi_{i,j}(x_1,x_2) = \cos\left(\frac{i\pi}{L}x_1\right)\cos(j\pi x_2) \quad \lambda_{i,j} = \left(\frac{i\pi}{L}\right)^2 + (j\pi)^2 \quad \text{for } i,j = 0,1,2,\ldots.$$

When the aspect ratio of the strip satisfies $L > M \in \mathbb{N}$, the first M non-trivial eigenfunctions are $\varphi_{i,0}$, $i = 1,\ldots,M$, which are functions only of the first variable x_1. Any embedding of the strip based on the first M eigenfunctions is therefore a function of only the first variable x_1. Specifically, whenever $L > 2$ the two-dimensional embedding is a function of the first variable only, and therefore clearly cannot establish a faithful embedding of the strip. Note that here we have obtained the same ratio constant $L > 2$ computed for the grid (see Section 4 and Figs. 4 and 5) and not the looser constant $L > 4$ that was obtained in Corollary 5.2 for general manifolds.

6.2 LLE, LTSA and HLLE

As mentioned in the beginning of this section, Huo and Smith (2006) proved the convergence of the LTSA algorithm. The authors of HLLE proved that the continuous manifold can be recovered by finding the null space of the continuous Hessian operator (see Donoho and Grimes, 2004, Corollary). However, this is not a proof that the algorithm HLLE converges. In the sequel, we try to understand the relation between Corollary 5.2 and the convergence proof of LTSA.

Let $x_1, x_2, \ldots$ be a sample from a compact and convex domain Ω in $\mathbb{R}^2$. Let $X_n = [x_1, \ldots, x_n]'$ be the sample of size n. Let ψ be an isometric mapping from $\mathbb{R}^2$ to $\mathbb{R}^{\mathcal{D}}$, where $\mathcal{D} > 2$. Let $\psi(X_n)$ be the input for the algorithms. We assume that there is an N such that for all $n > N$ the assumptions of Corollary 5.2 hold. This assumption is reasonable, for example, in the case of a uniform sample from the strip S. In this case Corollary 5.2 states that $\Phi(Z_n) < \Phi(Y_n)$ whenever

$$4\left(1 + \frac{|n_0|}{n}\frac{c_a r_{\max,n}^2}{\sqrt{2}\bar{e}_n^{(2)}}\right) < c_n\,,$$

where c_n is the ratio between the variance of $X_n^{(1)}$ and $X_n^{(2)}$ assumed to converge to a constant c. The expression $\frac{|n_0|}{n}$ is the fraction of neighborhoods $X_{i,n}$ such that $X_{i,n}^{(1)}$ is located on both sides of zero. $r_{\max,n}$ is the maximum radius of neighborhood in n_0. Note that we expect both $\frac{|n_0|}{n}$ and $r_{\max,n}$ to be bounded whenever the radius of the neighborhoods does not increase. Thus, Corollary 5.2 tells us that if $\{\bar{e}_n^{(2)}\}$ is bounded from below, we cannot expect convergence from LLE, LTSA or HLLE when c is large enough.

The consequence of this discussion is that a necessary condition for the convergence of LLE, LTSA and HLLE is that $\{\bar{e}_n^{(2)}\}$ (and hence, from the assumptions of Corollary 5.2, also $\{\bar{e}_n^{(1)}\}$) converges to zero. If the two-dimensional manifold $\psi(\Omega)$ is not contained in a linear two-dimensional subspace of $\mathbb{R}^{\mathcal{D}}$, the mean error $\bar{e}_n^{(2)}$ is typically not zero due to curvature. However, if the radii of the neighborhoods tend to zero while the number of points in each neighborhood tends to infinity, we expect $\bar{e}_n^{(2)} \to 0$ for both LTSA and HLLE. This is because the neighborhood matrices W_i are based on the linear approximation of the neighborhood as captured by the neighborhood SVD. When the radius of the neighborhood tends to zero, this approximation gets better and hence the error tends to zero. The same reasoning works for LLE, although the use of regularization in the second step of LLE may prevent $\bar{e}_n^{(2)}$ from converging to zero (see Section 2).

We conclude that a necessary condition for convergence is that the radii of the neighborhoods tend to zero. In the presence of noise, this requirement cannot be fulfilled. Assume that each input point is of the form $\psi(x_i) + \varepsilon_i$ where $\varepsilon_i \in \mathbb{R}^{\mathcal{D}}$ is a random error that is independent of ε_j for $j \neq i$. We may assume that $\varepsilon_i \sim N(0, \alpha^2 I)$, where α is a small constant. If the radius of the neighborhood is smaller than α, the neighborhood cannot be approximated reasonably by a two-dimensional projection. Hence, in the presence of noise of a constant magnitude, the radii of the neighborhoods cannot tend to zero. In that case, LLE, LTSA and HLLE might not converge, depending on the ratio c. This observation seems to be known also to Huo and Smith (2006), who wrote:

> "... we assume $\alpha = o(r)$; that is, we have $\frac{\alpha}{r} \to 0$, as $r \to 0$.
>
> It is reasonable to require that the error bound (α) be smaller than the size of the neighborhood (r), which is reflected in the above condition. Notice that this condition is also

somewhat nonstandard, since the magnitude of the errors is assumed to depend on n, but it seems to be necessary to ensure the consistency of LTSA."[2]

Summarizing, convergence may be expected when $n \to \infty$, if no noise is introduced. If noise is introduced and if σ/τ is large enough (depending on the level of noise α), convergence cannot be expected (see Fig. 1).

7. Concluding Remarks

In the introduction to this paper we posed the following question: Do the normalized-output algorithms succeed in revealing the underlying low-dimensional structure of manifolds embedded in high-dimensional spaces? More specifically, does the output of the normalized-output algorithms resemble the original sample up to affine transformation?

The answer, in general, is no. As we have seen, Theorem 5.1 and Corollary 5.2 show that there are simple low-dimensional manifolds, isometrically embedded in high-dimensional spaces, for which the normalized-output algorithms fail to find the appropriate output. Moreover, the discussion in Section 6 shows that when noise is introduced, even of small magnitude, this result holds asymptotically for all the normalized-output algorithms. We have demonstrated these results numerically for four different examples: the swissroll, the noisy strip, the (non-isometrically embedded) "fishbowl", and a real-world data set of globe images. Thus, we conclude that the use of the normalized-output algorithms on arbitrary data can be problematic.

The main challenge raised by this paper is the need to develop manifold-learning algorithms that have low computational demands, are robust against noise, and have theoretical convergence guarantees. Existing algorithms are only partially successful: normalized-output algorithms are efficient, but are not guaranteed to converge, while Isomap is guaranteed to converge, but is computationally expensive. A possible way to achieve all of the goals simultaneously is to improve the existing normalized-output algorithms. While it is clear that, due to the normalization constraints, one cannot hope for geodesic distances preservation nor for neighborhoods structure preservation, success as measured by other criteria may be achieved. A suggestion of improvement for LEM appears in Gerber et al. (2007), yet this improvement is both computationally expensive and lacks a rigorous consistency proof. We hope that future research finds additional ways to improve the existing methods, given the improved understanding of the underlying problems detailed in this paper.

Acknowledgments

We are grateful to the anonymous reviewers of present and earlier versions of this manuscript for their helpful suggestions. We thank an anonymous referee for pointing out errors in the proof of Lemma 3.1. We thank J. Hamm for providing the database of globe images. This research was supported in part by Israeli Science Foundation grant and in part by NSF, grant DMS-0605236.

2. We replaced the original τ and σ with r and α respectively to avoid confusion with previous notations.

Appendix A. Detailed Proofs and Discussions

This section contains detailed proofs of Equations 4 and 7, Lemmas 3.1 and A.2, and Theorem 5.1. It also contains discussions regarding the equivalence of the normalized-output algorithms' representations, and the estimation of $F(K)$ and $\widetilde{F}(K)$ for a ball of radius r (see Section 4).

A.1 The Equivalence of the Algorithms' Representations

For LEM, note that according to our representation, one needs to minimize

$$\Phi(Y) = \sum_{i=1}^{N} \|W_i Y_i\|_F^2 = \sum_{i=1}^{N} \sum_{j=1}^{K} w_{i,j} \|y_i - y_{i,j}\|^2,$$

under the constraints $Y'D\mathbf{1} = \mathbf{0}$ and $Y'DY = I$. Define $\hat{w}_{rs} = w_{r,j}$ if s is the j-th neighbor of r and zero otherwise. Define $\hat{D}$ to be the diagonal matrix such that $d_{rr} = \sum_{s=1}^{N} \hat{w}_{rs}$; note that $\hat{D} = D$. Using these definitions, one needs to minimize $\Phi(Y) = \sum_{r,s} \hat{w}_{rs} \|y_r - y_s\|^2$ under the constraints $Y'\hat{D}\mathbf{1} = \mathbf{0}$ and $Y'\hat{D}Y = I$, which is the the authors' representation of the algorithm.

For DFM, as for LEM, we define the weights $\hat{w}_{rs}$. Define the $N \times N$ matrix $\hat{W} = (\hat{w}_{rs})$. Define the matrix $D^{-1}\hat{W}$; note that this matrix is a Markovian matrix and that $v^{(0)} \equiv \mathbf{1}$ is its eigenvector corresponding to eigenvalue 1, which is the largest eigenvalue of the matrix. Let $v^{(p)}$, $p = 1, \ldots, d$ be the next d eigenvectors, corresponding to the next d largest eigenvalues λ_p, normalized such that $v^{(p)\prime} D v^{(p)} = 1$. Note that the vectors $v^{(0)}, \ldots, v^{(d)}$ are also the eigenvectors of $I - D^{-1}W$ corresponding to the $d+1$ lowest eigenvalues. Thus, the matrix $[v^{(1)}, \ldots, v^{(d)}]$ (up to rotation) can be computed by minimizing $\operatorname{tr}(Y'(D-W)Y)$ under the constraints $Y'DY = I$ and $Y'D\mathbf{1} = \mathbf{0}$. Simple computation shows (see Belkin and Niyogi, 2003, Eq. 3.1) that $\operatorname{tr}(Y'(D-W)Y) = \frac{1}{2}\sum_{r,s} \hat{w}_{rs} \|y_r - y_s\|^2$. We already showed that $\Phi(Y) = \sum_{r,s} \hat{w}_{rs} \|y_r - y_s\|^2$. Hence, minimizing $\operatorname{tr}(Y'(D-W)Y)$ under the constraints $Y'DY = I$ and $Y'D\mathbf{1} = \mathbf{0}$ is equivalent to minimizing $\Phi(Y)$ under the same constraints. The embedding suggested by Coifman and Lafon (2006) (up to rotation) is the matrix $\left[\lambda_1 \frac{v^{(1)}}{\|v^{(1)}\|}, \ldots, \lambda_d \frac{v^{(d)}}{\|v^{(d)}\|}\right]$. Note that this embedding can be obtained from the output matrix Y by a simple linear transformation.

For LLE, note that according to our representation, one needs to minimize

$$\Phi(Y) = \sum_{i=1}^{N} \|W_i Y_i\|_F^2 = \sum_{i=1}^{N} \|y_i - \sum_{j=1}^{K} w_{i,j} y_{i,j}\|^2$$

under the constraints $Y'\mathbf{1} = \mathbf{0}$ and $\operatorname{Cov}(Y) = I$, which is the minimization problem given by Roweis and Saul (2000).

The representation of LTSA is similar to the representation that appears in the original paper, differing only in the weights' definition. We defined the weights W_i following Huo and Smith (2006), who showed that both definitions are equivalent.

For HLLE, note that according to our representation, one needs to minimize

$$\Phi(Y) = \sum_{i=1}^{N} \|W_i Y_i\|_F^2 = \sum_{i=1}^{N} \operatorname{tr}\left(Y_i' H_i' H_i Y_i\right)$$

under the constraint $\operatorname{Cov}(Y) = I$. This is equivalent (up to a multiplication by $\sqrt{(N)}$) to minimizing $\operatorname{tr}(Y'\mathcal{H}Y)$ under the constraint $Y'Y = I$, where $\mathcal{H}$ is the matrix that appears in the original definition

of the algorithm. This minimization can be calculated by finding the $d+1$ lowest eigenvectors of $\mathcal{H}$, which is the embedding suggested by Donoho and Grimes (2004).

A.2 Proof of Lemma 3.1

We begin by estimating $\Phi(\widetilde{Y})$.

$$\begin{aligned}
\Phi(\widetilde{Y}) &= \sum_{i=1}^{N} \|W_i Y_i + \varepsilon W_i E_i\|_F^2 = \sum_{i=1}^{N}\sum_{j=0}^{K} \left\|W_i y_{i,j} + \varepsilon W_i e_{i,j}\right\|^2 \qquad (14)\\
&\geq \sum_{i=1}^{N}\sum_{j=0}^{K} \left(\left\|W_i y_{i,j}\right\|^2 - 2\varepsilon |(W_i y_{i,j})' W_i e_{i,j}|\right)\\
&\geq \sum_{i=1}^{N}\sum_{j=0}^{K} \left((1-\varepsilon)\left\|W_i y_{i,j}\right\|^2 - \varepsilon \left\|W_i e_{i,j}\right\|^2\right)\\
&= (1-\varepsilon)\sum_{i=1}^{N} \|W_i Y_i\|_F^2 - \varepsilon \sum_{i=1}^{N} \|W_i E_i\|_F^2\\
&\geq (1-\varepsilon)\Phi(Y) - \varepsilon \sum_{i=1}^{N} \|W_i\|_F^2 \|E_i\|_F^2 ,
\end{aligned}$$

where $e_{i,j}$ denotes the j-th row of E_i.

We bound $\|W_i\|_F^2$ for each of the algorithms by a constant C_a. It can be shown that for LEM and DFM, $C_a \leq 2K$; for LTSA, $C_a \leq K$; for HLLE $C_a \leq \frac{d(d+1)}{2}$. For LLE in the case of positive weights $w_{i,j}$, we have $C_a \leq 2$. Thus, substituting C_a in Eq. 14, we obtain

$$\begin{aligned}
\Phi(\widetilde{Y}) &\geq (1-\varepsilon)\Phi(Y) - \varepsilon C_a \sum_{i=1}^{N}\sum_{j=0}^{K} \left\|e_{i,j}\right\|^2\\
&\geq (1-\varepsilon)\Phi(Y) - \varepsilon C_a S \|E\|_F^2 = (1-\varepsilon)\Phi(Y) - \varepsilon C_a S .
\end{aligned}$$

The last inequality holds true since S is the maximum number of neighborhoods to which a single observation belongs.

A.3 Proof of Equation 4

By definition $\sigma^2 = \mathrm{Var}(X^{(1)})$ and hence,

$$\begin{aligned}
\sigma^2 &= \frac{1}{N}\sum_{i=-m}^{m}\sum_{j=-q}^{q} \left(x_{ij}^{(1)}\right)^2\\
&= \frac{1}{(2m+1)(2q+1)}\sum_{i=-m}^{m}\sum_{j=-q}^{q} i^2\\
&= \frac{2}{2m+1}\sum_{i=1}^{m} i^2\\
&= \frac{2}{2m+1}\frac{(2m+1)(m+1)m}{6}\\
&= \frac{(m+1)m}{3} .
\end{aligned}$$

The computation for τ is similar.

A.4 Estimation of $F(K)$ and $\widetilde{F}(K)$ for a Ball of Radius r

Calculation of $\phi(Y_{ij})$ for general K can be different for different choices of neighborhoods. Therefore, we restrict ourselves to estimating $\phi(Y_{ij})$ when the neighbors are all the points inside an r-ball in the original grid. Recall that $\phi(Y_{ij})$ for an inner point is equal to the sum of the squared distance between y_{ij} and its neighbors. The function

$$f(x_1,x_2) = \left(\frac{x_1}{\sigma}\right)^2 + \left(\frac{x_2}{\tau}\right)^2$$

agrees with the squared distance for points on the grid, where x_1 and x_2 indicate the horizontal and vertical distances from x_{ij} in the original grid, respectively. We estimate $\phi(Y_{ij})$ using integration of $f(x_1,x_2)$ on $B(r)$, a ball of radius r, which yields

$$\phi(Y_{ij}) \approx \int\limits_{(x_1^2+x_2^2)<r^2} f(x_1,x_2)\mathrm{d}x_1\mathrm{d}x_2 = \frac{\pi r^4}{4}\left(\frac{1}{\sigma^2}+\frac{1}{\tau^2}\right). \tag{15}$$

Thus, we obtain $F(K) \approx \frac{\pi r^4}{4}$.

We estimate $\phi(Z_{ij})$ similarly. We define the continuous version of the squared distance in the case of the embedding Z by

$$g(x_1,x_2) = x_1^2\left(\frac{1}{\sigma^2}+\frac{4}{\rho^2}\right).$$

Integration yields

$$\phi(Z_{ij}) \approx \int\limits_{(x_1^2+x_2^2)<r^2} g(x_1,x_2)\mathrm{d}x_1\mathrm{d}x_2 = \frac{\pi r^4}{4}\left(\frac{1}{\sigma^2}+\frac{4}{\rho^2}\right). \tag{16}$$

Hence, we obtain $\widetilde{F}(K) \approx \frac{\pi r^4}{4}$ and the relations between Eqs. 5 and 6 are preserved for a ball of general radius.

For DFM, a general rotation-invariant kernel was considered for the weights. As with Eqs. 15 and 16, the approximations of $\phi(Y_{ij})$ and $\phi(Z_{ij})$ for the general case with neighborhood radius r are given by

$$\int\limits_{(x_1^2+x_2^2)<r^2} f(x_1,x_2)k(x_1,x_2)\mathrm{d}x_1\mathrm{d}x_2 = \left(\pi\int\limits_{0<t<r} k(t^2)t^3\mathrm{d}t\right)\left(\frac{1}{\sigma^2}+\frac{1}{\tau^2}\right)$$

and

$$\int\limits_{(x_1^2+x_2^2)<r^2} g(x_1,x_2)k(x_1,x_2)\mathrm{d}x_1\mathrm{d}x_2 = \left(\pi\int\limits_{0<t<r} k(t^2)t^3\mathrm{d}t\right)\left(\frac{1}{\sigma^2}+\frac{4}{\rho^2}\right).$$

Note that the ratio between these approximations of $\phi(Y_{ij})$ and $\phi(Z_{ij})$ is preserved. In light of these computations it seems that for the general case of rotation-invariant kernels, $\phi(Y_{ij}) > \phi(Z_{ij})$ for aspect ratio sufficiently greater than 2.

A.5 Proof of Equation 7

Direct computation shows that

$$\bar{z}^{(2)} = \frac{(2q+1)2}{N\rho}\sum_{i=1}^{m}(2i) = \frac{2m(m+1)}{(2m+1)\rho}\,.$$

Recall that by definition ρ ensures that $\mathrm{Var}(Z^{(2)}) = 1$. Hence,

$$\begin{aligned} 1 &= \frac{1}{N}\sum_{i=-m}^{m}\sum_{j=-q}^{q}\frac{(2i)^2}{\rho^2} - \left(\bar{z}^{(2)}\right)^2 \\ &= \frac{2}{2m+1}\frac{4m(m+1)(2m+1)}{6\rho^2} - \frac{4m^2(m+1)^2}{(2m+1)^2\rho^2} \\ &= \frac{4m(m+1)}{3\rho^2} - \frac{4m^2(m+1)^2}{(2m+1)^2\rho^2}\,. \end{aligned}$$

Further computation shows that

$$(m+1)m > \frac{4(m+1)^2m^2}{(2m+1)^2}\,.$$

Hence,

$$\rho^2 > \frac{4(m+1)m}{3} - (m+1)m = \sigma^2\,.$$

A.6 Proof of Theorem 5.1

The proof consists of computing $\Phi(Y)$ and bounding $\Phi(Z)$ from above. We start by computing $\Phi(Y)$.

$$\begin{aligned} \Phi(Y) &= \sum_{i=1}^{N}\|W_iY_i\|_F^2 = \sum_{i=1}^{N}\left\|W_iX_i^{(1)}/\sigma\right\|^2 + \sum_{i=1}^{N}\left\|W_iX_i^{(2)}/\tau\right\|^2 \\ &= N\frac{\bar{e}^{(1)}}{\sigma^2} + N\frac{\bar{e}^{(2)}}{\tau^2}\,. \end{aligned}$$

The computation of $\Phi(Z)$ is more delicate because it involves neighborhoods Z_i that are not linear transformations of their original sample counterparts.

$$\begin{aligned} \Phi(Z) &= \sum_{i=1}^{N}\|W_iZ_i\|_F^2 = \sum_{i=1}^{N}\left\|W_iZ_i^{(1)}\right\|^2 + \sum_{i=1}^{N}\left\|W_iZ_i^{(2)}\right\|^2 \\ &= N\frac{\bar{e}^{(1)}}{\sigma^2} + \sum_{i:x_i^{(1)}<0\,,\,i\notin N_0}\left\|W_iX_i^{(1)}/\rho\right\|^2 + \sum_{i:x_i^{(1)}>0\,,\,i\notin N_0}\left\|\kappa W_iX_i^{(1)}/\rho\right\|^2 + \sum_{i\in N_0}\left\|W_iZ_i^{(2)}\right\|^2 \qquad (17) \\ &< N\frac{\bar{e}^{(1)}}{\sigma^2} + N\frac{\kappa^2\bar{e}^{(1)}}{\rho^2} + \sum_{i\in N_0}\left\|W_iZ_i^{(2)}\right\|^2\,. \qquad (18) \end{aligned}$$

Note that $\max_{j,k\in\{0,\ldots,K\}}\left\|z_{i,j}-z_{i,k}\right\| \le \kappa r(i)/\rho$. Hence, using Lemma A.1 we get

$$\left\|W_iZ_i^{(2)}\right\|^2 < \frac{c_a\kappa^2 r(i)^2}{\rho^2}\,, \qquad (19)$$

where c_a is a constant that depends on the specific algorithm. Combining Eqs. 18 and 19 we obtain

$$\Phi(Z) < N\frac{\overline{e}^{(1)}}{\sigma^2} + N\frac{\kappa^2\overline{e}^{(1)}}{\rho^2} + |N_0|c_a r_{\max}^2\frac{\kappa^2}{\rho^2}.$$

In the specific case of LEM and DFM, a tighter bound can be obtained for $\left\|W_i Z_i^{(2)}\right\|^2$. Note that for LEM and DFM

$$\begin{aligned}\left\|W_i Z_i^{(2)}\right\|^2 &= \sum_{j=1^K} w_{i,j}(z_i^{(2)} - z_{i,j}^{(2)})^2 \\ &\leq \sum_{j=1}^{K} w_{i,j}\frac{\kappa^2}{\rho^2}(x_i^{(2)} - x_{i,j}^{(2)})^2 = \frac{\kappa^2}{\rho^2}e_i^{(1)}.\end{aligned}$$

Combining Eq. 17 and the last inequality we obtain in this case that

$$\Phi(Z) \leq N\frac{\overline{e}^{(1)}}{\sigma^2} + N\frac{\kappa^2\overline{e}^{(1)}}{\rho^2},$$

which completes the proof.

A.7 Lemma A.1

Lemma A.1 *Let $X_i = [x_i, x_{i,1}, \ldots, x_{i,K}]'$ be a local neighborhood. Let $r_i = \max_{j,k}\left\|x_{i,j} - x_{i,k}\right\|$. Then*

$$\|W_i X_i\|_F^2 < c_a r_i^2,$$

where c_a is a constant that depends on the algorithm.

Proof We prove this lemma for each of the different algorithms separately.

- LEM and DFM:

  $$\|W_i X_i\|_F^2 = \sum_{j=1}^{K} w_{i,j}\left\|x_{i,j} - x_i\right\|^2 \leq \left(\sum_{j=1}^{K} w_{i,j}\right) r_i^2 \leq K r_i^2,$$

  where the last inequality holds since $w_{i,j} \leq 1$. Hence $c_a = K$.

- LLE:

  $$\begin{aligned}\|W_i X_i\|_F^2 &= \left\|\sum_{j=1}^{K} w_{i,j}(x_{i,j} - x_i)\right\|^2 \leq \left\|\frac{1}{K}\sum_{j=1}^{K}(x_{i,j} - x_i)\right\|^2 \\ &\leq \frac{1}{K^2}\sum_{j=1}^{K}\left\|x_{i,j} - x_i\right\|^2 \leq \frac{r_i^2}{K},\end{aligned}$$

  where the first inequality holds since $w_{i,j}$ were chosen to minimize $\left\|\sum_{j=1}^{K}\tilde{w}_{i,j}(x_{i,j} - x_i)\right\|^2$. Hence $c_a = 1/K$.

- LTSA:

$$\begin{aligned} \|W_i X_i\|_F^2 &= \left\|(I - P_i P_i')HX_i\right\|_F^2 \leq \left\|(I - P_i P_i')\right\|_F^2 \|HX_i\|_F^2 \\ &\leq K \sum_j \left\|x_{i,j} - \bar{x_i}\right\|^2 \leq K^2 r_i^2 . \end{aligned}$$

  The first equality is just the definition of W_i (see Sec. 2). The matrix $I - P_i P_i'$ is a projection matrix and its square norm is the dimension of its range, which is smaller than $K+1$. Hence $c_a = K^2$.

- HLLE:

$$\|W_i X_i\|_F^2 = \|W_i H X_i\|_F^2 \leq \|W_i\|_F^2 \|HX_i\|_F^2 \leq \frac{d(d+1)}{2}(K+1) r_i^2 .$$

  The first equality holds since $W_i H = W_i(I - \frac{1}{K}\mathbf{1}\mathbf{1}') = W_i$, since the rows of W_i are orthogonal to the vector $\mathbf{1}$ by definition (see Sec. 2). Hence $c_a = \frac{d(d+1)}{2}(K+1)$.

■

A.8 Lemma A.2

Lemma A.2 *Let X be a random variable symmetric around zero with unimodal distribution. Assume that $Var(X) = \sigma^2$. Then $Var(|X|) \geq \frac{\sigma^2}{4}$.*

Proof First note that that the equality holds for $X \sim U(-\sqrt{3}\sigma, \sqrt{3}\sigma)$, where U denotes the uniform distribution. Assume by contradiction that there is a random variable X, symmetric around zero and with unimodal distribution such that $\mathrm{Var}(|X|) < \frac{\sigma^2}{4} - \varepsilon$, where $\varepsilon > 0$. Since $\mathrm{Var}(|X|) = E(|X|^2) - E(|X|)^2$, and $E(|X|^2) = E(X^2) = \mathrm{Var}(X) = \sigma^2$, we have $E(|X|)^2 > \frac{3\sigma^2}{4} + \varepsilon$.

We approximate X by X_n, where X_n is a mixture of uniform random variables, defined as follows. Define $X_n \sim \sum_{i=1}^n p_i^n U(-c_i^n, c_i^n)$ where $p_i^n > 0$, $\sum_{i=1}^n p_i^n = 1$. Note that $E(X_n) = 0$ and that $\mathrm{Var}(X_n) = \sum_{i=1}^n p_i^n (c_i^n)^2/3$. For large enough n, we can choose p_i^n and c_i^n such that $\mathrm{Var}(X_n) = \sigma^2$ and $E(|X - X_n|) < \frac{\varepsilon}{2E(|X|)}$.

Consider the random variable $|X_n|$. Note that using the definitions above we may write $|X_n| = \sum_{i=1}^n p_i^n U(0, c_i^n)$, hence $E(|X_n|) = \frac{1}{2}\sum_{i=1}^n p_i^n c_i^n$. We bound this expression from below. We have

$$\begin{aligned} E(|X_n|)^2 &= E(|X_n - X + X|)^2 \geq (E(|X|) - E(|X_n - X|))^2 \\ &\geq E(|X|)^2 - 2E(|X|)E(|X_n - X|) > \frac{3\sigma^2}{4} . \end{aligned} \tag{20}$$

Let $X_{n-1} = \sum_{i=1}^{n-1} p_i^{n-1} U(-c_i^{n-1}, c_i^{n-1})$ where

$$p_i^{n-1} = \begin{cases} p_i^n & i < n-1 \\ p_{n-1}^n + p_n^n & i = n-1 \end{cases} ,$$

and

$$c_i^{n-1} = \begin{cases} c_i^n & i < n-1 \\ \sqrt{\left((c_{n-1}^n)^2 + (c_n^n)^2\right)} & i = n-1 \end{cases} .$$

Note that $\mathrm{Var}(X_{n-1}) = \sigma^2$ by construction and X_{n-1} is symmetric around zero with unimodal distribution. Using the triangle inequality we obtain

$$E(|X_{n-1}|) = \frac{1}{2}\sum_{i=1}^{n-1} p_i^{n-1} c_i^{n-1} \geq \frac{1}{2}\sum_{i=1}^{n} p_i^n c_i^n = E(|X_n|)\,.$$

Using the same argument recursively, we obtain that $E(|X_1|) \geq E(|X_n|)$. However, $X_1 \sim U(-\sqrt{3}\sigma, \sqrt{3}\sigma)$ and hence $E(|X_1|)^2 = \frac{3\sigma^2}{4}$. Since by Eq. 20, $E(|X_n|)^2 > \frac{3\sigma^2}{4}$ we have a contradiction. ■

Abstract

We consider a hierarchy of queries about causal relationships in graphical models, where each level in the hierarchy requires more detailed information than the one below. The hierarchy consists of three levels: associative relationships, derived from a joint distribution over the observable variables; cause-effect relationships, derived from distributions resulting from external interventions; and counterfactuals, derived from distributions that span multiple "parallel worlds" and resulting from simultaneous, possibly conflicting observations and interventions. We completely characterize cases where a given causal query can be computed from information lower in the hierarchy, and provide algorithms that accomplish this computation. Specifically, we show when effects of interventions can be computed from observational studies, and when probabilities of counterfactuals can be computed from experimental studies. We also provide a graphical characterization of those queries which cannot be computed (by any method) from queries at a lower layer of the hierarchy.

Keywords: causality, graphical causal models, identification

1. Introduction

The human mind sees the world in terms of causes and effects. Understanding and mastering our environment hinges on answering questions about cause-effect relationships. In this paper we consider three distinct classes of causal questions forming a hierarchy.

The first class of questions involves associative relationships in domains with uncertainty, for example, "I took an aspirin after dinner, will I wake up with a headache?" The tools needed to formalize and answer such questions are the subject of probability theory and statistics, for they require computing or estimating some aspects of a joint probability distribution. In our aspirin example, this requires estimating the conditional probability $P(headache|aspirin)$ in a population that resembles the subject in question, that is, sharing age, sex, eating habits and any other traits that can be measured. Associational relationships, as is well known, are insufficient for establishing causation. We nevertheless place associative questions at the base of our causal hierarchy, because the probabilistic tools developed in studying such questions are instrumental for computing more informative causal queries, and serve therefore as an easily available starting point from which such computations can begin.

The second class of questions involves responses of outcomes of interest to outside interventions, for instance, "if I take an aspirin now, will I wake up with a headache?" Questions of this type are normally referred to as *causal effects*, sometimes written as $P(headache|do(aspirin))$. They

differ, of course from the associational counterpart
$P(headache|aspirin)$, because all mechanisms which normally determine aspirin taking behavior, for example, taste of aspirin, family advice, time pressure, etc. are irrelevant in evaluating the effect of a new decision.

To estimate effects, scientists normally perform randomized experiments where a sample of units drawn from the population of interest is subjected to the specified manipulation directly. In our aspirin example, this might involve treating a group of subjects with aspirin and comparing their response to untreated subjects, both groups being selected at random from a population resembling the decision maker in question. In many cases, however, such a direct approach is not possible due to expense or ethical considerations. Instead, investigators have to rely on observational studies to infer effects. A fundamental question in causal analysis is to determine when effects can be inferred from statistical information, encoded as a joint probability distribution, obtained under normal, intervention-free behavior. A key point here is that in order to make causal inferences from statistics, additional causal assumptions are needed. This is because without any assumptions it is possible to construct multiple "causal stories" which can disagree wildly on what effect a given intervention can have, but agree precisely on all observables. For instance, smoking may be highly correlated with lung cancer either because it causes lung cancer, or because people who are genetically predisposed to smoke may also have a gene responsible for a higher cancer incidence rate. In the latter case there will be no effect of smoking on cancer. Distinguishing between such causal stories requires additional, non-statistical language. In this paper, the language that we use for this purpose is the language of graphs, and our causal assumptions will be encoded by a special directed graph called a *causal diagram*.

The use of directed graphs to represent causality is a natural idea that arose multiple times independently: in genetics (Wright, 1921), econometrics (Haavelmo, 1943), and artificial intelligence (Pearl, 1988; Spirtes et al., 1993; Pearl, 2000). A causal diagram encodes variables of interest as nodes, and possible direct causal influences between two variables as arrows. Associated with each node in a causal diagram is a stable causal mechanism which determines its value in terms of the values of its parents. Unlike Bayesian networks (Pearl, 1988), the relationships between variables are assumed to be deterministic and uncertainty arises due to the presence of unobserved variables which have influence on our domain.

The first question we consider is under what conditions the effect of a given intervention can be computed from just the joint distribution over observable variables, which is obtainable by statistical means, and the causal diagram, which is either provided by a human expert, or inferred from experimental studies. This *identification problem* has received consideration attention in the statistics, epidemiology, and causal inference communities (Pearl, 1993a; Spirtes et al., 1993; Pearl and Robins, 1995; Pearl, 1995; Kuroki and Miyakawa, 1999; Pearl, 2000). In the subsequent sections, we solve the identification problem for causal effects by providing a graphical characterization for all non-identifiable effects, and an algorithm for computing all identifiable effects. Note that this identification problem actually involves two "worlds:" the original world where no interventions took place furnishes us with a probability distribution from which to make inferences about the second, post-intervention world. The crucial feature of causal effect queries which distinguishes them from more complex questions in our hierarchy is that they are restricted to the post-intervention world alone.

The third and final class of queries we consider are *counterfactual* or "what-if" questions which arise when we simultaneously ask about multiple hypothetical worlds, with potentially conflicting

interventions or observations. An example of such a question would be "I took an aspirin, and my headache is gone; would I have had a headache had I not taken that aspirin?" Unlike questions involving interventions, counterfactuals contain conflicting information: in one world aspirin was taken, in another it was not. It is unclear therefore how to set up an effective experimental procedure for evaluating counterfactuals, let alone how to compute counterfactuals from observations alone. If everything about our causal domain is known, in other words if we have knowledge of both the causal mechanisms and the distributions over unobservable variables, it is possible to compute counterfactual questions directly (Balke and Pearl, 1994b). However, knowledge of precise causal mechanisms is not generally available, and the very nature of unobserved variables means their stochastic behavior cannot be estimated directly. We therefore consider the more practical question of how to compute counterfactual questions from both experimental studies and the structure of the causal diagram.

It may seem strange, in light of what we said earlier about the difficulty of conducting experimental studies, that we take such studies as given. It is nevertheless important that we understand when it is that "what-if" questions involving multiple worlds can be inferred from quantities computable in one world. Our hierarchical approach to identification allows us to cleanly separate difficulties that arise due to multiplicity of worlds from those involved in the identification of causal effects. We provide a complete solution to this version of the identification problem by giving algorithms which compute identifiable counterfactuals from experimental studies, and provide graphical conditions for the class of non-identifiable counterfactuals, where our algorithms fail. Our results can, of course, be combined to give conditions where counterfactuals can be computed from observational studies.

The paper is organized as follows. Section 2 introduces the notation and mathematical machinery needed for causal analysis. Section 3 considers the problem of identifying causal effects from observational studies. Section 4 considers identification of counterfactual queries, while Section 5 summarizes the conclusions. Most of the proofs are deferred to the appendix. This paper consolidates and expands previous results (Shpitser and Pearl, 2006a,b, 2007). Some of the results found in this paper were also derived independently elsewhere (Huang and Valtorta, 2006b,a).

2. Notation and Definitions

The primary object of causal inquiry is a probabilistic causal model. We will denote variables by uppercase letters, and their values by lowercase letters. Similarly, sets of variables will be denoted by bold uppercase, and sets of values by bold lowercase.

Definition 1 *A probabilistic causal model (PCM) is a tuple* $M = \langle \boldsymbol{U}, \boldsymbol{V}, \boldsymbol{F}, P(\boldsymbol{u}) \rangle$*, where*

- $\boldsymbol{U}$ *is a set of background or exogenous variables, which cannot be observed or experimented on, but which affect the rest of the model.*
- $\boldsymbol{V}$ *is a set* $\{V_1, ..., V_n\}$ *of observable or endogenous variables. These variables are functionally dependent on some subset of* $\boldsymbol{U} \cup \boldsymbol{V}$*.*
- $\boldsymbol{F}$ *is a set of functions* $\{f_1, ..., f_n\}$ *such that each* f_i *is a mapping from a subset of* $\boldsymbol{U} \cup \boldsymbol{V} \setminus \{V_i\}$ *to* V_i*, and such that* $\bigcup \boldsymbol{F}$ *is a function from* $\boldsymbol{U}$ *to* $\boldsymbol{V}$*.*
- $P(\boldsymbol{u})$ *is a joint probability distribution over* $\boldsymbol{U}$*.*

The set of functions **F** in this definition corresponds to the causal mechanisms, while **U** represents the background context that influences the observable domain of discourse **V**, yet remains outside it. Our ignorance of the background context is represented by a distribution $P(\mathbf{u})$. This distribution, together with the mechanisms in **F**, induces a distribution $P(\mathbf{v})$ over the observable domain. The causal diagram, our vehicle for expressing causal assumptions, is defined by the causal model as follows. Each observable variable $V_i \in \mathbf{V}$ corresponds to a vertex in the graph. Any two variables $V_i \in \mathbf{U} \cup \mathbf{V}$, $V_j \in \mathbf{V}$ such that V_i appears in the description of f_j are connected by a directed arrow from V_i to V_j. Furthermore, we make two additional assumptions in this paper. The first is that $P(\mathbf{u}) = \prod_{u_i \in \mathbf{u}} P(u_i)$, and each $U_i \in \mathbf{U}$ is used in at most two functions in F.[1] The second is that all induced graphs must be acyclic. Models in which these two assumptions hold are called recursive semi-Markovian. A graph defined as above from a causal model M is said to be a causal diagram *induced* by M. Graphs induced by semi-Markovian models are themselves called semi-Markovian. Fig. 1 and Fig. 2 show some examples of causal diagrams of recursive semi-Markovian models.

The functions in **F** are assumed to be *modular* in a sense that changes to one function do not affect any other. This assumption allows us to model how a PCM would react to changes imposed from the outside. The simplest change that is possible for causal mechanisms of a variable set **X** would be one that removes the mechanisms entirely and sets **X** to a specific value **x**. This change, denoted by $do(\mathbf{x})$ (Pearl, 2000), is called an *intervention*. An intervention $do(\mathbf{x})$ applied to a model M results in a *submodel* $M_{\mathbf{X}}$. The effects of interventions will be formulated in several ways. For any given **u**, the effect of $do(\mathbf{x})$ on a set of variables **Y** will be represented by *counterfactual variables* $Y_{\mathbf{X}}(\mathbf{u})$, where $Y \in \mathbf{Y}$. As **U** varies, the counterfactuals $Y_{\mathbf{X}}(\mathbf{u})$ will vary as well, and their *interventional distribution*, denoted by $P(\mathbf{y}|do(\mathbf{x}))$ or $P_{\mathbf{x}}(\mathbf{y})$ will be used to define the effect of **x** on **Y**. We will denote the event "variable Y attains value y in $M_{\mathbf{X}}$" by the shorthand $y_{\mathbf{X}}$.

Interventional distributions are a mathematical formalization of an intuitive notion of effect of action. We now define joint probabilities on counterfactuals, in multiple worlds, which will serve as the formalization of counterfactual queries. Consider a conjunction of events $\gamma = y^1_{\mathbf{X}^1} \wedge ... \wedge y^k_{\mathbf{X}^k}$. If all the subscripts $\mathbf{x}^i$ are the same and equal to **x**, γ is simply a set of assignments of values to variables in $M_{\mathbf{X}}$, and $P(\gamma) = P_{\mathbf{X}}(y^1, ..., y^k)$. However, if the actions $do(\mathbf{x}^i)$ are not the same, and potentially contradictory, a single submodel is no longer sufficient. Instead, γ is really invoking multiple causal worlds, each represented by a submodel $M_{\mathbf{x}^i}$. We assume each submodel shares the same set of exogenous variables **U**, corresponding to the shared causal context or background history of the hypothetical worlds. Because the submodels are linked by common context, they can really be considered as one large causal model, with its own induced graph, and joint distribution over observable variables. $P(\gamma)$ can then be defined as a marginal distribution in this causal model. Formally, $P(\gamma) = \sum_{\{\mathbf{u}|\mathbf{u} \models \gamma\}} P(\mathbf{u})$, where $\mathbf{u} \models \gamma$ is taken to mean that each variable assignment in γ holds true in the corresponding submodel of M when the exogenous variables **U** assume values **u**. In this way, $P(\mathbf{u})$ induces a distribution on all possible counterfactual variables in M. In this paper, we will represent counterfactual utterances by joint distributions such as $P(\gamma)$ or conditional distributions such as $P(\gamma|\delta)$, where γ and δ are conjunctions of counterfactual events. Pearl (2000) discusses counterfactuals, and their probabilistic representation used in this paper in greater depth.

1. Our results are generalizable to other $P(\mathbf{u})$ distributions which may not have such a simple form, but which can be represented by a set of bidirected arcs in such a way that whenever two sets of **U** variables are d-separated from each other, they are marginally independent. However, the exact conditions under which this graphical representation is valid are beyond the scope of this paper.

A fundamental question in causal inference is whether a given causal question, either interventional or counterfactual in nature, can be uniquely specified by the assumptions embodied in the causal diagram, and easily available information, usually statistical, associated with the causal model. To get a handle on this question, we introduce an important notion of *identifiability* (Pearl, 2000).

Definition 2 (identifiability) *Consider a class of models $\mathbf{M}$ with a description T, and objects ϕ and θ computable from each model. We say that ϕ is θ-identified in T if ϕ is uniquely computable from θ in any $M \in \mathbf{M}$. In this case all models in $\mathbf{M}$ which agree on θ will also agree on ϕ.*

If ϕ is θ-identifiable in T, we write $T, \theta \vdash_{id} \phi$. Otherwise, we write $T, \theta \nvdash_{id} \phi$. The above definition leads immediately to the following corollary which we will use to prove non-identifiability results.

Corollary 3 *Let T be a description of a class of models $\mathbf{M}$. Assume there exist $M^1, M^2 \in \mathbf{M}$ that share objects θ, while ϕ in M^1 is different from ϕ in M^2. Then $T, \theta \nvdash_{id} \phi$.*

In our context, the objects ϕ, θ are probability distributions derived from the PCM, where θ represents available information, while ϕ represents the quantity of interest. The description T is a specification of the properties shared all causal models under consideration, or, in other words, the set of assumptions we wish to impose on those models. Since we chose causal graphs as a language for specifying assumptions, T corresponds to a given graph.

Graphs earn their ubiquity as a specification language because they reflect in many ways the way people store experiential knowledge, especially cause-effect relationships. The ease with which people embrace graphical metaphors for causal and probabilistic notions—ancestry, neighborhood, flow, and so on—are proof of this affinity, and help ensure that the assumptions specified are meaningful and reliable. A consequence of this is that probabilistic dependencies among variables can be verified by checking if the flow of influence is blocked along paths linking the variables. By a path we mean a sequence of distinct nodes where each node is connected to the next in the sequence by an edge. The precise way in which the flow of dependence can be blocked is defined by the notion of d-separation (Pearl, 1986; Verma, 1986; Pearl, 1988). Here we generalize d-separation somewhat to account for the presence of bidirected arcs in causal diagrams.

Definition 4 (d-separation) *A path p in G is said to be d-separated by a set $\mathbf{Z}$ if and only if either*

1. *p contains one of the following three patterns of edges: $I \rightarrow M \rightarrow J$, $I \leftrightarrow M \rightarrow J$, or $I \leftarrow M \rightarrow J$, such that $M \in \mathbf{Z}$, or*

2. *p contains one of the following three patterns of edges: $I \rightarrow M \leftarrow J$, $I \leftrightarrow M \leftarrow J$, $I \leftrightarrow M \leftrightarrow J$, such that $De(M)_G \cap \mathbf{Z} = \emptyset$.*

Two sets $\mathbf{X}, \mathbf{Y}$ are said to be d-separated given $\mathbf{Z}$ in G if all paths from $\mathbf{X}$ to $\mathbf{Y}$ in G are d-separated by $\mathbf{Z}$. Paths or sets which are not d-separated are said to be d-connected. What allows us to connect this notion of blocking of paths in a causal diagram to the notion of probabilistic independence among variables is that the probability distribution over $\mathbf{V}$ and $\mathbf{U}$ in a causal model can be represented as a product of factors, such that each observable node has a factor corresponding

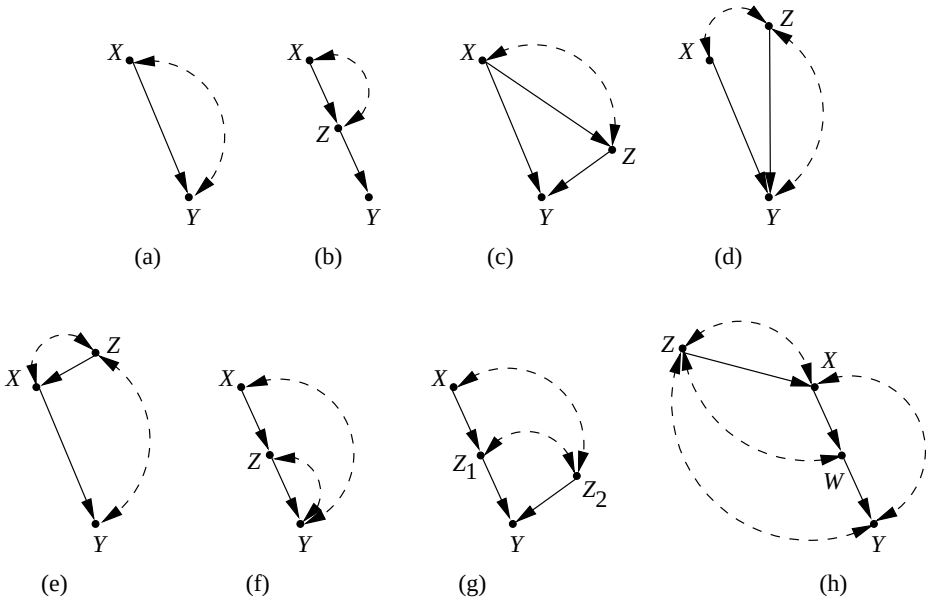

Figure 1: Causal graphs where $P(y|do(\mathbf{x}))$ is not identifiable

to its conditional distribution given the values of its parents in the graph. In other words, $P(\mathbf{v},\mathbf{u}) = \prod_i P(x_i|pa(x_i)_G)$.

Whenever the above factor decomposition holds for a distribution $P(\mathbf{v},\mathbf{u})$ and a graph G, we say G is an I-map of $P(\mathbf{v},\mathbf{u})$. The following theorem links d-separation of vertex sets in an I-map G with the independence of corresponding variable sets in P.

Theorem 5 *If sets $\boldsymbol{X}$ and $\boldsymbol{Y}$ are d-separated by $\boldsymbol{Z}$ in G, then $\boldsymbol{X}$ is independent of $\boldsymbol{Y}$ given $\boldsymbol{Z}$ in every P for which G is an I-map. Furthermore, the causal diagram induced by any semi-Markovian PCM M is an I-map of the distribution $P(\boldsymbol{v},\boldsymbol{u})$ induced by M.*

Note that it's easy to rephrase the above theorem in terms of ordinary directed acyclic graphs, since each semi-Markovian graph is really an abbreviation where each bidirected arc stands for two directed arcs emanating from a hidden common cause. We will abbreviate this statement of d-separation, and corresponding independence by $(\mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{Z})_G$, following the notation of Dawid (1979). For example in the graph shown in Fig. 6 (a), $X \not\perp\!\!\!\perp Y$ and $X \perp\!\!\!\perp Y|Z$, while in Fig. 6 (b), $X \perp\!\!\!\perp Y$ and $X \not\perp\!\!\!\perp Y|Z$.

Finally we consider the axioms and inference rules we will need. Since PCMs contain probability distributions, the inference rules we would use to compute queries in PCMs would certainly include the standard axioms of probability. They also include a set of axioms which govern the behavior of counterfactuals, such as Effectiveness, Composition, etc. (Galles and Pearl, 1998; Halpern, 2000; Pearl, 2000). However, in this paper, we will concentrate on a set of three identities applicable to interventional distributions known as do-calculus (Pearl, 1993b, 2000):

- Rule 1: $P_{\mathbf{X}}(\mathbf{y}|\mathbf{z},\mathbf{w}) = P_{\mathbf{X}}(\mathbf{y}|\mathbf{w})$ if $(\mathbf{Y} \perp\!\!\!\perp \mathbf{Z}|\mathbf{X},\mathbf{W})_{G_{\overline{\mathbf{X}}}}$
- Rule 2: $P_{\mathbf{X},\mathbf{Z}}(\mathbf{y}|\mathbf{w}) = P_{\mathbf{X}}(\mathbf{y}|\mathbf{z},\mathbf{w})$ if $(\mathbf{Y} \perp\!\!\!\perp \mathbf{Z}|\mathbf{X},\mathbf{W})_{G_{\overline{\mathbf{X}}\underline{\mathbf{Z}}}}$

- Rule 3: $P_{\mathbf{X},\mathbf{Z}}(\mathbf{y}|\mathbf{w}) = P_{\mathbf{X}}(\mathbf{y}|\mathbf{w})$ if $(\mathbf{Y} \perp\!\!\!\perp \mathbf{Z}|\mathbf{X},\mathbf{W})_{G_{\overline{\mathbf{X}},\underline{Z(\mathbf{W})}}}$

where $Z(\mathbf{W}) = \mathbf{Z} \setminus An(\mathbf{W})_{G_{\overline{\mathbf{X}}}}$, and $G_{\overline{\mathbf{X}},\underline{\mathbf{Y}}}$ stands for a directed graph obtained from G by removing all incoming arrows to $\mathbf{X}$ and all outgoing arrows from $\mathbf{Y}$. The rules of do-calculus provide a way of linking ordinary statistical distributions with distributions resulting from various manipulations.

In the remainder of this section we will introduce relevant graphs and graph-theoretic terminology which we will use in the rest of the paper. First, having defined causal diagrams induced by natural causal models, we consider the graphs induced by models derived from interventional and counterfactual queries. We note that in a given submodel $M_{\mathbf{X}}$, the mechanisms determining $\mathbf{X}$ no longer make use of the parents of $\mathbf{X}$ to determine their values, but instead set them independently to constant values $\mathbf{x}$. This means that the induced graph of $M_{\mathbf{X}}$ derived from a model M inducing graph G can be obtained from G by removing all arrows incoming to $\mathbf{X}$, in other words $M_{\mathbf{X}}$ induces $G_{\overline{\mathbf{X}}}$. A counterfactual $\gamma = y^1_{\mathbf{x}^1} \wedge \ldots \wedge y^k_{\mathbf{x}^k}$, as we already discussed invokes multiple hypothetical causal worlds, each represented by a submodel, where all worlds share the same background context $\mathbf{U}$. A naive way to graphically represent these worlds would be to consider all the graphs $G_{\overline{\mathbf{X}^i}}$ and have them share the $\mathbf{U}$ nodes. It turns out this representation suffers from certain problems. In Section 4 we discuss this issue in more detail and suggest a more appropriate graphical representation of counterfactual situations.

We denote $Pa(.)_G, Ch(.)_G, An(.)_G, De(.)_G$ as the sets of parents, children, ancestors, and descendants of a given set in G. We denote $G_{\mathbf{X}}$ to be the subgraph of G containing all vertices in $\mathbf{X}$, and edges between these vertices, while the set of vertices in a given graph G is given by $\mathbf{ver}(G)$. As a shorthand, we denote $G_{\mathbf{ver}(G)\setminus\mathbf{ver}(G')}$ as $G \setminus G'$ or $G \setminus \mathbf{X}$, if $\mathbf{X} = \mathbf{ver}(G')$, and G' is a subgraph of G. We will call the set $\{X \in G | De(X)_G = \emptyset\}$ the *root set* of G. A path connecting X and Y which begins with an arrow pointing to X is called a *back-door path* from X, while a path beginning with an arrow pointing away from X is called a *front-door path* from X.

The goal of this paper is a complete characterization of causal graphs which permit the answering of causal queries of a given type. This characterization requires the introduction of certain key graph structures.

Definition 6 (tree) *A graph G such that each vertex has at most one child, and only one vertex (called the root) has no children is called a tree.*

Note that this definition reverses the usual direction of arrows in trees as they are generally understood in graph theory. If we ignore bidirected arcs, graphs in Fig. 1 (a), (b), (d), (e), (f), (g), and (h) are trees.

Definition 7 (forest) *A graph G such that each vertex has at most one child is called a forest.*

Note that the above two definitions reverse the arrow directionality usual for these structures.

Definition 8 (confounded path) *A path where all directed arrowheads point at observable nodes, and never away from observable nodes is called a confounded path.*

The graph in Fig. 1 (g) contains a confounded path from Z_1 to Z_2.

Definition 9 (c-component) *A graph G where any pair of observable nodes is connected by a confounded path is called a c-component (confounded component).*

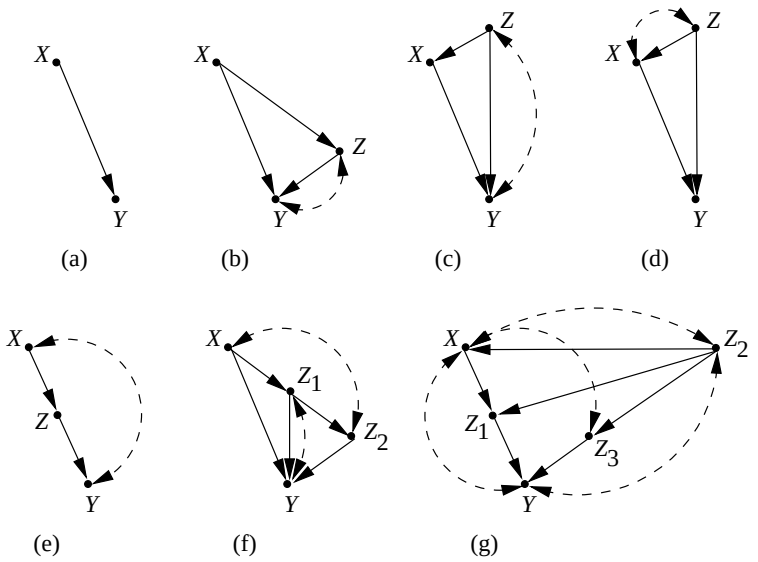

Figure 2: Causal graphs admitting identifiable effect $P(y|do(x))$

Graphs in Fig. 1 (a), (d), (e), (f), and (h) are c-components. Some graphs contain multiple c-components, for example the graph in Fig. 1 (b) has two maximal c-components: $\{Y\}$, and $\{X,Z\}$. We will denote the set of maximal c-components of a given graph G by $C(G)$. The importance of c-components stems from the fact that that the observational distribution $P(\mathbf{v})$ can be expressed as a product of factors $P_{\mathbf{V}\setminus\mathbf{S}}(\mathbf{s})$, where each $\mathbf{s}$ is a set of nodes forming a c-component. This important property is known as *c-component factorization*, and we will this property extensively in the remainder of the manuscript to decompose identification problems into smaller subproblems.

In the following sections, we will show how the graph structures we defined in this section are key for characterizing cases when $P_{\mathbf{X}}(\mathbf{y})$ and $P(\gamma)$ can be identified from available information.

3. Identification of Causal Effects

Like probabilistic dependence, the notion of causal effect of X on Y has an interpretation in terms of flow. Intuitively, X has an effect on Y if changing X causes Y to change. Since intervening on X cuts off X from the normal causal influences of its parents in the graph, we can interpret the causal effect of X on Y as the flow of dependence which leaves X via outgoing arrows only.

Recall that our ultimate goal is to express distributions of the form $P(\mathbf{y}|do(\mathbf{x}))$ in terms of the joint distribution $P(\mathbf{v})$. The interpretation of effect as downward dependence immediately suggests a set of graphs where this is possible. Specifically, whenever all d-connected paths from $\mathbf{X}$ to $\mathbf{Y}$ are front-door from $\mathbf{X}$, the causal effect $P(\mathbf{y}|do(\mathbf{x}))$ is equal to $P(\mathbf{y}|\mathbf{x})$. In graphs shown in Fig. 2 (a) and (b) causal effect $P(y|do(x))$ has this property.

In general, we don't expect acting on $\mathbf{X}$ to produce the same effect as observing $\mathbf{X}$ due to the presence of back-door paths between $\mathbf{X}$ and $\mathbf{Y}$. However, d-separation gives us a way to block undesirable paths by conditioning. If we can find a set $\mathbf{Z}$ that blocks all back-door paths from $\mathbf{X}$ to $\mathbf{Y}$, we obtain the following: $P(\mathbf{y}|do(\mathbf{x})) = \sum_{\mathbf{Z}} P(\mathbf{y}|\mathbf{z},do(\mathbf{x}))P(\mathbf{z}|do(\mathbf{x}))$. The term $P(\mathbf{y}|\mathbf{z},do(\mathbf{x}))$ is reduced to $P(\mathbf{y}|\mathbf{z},\mathbf{x})$ since the influence flow from $\mathbf{X}$ to $\mathbf{Y}$ is blocked by $\mathbf{Z}$. However, the act of

adjusting for $\mathbf{Z}$ introduced a new effect we must compute, corresponding to the term $P(\mathbf{z}|do(\mathbf{x}))$. If it so happens that no variable in $\mathbf{Z}$ is a descendant of $\mathbf{X}$, we can reduce this term to $P(\mathbf{z})$ using the intuitive argument that acting on effects should not influence causes, or a more formal appeal to rule 3 of do-calculus. Computing effects in this way is always possible if we can find a set $\mathbf{Z}$ blocking all back-door paths which contains no descendants of $\mathbf{X}$. This is known as the *back-door criterion* (Pearl, 1993a, 2000). Figs. 2 (c) and (d) show some graphs where the node z satisfies the back-door criterion with respect to $P(y|do(x))$, which means $P(y|do(x))$ is identifiable.

The back-door criterion can fail—a common way involves a confounder that is unobserved, which prevents adjusting for it. Surprisingly, it is sometimes possible to identify the effect of $\mathbf{X}$ on $\mathbf{Y}$ even in the presence of such a confounder. To do so, we want to find a set $\mathbf{Z}$ located downstream of $\mathbf{X}$ but upstream of $\mathbf{Y}$, such that the downward flow of the effect of $\mathbf{X}$ on $\mathbf{Y}$ can be decomposed into the flow from $\mathbf{X}$ to $\mathbf{Z}$, and the flow from $\mathbf{Z}$ to $\mathbf{Y}$. Clearly, in order for this to happen $\mathbf{Z}$ must d-separate all front-door paths from $\mathbf{X}$ to $\mathbf{Y}$. However, in order to make sure that the component effects $P(\mathbf{z}|do(\mathbf{x}))$ and $P(\mathbf{y}|do(\mathbf{z}))$ are themselves identifiable, and combine appropriately to form $P(\mathbf{y}|do(\mathbf{x}))$, we need two additional assumptions: there are no back-door paths from $\mathbf{X}$ to $\mathbf{Z}$, and all back-door paths from $\mathbf{Z}$ to $\mathbf{Y}$ are blocked by $\mathbf{X}$. It turns out that these three conditions imply that $P(\mathbf{y}|do(\mathbf{x})) = \sum_{\mathbf{Z}} P(\mathbf{y}|do(\mathbf{z}))P(\mathbf{z}|do(\mathbf{x}))$, and the latter two conditions further imply that the first term is identifiable by the back-door criterion and equal to $\sum_{\mathbf{Z}} P(\mathbf{y}|\mathbf{z},\mathbf{x})P(\mathbf{x})$, while the second term is equal to $P(\mathbf{z}|\mathbf{x})$. Whenever these three conditions hold, the effect of $\mathbf{X}$ on $\mathbf{Y}$ is identifiable. This is known as the *front-door criterion* (Pearl, 1995, 2000). The front-door criterion holds in the graph shown in Fig. 2 (e).

Unfortunately, in some graphs neither the front-door, nor the back-door criterion holds. The simplest such graph, known as the bow arc graph due to its shape, is shown in Fig. 1 (a). The back-door criterion fails since the confounder node is unobservable, while the front-door criterion fails since no intermediate variables between X and Y exist in the graph. While the failure of these two criteria does not imply non-identification, in fact the effect $P(y|do(x))$ is identifiable in Fig. 2 (f), (g) despite this failure, a simple argument shows that $P(y|do(x))$ is not identifiable in the bow arc graph.

Theorem 10 *$P(\boldsymbol{v}), G \not\vdash_{id} P(y|do(x))$ in G shown in Fig. 1 (a).*

Since we are interested in completely characterizing graphs where a given causal effect $P(\mathbf{y}|do(\mathbf{x}))$ is identifiable, it would be desirable to list difficult graphs like the bow arc graph which prevent identification of causal effects, in the hope of eventually making such a list complete and finding a way to identify effects in all graphs not on the list. We start constructing this list by considering graphs which generalize the bow arc graph since they can contain more than two nodes, but which also inherit its difficult structure. We call such graphs C-trees.

Definition 11 (C-tree) *A graph G which is both a C-component and a tree is called a C-tree.*

We call a C-tree with a root node Y Y-rooted. The graphs in Fig. 1 (a), (d), (e), (f), and (h) are Y-rooted C-trees. It turns out that in any Y-rooted C-tree, the effect of any subset of nodes, other than Y, on the root Y is not identifiable.

Theorem 12 *Let G be a Y-rooted C-tree. Let $\boldsymbol{X}$ be any subset of observable nodes in G which does not contain Y. Then $P(\boldsymbol{v}), G \not\vdash_{id} P(y|do(\boldsymbol{x}))$.*

C-trees play a prominent role in the identification of *direct effects*. Intuitively, the direct effect of X on Y exists if there is an arrow from X to Y in the graph, and corresponds to the flow of influence along this arrow. However, simply considering changes in Y after fixing X is insufficient for isolating direct effect, since X can influence Y along other, longer front-door paths than the direct arrow. In order to disregard such influences, we also fix all other parents of Y (which as noted earlier removes all arrows incoming to these parents and thus to Y). The expression corresponding to the direct effect of X on Y is then $P(y|do(pa(y)))$. The following theorem links C-trees and direct effects.

Theorem 13 *$P(\boldsymbol{v}), G \not\vdash_{id} P(y|do(pa(y)))$ if and only if there exists a subgraph of G which is a Y-rooted C-tree.*

This theorem might suggest that C-trees might play an equally strong role in identifying arbitrary effects on a single variable, not just direct effects. Unfortunately, this turns out not to be the case, due to the following lemma.

Lemma 14 (downward extension lemma) *Let $\boldsymbol{V}$ be the set of observable nodes in G, and $P(\boldsymbol{v})$ the observable distribution of models inducing G. Assume $P(\boldsymbol{v}), G \not\vdash_{id} P(\boldsymbol{y}|do(\boldsymbol{x}))$. Let G' contain all the nodes and edges of G, and an additional node Z which is a child of all nodes in $\boldsymbol{Y}$. Then if $P(\boldsymbol{v}, z)$ is the observable distribution of models inducing G', then $P(\boldsymbol{v}, z), G' \not\vdash_{id} P(z|do(\boldsymbol{x}))$.*

Proof Let $|Z| = \prod_{Y_i \in \mathbf{Y}} |Y_i| = n$. By construction, $P(z|do(\mathbf{x})) = \sum_{\mathbf{y}} P(z|\mathbf{y})P(\mathbf{y}|do(\mathbf{x}))$. Due to the way we set the arity of Z, $P(Z|\mathbf{Y})$ is an n by n matrix which acts as a linear map which transforms $P(\mathbf{y}|do(\mathbf{x}))$ into $P(z|do(\mathbf{x}))$. Since we can arrange this linear map to be one to one, any proof of non-identifiability of $P(\mathbf{y}|do(\mathbf{x}))$ immediately extends to the proof of non-identifiability of $P(z|do(\mathbf{x}))$. ■

What this lemma shows is that identification of effects on a singleton is not any simpler than the general problem of identification of effect on a set. To find difficult graphs which prevent identification of effects on sets, we consider a multi-root generalization of C-trees.

Definition 15 (c-forest) *A graph G which is both a C-component and a forest is called a C-forest.*

If a given C-forest has a set of root nodes $\mathbf{R}$, we call it $\mathbf{R}$-rooted. Graphs in Fig. 3 (a), (b) are $\{Y1, Y2\}$-rooted C-forests. A naive way to generalize Theorem 12 would be to state that if G is an $\mathbf{R}$-rooted C-forest, then the effect of any set $\mathbf{X}$ that does not intersect $\mathbf{R}$ is not identifiable. However, as we later show, this is not true. Specifically, we later prove that $P(y1, y2|do(x))$ in the graph in Fig. 3 (a) is identifiable. To formulate the correct generalization of Theorem 12, we must understand what made C-trees difficult for the purposes of identifying effects on the root Y. It turned out that for particular function choices, the effects of ancestors of Y on Y precisely cancelled themselves out so even though Y itself was dependent on its parents, it was observationally indistinguishable from a constant function. To get the same canceling of effects with C-forests, we must define a more complex graphical structure.

Definition 16 (hedge) *Let $\boldsymbol{X}, \boldsymbol{Y}$ be sets of variables in G. Let F, F' be $\boldsymbol{R}$-rooted C-forests in G such that F' is a subgraph of F, $\boldsymbol{X}$ only occur in F, and $\boldsymbol{R} \in An(\boldsymbol{Y})_{G_{\overline{\boldsymbol{X}}}}$. Then F and F' form a hedge for $P(\boldsymbol{y}|do(\boldsymbol{x}))$.*

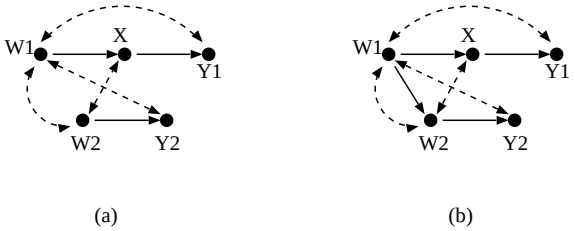

Figure 3: (a) A graph hedge-less for $P(y|do(x))$. (b) A graph containing a hedge for $P(y|do(x))$.

The graph in Fig. 3 (b) contains a hedge for $P(y1,y2|do(x))$. The mental picture for a hedge is as follows. We start with a C-forest F'. Then, F' grows new branches, while retaining the same root set, and becomes F. Finally, we "trim the hedge," by performing the action $do(\mathbf{x})$ which has the effect of removing some incoming arrows in $F \setminus F'$ (the subgraph of F consisting of vertices not a part of F'). Note that any Y-rooted C-tree and its root node Y form a hedge. The right generalization of Theorem 12 can be stated on hedges.

Theorem 17 *Let F, F' be subgraphs of G which form a hedge for $P(\boldsymbol{y}|do(\boldsymbol{x}))$. Then $P(\boldsymbol{v}), G \not\vdash_{id} P(\boldsymbol{y}|do(\boldsymbol{x}))$.*

Proof outline As before, assume binary variables. We let the causal mechanisms of one of the models consists entirely of bit parity functions. The second model also computes bit parity for every mechanism, except those nodes in F' which have parents in F ignore the values of those parents. It turns out that these two models are observationally indistinguishable. Furthermore, any intervention in $F \setminus F'$ will break the bit parity circuits of the models. This break will be felt at the root set **R** of the first model, but not of the second, by construction. ■

Unlike the bow arc graph, and C-trees, hedges prevent identification of effects on multiple variables at once. Certainly a complete list of all possible difficult graphs must contain structures like hedges. But are there other kinds of structures that present problems? It turns out that the answer is "no," any time an effect is not identifiable in a causal model (if we make no restrictions on the type of function that can appear), there is a hedge structure involved. To prove that this is so, we need an algorithm which can identify any causal effect lacking a hedge. This algorithm, which we call **ID**, and which can be viewed as a simplified version of the identification algorithm due to Tian (2002), appears in Fig. 4.

We will explain why each line of **ID** makes sense, and conclude by showing the operation of the algorithm on an example. The formal proof of soundness of **ID** can be found in the appendix. The first line merely asserts that if no action has been taken, the effect on **Y** is just the marginal of the observational distribution $P(\mathbf{v})$ on **Y**. The second line states that if we are interested in the effect on **Y**, it is sufficient to restrict our attention on the parts of the model ancestral to **Y**. One intuitive argument for this is that descendants of **Y** can be viewed as 'noisy versions' of **Y** and so any information they may impart which may be helpful for identification is already present in **Y**. On the other hand, variables which are neither ancestors nor descendants of **Y** lie outside the relevant causal chain entirely, and have no useful information to contribute.

Line 3 forces an action on any node where such an action would have no effect on **Y**—assuming we already acted on **X**. Since actions remove incoming arrows, we can view line 3 as simplifying

function **ID**(**y**, **x**, P, G)
INPUT: **x**,**y** value assignments, P a probability distribution, G a causal diagram.
OUTPUT: Expression for $P_{\mathbf{x}}(\mathbf{y})$ in terms of P or **FAIL**(F,F').

1 if $\mathbf{x} = \emptyset$ return $\sum_{\mathbf{v}\setminus\mathbf{y}} P(\mathbf{v})$.

2 if $\mathbf{V} \setminus An(\mathbf{Y})_G \neq \emptyset$
return $\mathbf{ID}(\mathbf{y}, \mathbf{x} \cap An(\mathbf{Y})_G, \sum_{\mathbf{V}\setminus An(\mathbf{Y})_G} P, G_{An(\mathbf{Y})})$.

3 let $\mathbf{W} = (\mathbf{V} \setminus \mathbf{X}) \setminus An(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$.
if $\mathbf{W} \neq \emptyset$, return $\mathbf{ID}(\mathbf{y}, \mathbf{x} \cup \mathbf{w}, P, G)$.

4 if $C(G \setminus \mathbf{X}) = \{S_1, ..., S_k\}$
return $\sum_{\mathbf{v}\setminus(\mathbf{y}\cup\mathbf{x})} \prod_i \mathbf{ID}(s_i, \mathbf{v} \setminus s_i, P, G)$.

if $C(G \setminus \mathbf{X}) = \{S\}$

5 if $C(G) = \{G\}$, throw $\mathbf{FAIL}(G, G \cap S)$.

6 if $S \in C(G)$ return $\sum_{s\setminus\mathbf{y}} \prod_{\{i|V_i \in S\}} P(v_i | v_\pi^{(i-1)})$.

7 if $(\exists S')S \subset S' \in C(G)$ return $\mathbf{ID}(\mathbf{y}, \mathbf{x} \cap S',$
$\prod_{\{i|V_i \in S'\}} P(V_i | V_\pi^{(i-1)} \cap S', v_\pi^{(i-1)} \setminus S'), G_{S'})$.

Figure 4: A complete identification algorithm. **FAIL** propagates through recursive calls like an exception, and returns the hedge which witnesses non-identifiability. $V_\pi^{(i-1)}$ is the set of nodes preceding V_i in some topological ordering π in G.

the causal graph we consider by removing certain arcs from the graph, without affecting the overall answer. Line 4 is the key line of the algorithm, it decomposes the problem into a set of smaller problems using the key property of *c-component factorization* of causal models. If the entire graph is a single C-component already, further problem decomposition is impossible, and we must provide base cases. **ID** has three base cases. Line 5 fails because it finds two C-components, the graph G itself, and a subgraph S that does not contain any $\mathbf{X}$ nodes. But that is exactly one of the properties of C-forests that make up a hedge. In fact, it turns out that it is always possible to recover a hedge from these two c-components. Line 6 asserts that if there are no bidirected arcs from $\mathbf{X}$ to the other nodes in the current subproblem under consideration, then we can replace acting on $\mathbf{X}$ by conditioning, and thus solve the subproblem. Line 7 is the most complex case where $\mathbf{X}$ is partitioned into two sets, $\mathbf{W}$ which contain bidirected arcs into other nodes in the subproblem, and $\mathbf{Z}$ which do not. In this situation, identifying $P(\mathbf{y}|do(\mathbf{x}))$ from $P(\mathbf{v})$ is equivalent to identifying $P(\mathbf{y}|do(\mathbf{w}))$ from $P(\mathbf{V}|do(\mathbf{z}))$, since $P(\mathbf{y}|do(\mathbf{x})) = P(\mathbf{y}|do(\mathbf{w}), do(\mathbf{z}))$. But the term $P(\mathbf{V}|do(\mathbf{z}))$ is identifiable using the previous base case, so we can consider the subproblem of identifying $P(\mathbf{y}|do(\mathbf{w}))$.

We give an example of the operation of the algorithm by identifying $P_x(y_1, y_2)$ from $P(\mathbf{v})$ in the graph shown in in Fig. 3 (a). Since $G = G_{An(\{Y_1,Y_2\})}, C(G \setminus \{X\}) = \{G\}$, and $\mathbf{W} = \{W_1\}$, we invoke line 3 and attempt to identify $P_{x,w}(y_1, y_2)$. Now $C(G \setminus \{X, W\}) = \{Y_1, W_2 \to Y_2\}$, so we invoke line

Figure 5: Subgraphs of G used for identifying $P_x(y_1, y_2)$.

4. Thus the original problem reduces to identifying $\sum_{w_2} P_{x,w_1,w_2,y_2}(y_1) P_{w,x,y_1}(w_2, y_2)$. Solving for the second expression, we trigger line 2, noting that we can ignore nodes which are not ancestors of W_2 and Y_2, which means $P_{w,x,y_1}(w_2, y_2) = P(w_2, y_2)$. Solving for the first expression, we first trigger line 2 also, obtaining $P_{x,w_1,w_2,y_2}(y_1) = P_{x,w}(y_1)$. The corresponding G is shown in Fig. 5 (a). Next, we trigger line 7, reducing the problem to computing $P_w(y_1)$ from $P(Y_1|X, W_1)P(W_1)$. The corresponding G is shown in Fig. 5 (b). Finally, we trigger line 2, obtaining $P_w(y_1) = \sum_{w_1} P(y_1|x, w_1)P(w_1)$. Putting everything together, we obtain: $P_x(y_1, y_2) = \sum_{w_2} P(y_1, w_2) \sum_{w_1} P(y_1|x, w_1)P(w_1)$.

As mentioned earlier, whenever the algorithm fails at line 5, it is possible to recover a hedge from the C-components S and G considered for the subproblem where the failure occurs. In fact, it can be shown that this hedge implies the non-identifiability of the original query with which the algorithm was invoked, which implies the following result.

Theorem 18 ***ID*** *is complete.*

The completeness of **ID** implies that hedges can be used to characterize all cases where effects of the form $P(\mathbf{y}|do(\mathbf{x}))$ cannot be identified from the observational distribution $P(\mathbf{v})$.

Theorem 19 (hedge criterion) $P(\boldsymbol{v}), G \not\vdash_{id} P(\boldsymbol{y}|do(\boldsymbol{x}))$ *if and only if* G *contains a hedge for some* $P(\boldsymbol{y}'|do(\boldsymbol{x}'))$, *where* $\boldsymbol{y}' \subseteq \boldsymbol{y}$, $\boldsymbol{x}' \subseteq \boldsymbol{x}$.

We close this section by considering identification of *conditional effects* of the form $P(\mathbf{y}|do(\mathbf{x}), \mathbf{z})$ which are defined to be equal to $P(\mathbf{y}, \mathbf{z}|do(\mathbf{x}))/P(\mathbf{z}|do(\mathbf{x}))$. Such expressions are a formalization of an intuitive notion of "effect of action in the presence of non-contradictory evidence," for instance the effect of smoking on lung cancer incidence rates in a particular age group (as opposed to the effect of smoking on cancer in the general population). We say that evidence $\mathbf{z}$ is non-contradictory since it is conceivable to consider questions where the evidence $\mathbf{z}$ stands in logical contradiction to the proposed hypothetical action $do(\mathbf{x})$: for instance what is the effect of smoking on cancer among the non-smokers. Such counterfactual questions will be considered in the next section. Conditioning can both help and hinder identifiability. $P(y|do(x))$ is not identifiable in the graph shown in Fig. 6 (a), while it is identifiable in the graph shown in Fig. 6 (b). Conditioning reverses the situation. In Fig. 6 (a), conditioning on Z renders Y independent of any changes to X, making $P_x(y|z)$ equal to $P(y|z)$. On the other hand, in Fig. 6 (b), conditioning on Z makes X and Y dependent, resulting in $P_x(y|z)$ becoming non-identifiable.

We would like to reduce the problem of identifying conditional effects to the familiar problem of identifying causal effects without evidence for which we already have a complete algorithm. Fortunately, rule 2 of do-calculus provides us with a convenient way of converting the unwanted evidence $\mathbf{z}$ into actions $do(\mathbf{x})$ which we know how to handle. The following convenient lemma allows us to remove as many evidence variables as possible from a conditional effect.

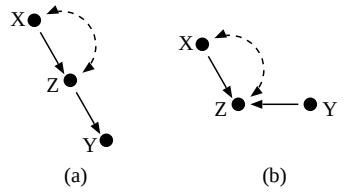

Figure 6: (a) Causal graph with an identifiable conditional effect $P(y|do(x),z)$. (b) Causal graph with a non-identifiable conditional effect $P(y|do(x),z)$.

function **IDC**(**y**, **x**, **z**, P, G)
INPUT: **x**,**y**,**z** value assignments, P a probability distribution, G a causal diagram (an I-map of P).
OUTPUT: Expression for $P_{\mathbf{x}}(\mathbf{y}|\mathbf{z})$ in terms of P or **FAIL**(F,F').

1 if $(\exists Z \in \mathbf{Z})(\mathbf{Y} \perp\!\!\!\perp Z|\mathbf{X},\mathbf{Z}\setminus\{Z\})_{G_{\overline{\mathbf{X}},\underline{z}}}$,
return $\mathbf{IDC}(\mathbf{y},\mathbf{x}\cup\{z\},\mathbf{z}\setminus\{z\},P,G)$.

2 else let $P' = \mathbf{ID}(\mathbf{y}\cup\mathbf{z},\mathbf{x},P,G)$.
return $P'/\sum_{\mathbf{y}} P'$.

Figure 7: A complete identification algorithm for conditional effects.

Theorem 20 *For any G and any conditional effect $P_{\boldsymbol{x}}(\boldsymbol{y}|\boldsymbol{w})$ there exists a unique maximal set $\boldsymbol{Z} = \{Z \in \boldsymbol{W}|P_{\boldsymbol{x}}(\boldsymbol{y}|\boldsymbol{w}) = P_{\boldsymbol{x},z}(\boldsymbol{y}|\boldsymbol{w}\setminus\{z\})\}$ such that rule 2 applies to $\boldsymbol{Z}$ in G for $P_{\boldsymbol{x}}(\boldsymbol{y}|\boldsymbol{w})$. In other words, $P_{\boldsymbol{x}}(\boldsymbol{y}|\boldsymbol{w}) = P_{\boldsymbol{x},\boldsymbol{z}}(\boldsymbol{y}|\boldsymbol{w}\setminus\boldsymbol{z})$.*

Of course Theorem 20 does not guarantee that the entire set **z** can be handled in this way. In many cases, even after rule 2 is applied, some set of evidence will remain in the expression. Fortunately, the following result implies that identification of unconditional causal effects is all we need.

Theorem 21 *Let $\boldsymbol{Z} \subseteq \boldsymbol{W}$ be the maximal set such that $P_{\boldsymbol{x}}(\boldsymbol{y}|\boldsymbol{w}) = P_{\boldsymbol{x},\boldsymbol{z}}(\boldsymbol{y}|\boldsymbol{w}\setminus\boldsymbol{z})$. Then $P_{\boldsymbol{x}}(\boldsymbol{y}|\boldsymbol{w})$ is identifiable in G if and only if $P_{\boldsymbol{x},\boldsymbol{z}}(\boldsymbol{y},\boldsymbol{w}\setminus\boldsymbol{z})$ is identifiable in G.*

The previous two theorems suggest a simple addition to **ID**, which we call **IDC**, shown in Fig. 7, which handles identification of conditional causal effects.

Theorem 22 ***IDC** is sound and complete.*

Proof This follows from Theorems 20 and 21. ■

We conclude this section by showing that our notion of a causal theory as a set of independencies embodied by the causal graph, together with rules of probability and do-calculus is complete for computing causal effects, if we also take statistical data embodied by $P(\mathbf{v})$ as axiomatic.

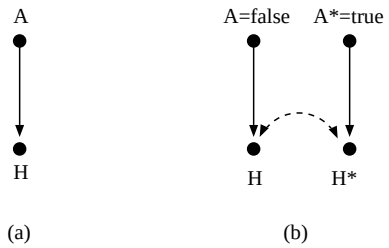

Figure 8: (a) A causal graph for the aspirin/headache domain (b) A corresponding twin network graph for the query $P(H^*_{a^*=true}|A = false)$.

Theorem 23 *The rules of do-calculus are complete for identifying effects of the form* $P(\boldsymbol{y}|do(\boldsymbol{x}),\boldsymbol{z})$, *where* $\boldsymbol{x},\boldsymbol{y},\boldsymbol{z}$ *are arbitrary sets.*

Proof The proofs of soundness of **ID** and **IDC** in the appendix use do-calculus. This implies every line of the algorithms we presented can be rephrased as a sequence of do-calculus manipulations. But **ID** and **IDC** are also complete, which implies the conclusion. ■

4. Identification of Counterfactuals

While effects of actions have an intuitive interpretation as downward flow, the interpretation of counterfactuals, or what-if questions is more complex. An informal counterfactual statement in natural language such as "would I have a headache had I taken an aspirin" talks about multiple worlds: the actual world, and other, hypothetical worlds which differ in some small respect from the actual world (e.g., the aspirin was taken), while in most other respects are the same. In this paper, we represent the actual world by a causal model in its natural state, devoid of any interventions, while the alternative worlds are represented by submodels $M_{\mathbf{x}}$ where the action $do(\mathbf{x})$ implements the hypothetical change from the actual state of affairs considered. People make sense of informal statements involving multiple, possibly conflicting worlds because they expect not only the causal rules to be invariant across these worlds (e.g., aspirin helps headaches in all worlds), but the worlds themselves to be similar enough where evidence in one world has ramifications in another. For instance, if we find ourselves with a headache, we expect the usual causes of our headache to also operate in the hypothetical world, interacting there with the preventative influence of aspirin. In our representation of counterfactuals, we model this interaction between worlds by assuming that the world histories or background contexts, represented by the unobserved **U** variables are shared across all hypothetical worlds.

We illustrate the representation method for counterfactuals we introduced in Section 2 by modeling our example question "would I have a headache had I taken an aspirin?" The actual world referenced by this query is represented by a causal model containing two variables, headache and aspirin, with aspirin being a parent of headache, see Fig. 8 (a). In this world, we observe that aspirin has value false. The hypothetical world is represented by a submodel where the action $do(aspirin = true)$ has been taken. To distinguish nodes in this world we augment their names with an asterisk. The two worlds share the background variables **U**, and so can be represented by a

single causal model with the graph shown in Fig. 8 (b). Our query is represented by the distribution $P(H^*_{a^*=true}|A = false)$, where H is headache, and A is aspirin. Note that the nodes $A^* = true$ and $A = false$ in Fig. 8 (b) do not share a bidirected arc. This is because an intervention $do(a^* = true)$ removes all incoming arrows to A^*, which removes the bidirected arc between A^* and A.

The graphs representing two hypothetical worlds invoked by a counterfactual query like the one shown in Fig. 8 (b) are called *twin network graphs*, and were first proposed as a way to represent counterfactuals by Balke and Pearl (1994b) and Balke and Pearl (1994a). In addition, Balke and Pearl (1994b) proposed a method for evaluating expressions like $P(H^*_{a^*=true}|A = false)$ when all parameters of a causal model are known. This method can be explained as follows. If we forget the causal and counterfactual meaning behind the twin network graph, and simply view it as a Bayesian network, the query $P(H^*_{a^*=true}|A = false)$ can be evaluated using any of the standard inference algorithms available, provided we have access to all conditional probability tables generated by $\mathbf{F}$ and $\mathbf{U}$ of a causal model which gave rise to the twin network graph. In practice, however, complete knowledge of the model is too much to ask for; the functional relationships as well as the distribution $P(\mathbf{u})$ are not known exactly, though some of their aspects can be inferred from the observable distribution $P(\mathbf{v})$.

Instead, the typical state of knowledge of a causal domain is the statistical behavior of the observable variables in the domain, summarized by the distribution $P(\mathbf{v})$, together with knowledge of causal directionality, obtained either from expert judgment (e.g., we know that visiting the doctor does not make us sick, though disease and doctor visits are highly correlated), or direct experimentation (e.g., it's easy to imagine an experiment which establishes that wet grass does not cause sprinklers to turn on). We already used these two sources of knowledge in the previous section as a basis for computing causal effects. Nevertheless, there are reasons to consider computing counterfactual quantities from experimental, rather than observational studies. In general, a counterfactual can posit worlds with features contradictory to what has actually been observed. For instance, questions resembling the headache/aspirin question we used as an example are actually frequently asked in epidemiology in the more general form where we are interested in estimating the effect of a treatment x on the outcome variable Y for the patients that were not treated (x'). In our notation, this is just our familiar expression $P(Y_x|X = x')$. The problem with questions such as these is that no experimental setup exists in which someone is both given and not given treatment. Therefore, it makes sense to ask under what circumstances we can evaluate such questions even if we are given as input every experiment that is possible to perform in principle on a given causal model. In our framework the set of all experiments is denoted as P_*, and is formally defined as $\{P_{\mathbf{x}}|\mathbf{x}$ is any set of values of $\mathbf{X} \subseteq \mathbf{V}\}$. The question that we ask in this section, then, is whether it is possible to identify a query $P(\gamma|\delta)$, where γ, δ are conjunctions of counterfactual events (with δ possibly empty), from the graph G and the set of all experiments P_*. We can pose the problem in this way without loss of generality since we already developed complete methods for identifying members of P_* from G and $P(\mathbf{v})$. This means that if for some reason using P_* as input is not realistic we can combine the methods which we will develop in this section with those in the previous section to obtain identification results for $P(\gamma|\delta)$ from G and $P(\mathbf{v})$.

Before tackling the problem of identifying counterfactual queries from experiments, we extend our example in Fig. 8 (b) to a general graphical representation for worlds invoked by a counterfactual query. The twin network graph is a good first attempt at such a representation. It is essentially a causal diagram for a model encompassing two potential worlds. Nevertheless, the twin network graph suffers from a number of problems. Firstly, it can easily come to pass that a counterfactual

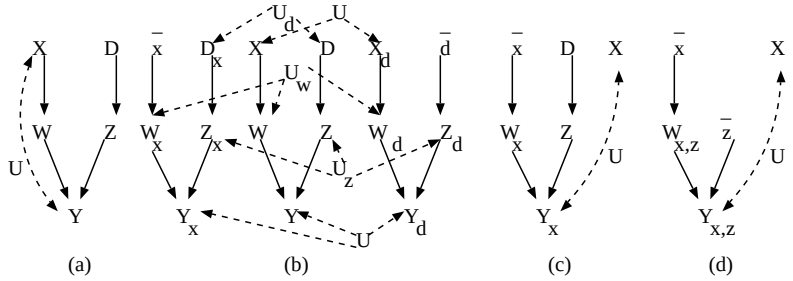

Figure 9: Nodes fixed by actions denoted with an overline, signifying that all incoming arrows are cut. (a) Original causal diagram (b) Parallel worlds graph for $P(y_x|x',z_d,d)$ (the two nodes denoted by U are the same). (c) Counterfactual graph for $P(y_x|x',z_d,d)$. (d) Counterfactual graph for $P(y_{x,z}|x')$.

query of interest would involve three or more worlds. For instance, we might be interested in how likely the patient would be to have a symptom Y given a certain dose x of drug X, assuming we know that the patient has taken dose x' of drug X, dose d of drug D, and we know how an intermediate symptom Z responds to treatment d. This would correspond to the query $P(y_x|x',z_d,d)$, which mentions three worlds, the original model M, and the submodels M_d, M_x. This problem is easy to tackle—we simply add more than two submodel graphs, and have them all share the same **U** nodes. This simple generalization of the twin network model was considered by Avin et al. (2005), and was called there the parallel worlds graph. Fig. 9 shows the original causal graph and the parallel worlds graph for $\gamma = y_x \wedge x' \wedge z_d \wedge d$.

The other problematic feature of the twin network graph, which is inherited by the parallel worlds graph, is that multiple nodes can sometimes correspond to the same random variable. For example, in Fig. 9 (b), the variables Z and Z_x are represented by distinct nodes, although it's easy to show that since Z is not a descendant of X, $Z = Z_x$. These equality constraints among nodes can make the d-separation criterion misleading if not used carefully. For instance, $Y_x \perp\!\!\!\perp D_x|Z$ even though using d-separation in the parallel worlds graph suggests the opposite. This sort of problem is fairly common in causal models which are not *faithful* (Spirtes et al., 1993) or *stable* (Pearl, 2000), in other words in models where d-separation statements in a causal diagram imply independence in a distribution, but not vice versa. However, lack of faithfulness usually arises due to "numeric coincidences" in the observable distribution. In this case, the lack of faithfulness is "structural," in a sense that it is possible to refine parallel worlds graphs in such a way that the node duplication disappears, and the attendant independencies not captured by d-separation are captured by d-separation in refined graphs.

This refinement has two additional beneficial side effects. The first is that by removing node duplication, we also determine which syntactically distinct counterfactual variables correspond to the same random variable. By identifying such equivalence classes of counterfactual variables, we guarantee that syntactically different variables are in fact different, and this makes it simpler to reason about counterfactuals in order to identify them. For instance, a counterfactual $P(y_x,y')$ may either be non-identifiable or inconsistent (and so identifiable to equal 0), depending on whether Y_x and Y are the same variable. The second benefit of this refinement is that resulting graphs are gen-

erally much smaller and less cluttered than parallel worlds graphs, and so are easier to understand. Compare, for instance, the graphs in Fig. 9 (b) and Fig. 9 (c). To rid ourselves of duplicates, we need a formal way of determining when variables from different submodels are in fact the same. The following lemma does this.

Lemma 24 *Let M be a model inducing G containing variables α, β with the following properties:*

- *α and β have the same domain of values.*
- *There is a bijection f from $Pa(\alpha)$ to $Pa(\beta)$ such that a parent γ and $f(\gamma)$ have the same domain of values.*
- *The functional mechanisms of α and β are the same (except whenever the function for α uses the parent γ, the corresponding function for β uses $f(\gamma)$).*

Assume an observable variable set $\mathbf{Z}$ was observed to attain values $\mathbf{z}$ in $M_{\mathbf{X}}$, the submodel obtained from M by forcing another observable variable set $\mathbf{X}$ to attain values $\mathbf{x}$. Assume further that for each $\gamma \in Pa(\alpha)$, either $f(\gamma) = \gamma$, or γ and $f(\gamma)$ attain the same values (whether by observation or intervention). Then α and β are the same random variable in $M_{\mathbf{X}}$ with observations $\mathbf{z}$.

Proof This follows from the fact that variables in a causal model are functionally determined from their parents. ■

If two distinct nodes in a causal diagram represent the same random variable, the diagram contains redundant information, and the nodes must be merged. If two nodes, say corresponding to $Y_{\mathbf{x}}, Y_{\mathbf{z}}$, are established to be the same in G, they are merged into a single node which inherits all the children of the original two. These two nodes either share their parents (by induction) or their parents attain the same values. If a given parent is shared, it becomes the parent of the new node. Otherwise, we pick one of the parents arbitrarily to become the parent of the new node. This operation is summarized by the following lemma.

Lemma 25 *Let $M_{\mathbf{X}}$ be a submodel derived from M with set $\mathbf{Z}$ observed to attain values $\mathbf{z}$, such that Lemma 24 holds for α, β. Let M' be a causal model obtained from M by merging α, β into a new node ω, which inherits all parents and the functional mechanism of α. All children of α, β in M' become children of ω. Then $M_{\mathbf{X}}, M'_{\mathbf{X}}$ agree on any distribution consistent with $\mathbf{z}$ being observed.*

Proof This is a direct consequence of Lemma 24. ■

The new node ω we obtain from Lemma 25 can be thought of as a new counterfactual variable. As mentioned in section 2, such variables take the form $Y_{\mathbf{x}}$ where Y is the variable in the original causal model, and $\mathbf{x}$ is a subscript specifying the action which distinguishes the counterfactual. Since we only merge two variables derived from the same original, specifying Y is simple. But what about the subscript? Intuitively, the subscript of ω contains those fixed variables which are ancestors of ω in the graph G' of M'. Formally the subscript is $\mathbf{w}$, where $\mathbf{W} = An(\omega)_{G'} \cap \mathbf{sub}(\gamma)$, where the $\mathbf{sub}(\gamma)$ corresponds to those nodes in G' which correspond to subscripts in γ. Since we replaced α, β by ω, we replace any mention of α, β in our given counterfactual query $P(\gamma)$ by ω.

function **make-cg**(G, γ)
INPUT: G a causal diagram, γ a conjunction of counterfactual events
OUTPUT: A counterfactual graph G_γ, and either a set of events γ' s.t. $P(\gamma') = P(\gamma)$ or **INCONSISTENT**

- Construct a submodel graph $G_{\mathbf{x}_i}$ for each action $do(\mathbf{x}_i)$ mentioned in γ. Construct the parallel worlds graph G' by having all such submodel graphs share their corresponding U nodes.
- Let π be a topological ordering of nodes in G', let $\gamma' := \gamma$.
- Apply Lemmas 24 and 25, in order π, to each observable node pair α, β derived from the same variable in G. For each α, β that are the same, do:
  - Let G' be modified as specified in Lemma 25.
  - Modify γ' by renaming all occurrences of β to α.
  - If $\mathbf{val}(\alpha) \neq \mathbf{val}(\beta)$, return $G', \mathbf{INCONSISTENT}$.
- return $(G'_{An(\gamma')}, \gamma')$, where $An(\gamma')$ is the set of nodes in G' ancestral to nodes corresponding to variables mentioned in γ'.

Figure 10: An algorithm for constructing counterfactual graphs

Note that since α, β are the *same*, their value assignments must be the same (say equal to y). The new counterfactual ω inherits this assignment.

We summarize the inductive applications of Lemma 24, and 25 by the **make-cg** algorithm, which takes γ and G as arguments, and constructs a version of the parallel worlds graph without duplicate nodes. We call the resulting structure the *counterfactual graph* of γ, and denote it by G_γ. The algorithm is shown in Fig. 10.

There are three additional subtleties in **make-cg**. The first is that if variables $Y_{\mathbf{X}}, Y_{\mathbf{Z}}$ were judged to be the same by Lemma 24, but γ assigns them different values, this implies that the original set of counterfactual events γ is inconsistent, and so $P(\gamma) = 0$. The second is that if we are interested in identifiability of $P(\gamma)$, we can restrict ourselves to the ancestors of γ in G'. We can justify this using the same intuitive argument we used in Section 3 to justify Line 2 in **ID**. The formal proof for line 2 we provide in the appendix applies with little change to **make-cg**. Finally, because the algorithm can make an arbitrary choice picking a parent of ω each time Lemma 25 is applied, both the counterfactual graph G', and the corresponding modified counterfactual γ' are not unique. This does not present a problem, however, as any such graph is acceptable for our purposes.

We illustrate the operation of **make-cg** by showing how the graph in Fig. 9 (c) is derived from the graph in Fig. 9 (b). We start the application of Lemma 24 from the topmost observable nodes, and conclude that the node pairs D_x, D, and X_d, X have the same functional mechanisms, and the same parent set (in this case the parents are unobservable nodes U_d for the first pair, and U for the second). We then use Lemma 25 to obtain the graph shown in Fig. 11 (a). Since the node pairs are the same, we pick the name of one of the nodes of the pair to serve as the name of the new node. In our case, we picked D and X. Note that for this graph, and all subsequent intermediate graphs we generate, we use the convention that if a merge creates a situation where an unobservable variable

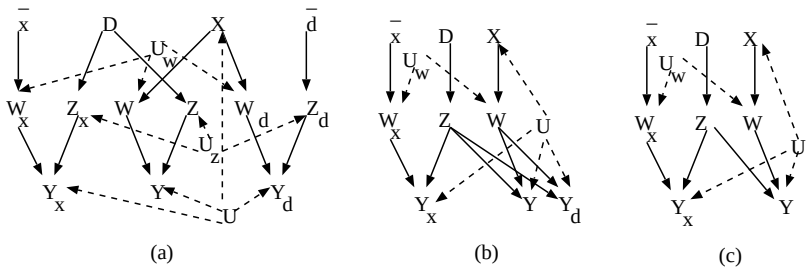

Figure 11: Intermediate graphs obtained by **make-cg** in constructing the counterfactual graph for $P(y_x|x',z_d,d)$ from Fig. 9 (b).

has a single child, that variable is omitted from the graph. For instance, in Fig. 11 (a), the variable U_d, and its corresponding arrow to D omitted.

Next, we apply Lemma 24 for the node pair W_d, W. In this case, the functional mechanisms are once again the same, while the parents of W_d, W are X and U_w. We can also apply Lemma 24 twice to conclude that Z, Z_x and Z_d are in fact the same node, and so can be merged. The functional mechanisms of these three nodes are the same, and they share the parent U_z. As far as the parents of this triplet, the U_z parent is shared by all three, while Z, Z_x share the parent D, and Z_d has a separate parent d, fixed by intervention. However, in our counterfactual query, which is $P(y_x|x',z_d,d)$, the variable D happens to be observed to attain the value d, the same as the intervention value for the parent of Z_d. This implies that for the purposes of the Z, Z_x, Z_d triplet, their D-derived parents share the same value, which allows us to conclude they are the same random variable. The intuition here is that while intervention and observation are not the same operation, they have the same effect if the relevant U variables happen to react in the same way to both the given intervention, and the given observation (this is the essence of the Axiom of Composition discussed by Pearl (2000).) In our case, U variables react the same way because the parallel worlds share all unobserved variables.

There is one additional subtlety in performing the merge of the triplet Z, Z_x, Z_d. If we examine our query $P(y_x|x',z_d,d)$, we notice that Z_d, or more precisely its value, appears in it. When we merge nodes, we only use one name out of the original two. It's possible that some of the old names appear in the query, which means we must replace all references to the old, pre-merge nodes with the new post-merge name we picked. Since we picked the name Z for the newly merged node, we replace the reference to Z_d in our query by the reference to Z, so our modified query is $P(y_x|x',z,d)$. Since the variables were established to be the same, this is a safe syntactic transformation.

After W_d, W, and the Z, Z_x, Z_d triplet are merged, we obtain the graph in Fig. 11 (b). Finally, we apply Lemma 24 one more time to conclude Y and Y_d are the same variable, using the same reasoning as before. After performing this final merge, we obtain the graph in Fig. 11 (c). It's easy to see that Lemma 24 no longer applies to any node pair: W and W_x differ in their X-derived parent, and Y, and Y_x differ on their W-derived parent, which was established inductively. The final operation which **make-cg** performs is restricting the graph in Fig. 11 (b) to variables actually relevant for computing the (potentially syntactically modified) query it was given as input, namely $P(y_x|x',z,d)$. These relevant variables are ancestral to variables in the query in the final intermediate graph we

5 else, let $P' =$ **ID***$(G, \gamma' \wedge \delta')$. return $P'/P'(\delta)$

Figure 12: Counterfactual identification algorithms.

obtained. In our case, we remove nodes W and Y (and their adjacent edges) from consideration, to finally obtain the graph in Fig. 9 (c), which is a counterfactual graph for our query.

Having constructed a graphical representation of worlds mentioned in counterfactual queries, we can turn to identification. We construct two algorithms for this task, the first is called **ID*** and works for unconditional queries, while the second, **IDC***, works on queries with counterfactual evidence and calls the first as a subroutine. These are shown in Fig. 12.

These algorithms make use of the following notation: **sub**$(.)$ returns the set of subscripts, **var**$(.)$ the set of variables, and **ev**$(.)$ the set of values (either set or observed) appearing in a given counterfactual conjunction (or set of counterfactual events), while **val**$(.)$ is the value assigned to a given counterfactual variable. This notation is used to extract variables and values present in the original causal model from a counterfactual which refers to parallel worlds. As before, $C(G')$ is the set of maximal C-components of G', except we don't count nodes in G' fixed by interventions as part of any C-component. $V(G')$ is the set of observable nodes of G' not fixed by interventions. Following Pearl (2000), $G'_{\underline{y_{\mathbf{X}}}}$ is the graph obtained from G' by removing all outgoing arcs from $Y_{\mathbf{X}}$; $\gamma'_{y_{\mathbf{X}}}$ is obtained from γ' by replacing all descendant variables $W_{\mathbf{Z}}$ of $Y_{\mathbf{X}}$ in γ' by $W_{\mathbf{Z},y}$. A counterfactual $\mathbf{s_r}$, where $\mathbf{s}, \mathbf{r}$ are value assignments to sets of nodes, represents the event "the node set $\mathbf{S}$ attains values $\mathbf{s}$ under intervention $do(\mathbf{r})$." For instance, the term $s^i_{v(g')\setminus s^i}$ stands for the event "the node set S^i attains values s^i under the intervention $do(v(g')\setminus s^i)$," in other words under the intervention where we fix the values of all observable nodes in G' except those in S^i. Finally, we take $x_{x..}$ to mean some counterfactual variable derived from X where x appears in the subscript (the rest of the subscript can be arbitrary), which also attains value x.

The notation used in these algorithms is somewhat intricate, so we give an intuitive description of each line. We start with **ID***. The first line states that if γ is an empty conjunction, then its probability is 1, by convention. The second line states that if γ contains a counterfactual which violates the Axiom of Effectiveness (Pearl, 2000), then γ is inconsistent, and we return probability 0. The third line states that if a counterfactual contains its own value in the subscript, then it is a tautological event, and it can be removed from γ without affecting its probability. Line 4 invokes **make-cg** to construct a counterfactual graph G', and the corresponding relabeled counterfactual γ'. Line 5 returns probability 0 if an inconsistency was found during the construction of the counterfactual graph, for example, if two variables found to be the same in γ had different value assignments. Line 6 is analogous to Line 4 in the **ID** algorithm, it decomposes the problem into a set of subproblems, one for each C-component in the counterfactual graph. In the **ID** algorithm, the term corresponding to a given C-component S_i of the causal diagram was the effect of all variables not in S_i on variables in S_i, in other words $P_{\mathbf{V}\setminus s_i}(s_i)$, and the outermost summation on line 4 was over values of variables not in $\mathbf{Y}, \mathbf{X}$. Here, the term corresponding to a given C-component S^i of the counterfactual graph G' is the conjunction of counterfactual variables where each variable contains in its subscript all variables not in the C-component S^i, in other words $\mathbf{v}(G')\setminus s^i$, and the outermost summation is over observable variables not in γ', that is over $\mathbf{v}(G')\setminus\gamma'$, where we interpret γ' as a set of counterfactuals, rather than a conjunction. Line 7 is the base case, where our counterfactual graph has a single C-component. There are two cases, corresponding to line 8 and line 9. Line 8 says that if γ' contains a "conflict," that is an inconsistent value assignment where at least one value is in the subscript, then we fail. Line 9 says if there are no conflicts, then its safe to take the union of all subscripts in γ', and return the effect of the subscripts in γ' on the variables in γ'.

The **IDC***, like its counterpart **IDC**, is shorter. The first line fails if δ is inconsistent. **IDC** did not have an equivalent line, since we can assume $P(\mathbf{v})$ is positive. The problem with counterfactual distributions is there is no simple way to prevent non-positive distributions spanning multiple worlds from arising, even if the original $P(\mathbf{v})$ was positive—hence the explicit check. The second line constructs the counterfactual graph, except since **make-cg** can only take conjunctions, we provide it with a joint counterfactual $\gamma\wedge\delta$. Line 3 returns 0 if an inconsistency was detected. Line 4 of **IDC*** is the central line of the algorithm and is analogous to line 1 of **IDC**. In **IDC**, we moved a

value assignment $Z = z$ from being observed to being fixed if there were no back-door paths from Z to the outcome variables $\mathbf{Y}$ given the context of the effect of $do(\mathbf{x})$. Here in **IDC***, we move a counterfactual value assignment $Y_{\mathbf{X}} = y$ from being observed (that is being a part of δ), to being fixed (that is appearing in every subscript of γ') if there are no back-door paths from $Y_{\mathbf{X}}$ to the counterfactual of interest γ'. Finally, line 5 of **IDC*** is the analogue of line 2 of **IDC**, we attempt to identify a joint counterfactual probability, and then obtain a conditional counterfactual probability from the result.

We illustrate the operation of these algorithms by considering the identification of a query $P(y_x|x',z_d,d)$ we mentioned earlier. Since $P(x',z_d,d)$ is not inconsistent, we proceed to construct the counterfactual graph on line 2. Suppose we produce the graph in Fig. 9 (c), where the corresponding modified query is $P(y_x|x',z,d)$. Since $P(y_x,x',z,d)$ is not inconsistent we proceed to the next line, which moves z,d (with d being redundant due to graph structure) to the subscript of y_x, to obtain $P(y_{x,z}|x')$, and calls **IDC*** with this query recursively. Note that since the subscripts in one of the variables of our query changed, the counterfactual graph generated will change as well. In particular, the invocation of **make-cg** with the joint distribution from which $P(y_{x,z}|x')$ is derived, namely $P(y_{x,z},x')$, will result in the graph shown in Fig. 9 (d). Since X' has a back-door path to $Y_{x,z}$ in this graph, we can no longer call **IDC*** recursively, so we invoke **ID*** with the query $P(y_{x,z},x')$.

The first interesting line in **ID*** is line 6, which first computes $P(y_{x,z},w_{x,z},x')$ by C-component factorization, and then computes $P(y_{x,z},x')$ from $P(y_{x,z},w_{x,z},x')$ by marginalizing over $W_{x,z}$.[2] Since the counterfactual graph for this query (Fig. 9 (d)) has two C-components, $\{Y_{x,z},X\}$ and $\{W_{x,z}\}$, $P(y_{x,z},w_{x,z},x') = P(y_{x,z,w},x'_w)P(w_{x,z})$, which can be simplified by removing redundant subscripts to $P(y_{z,w},x')P(w_x)$. Line 6 then recursively calls **ID*** with $P(y_{x,z,w},x')$ and $P(w_x)$, multiplies the results and marginalizes over W_x. The first recursive call reaches line 9 with $P(y_{z,w},x')$, which is identifiable as $P_{z,w}(y,x')$ from P_*. The second term is trivially identifiable as $P_x(w)$, which means our query is identifiable as $P' = \sum_w P_{z,w}(y,x')P_x(w)$, and the conditional query is equal to $P'/P'(x')$.

The definitions of **ID***, and **IDC*** reveal their close similarity to algorithms **ID** and **IDC** in the previous section. The major differences lie in the failure and success base cases, and slightly different subscript notation. This is not a coincidence, since a counterfactual graph can be thought of as a causal graph for a particular large causal model which happens to have some distinct nodes share the same causal mechanisms. This means that all the theorems and definitions used in the previous sections for causal diagrams transfer over without change to counterfactual graphs. Using this fact, we will show that **ID***, and **IDC*** are sound and complete for identifying $P(\gamma)$, and $P(\gamma|\delta)$ respectively.

Theorem 26 (soundness) *If **ID*** succeeds, the expression it returns is equal to $P(\gamma)$ in a given causal graph. Furthermore, if **IDC*** does not output **FAIL**, the expression it returns is equal to $P(\gamma|\delta)$ in a given causal graph, if that expression is defined, and **UNDEFINED** otherwise.*

Proof outline The first line merely states that the probability of an empty conjunction is 1, which is true by convention. Lines 2 and 3 follow by the Axiom of Effectiveness (Galles and Pearl, 1998). The soundness of **make-cg** has already been established, which implies the soundness of line 4. Line 6 decomposes the problem using c-component factorization. The soundness proof for this decomposition, also used in the previous section, is in the appendix. Line 9 asserts that if a set

2. Note that since $W_{x,z}$ is a counterfactual variable derived from W, it shares its domain with W. Therefore it makes sense when marginalizing to operate over the values of W, denoted by w in the subscript of the summation.

of counterfactual events does not contain conflicting value assignments to any variable, obtained either by observation or intervention, then taking the union of all actions of the events results in a consistent action. The probability of the set of events can then be computed from a submodel where this consistent action has taken place. A full proof of this is in the appendix. ■

To show completeness, we follow the same strategy we used in the previous section. We catalogue all difficult counterfactual graphs which arise from queries which cannot be identified from P_*. We then show these graphs arise whenever **ID*** and **IDC*** fail. This, together with the soundness theorem we already proved, implies that these algorithms are complete.

The simplest difficult counterfactual graph arises from the query $P(y_x, y'_{x'})$ named "probability of necessity and sufficiency" by Pearl (2000). This graph, shown in Fig. 8 (b) with variable relabeling, is called the "w-graph" due to its shape (Avin et al., 2005). This query is so named because if $P(y_x, y'_{x'})$ is high, this implies that if the variable X is forced to x, variable Y is likely to be y, while if X is forced to some other value, Y is likely to not be y. This means that the action $do(x)$ is likely a necessary and sufficient cause of Y assuming value y, up to noise. The w-graph starts our catalogue of bad graphs with good reason, as the following lemma shows.

Lemma 27 *Assume X is a parent of Y in G. Then $P_*, G \not\vdash_{id} P(y_x, y'_{x'}), P(y_x, y')$ for any value pair y, y'.*

Proof See Avin et al. (2005). ■

The intuitive explanation for this result is that $P(y_x, y'_{x'})$ is derived from the joint distribution over the counterfactual variables in the w-graph, while if we restrict ourselves to P_*, we only have access to marginal distributions—one marginal for each possible world. Because counterfactual variables Y_x and $Y_{x'}$ share an unobserved parent U, they are dependent, and their joint distribution cannot be decomposed into a product of marginals. This means that the information encoded in the marginals is insufficient to uniquely determine the joint we are interested in. This intuitive argument can be generalized to a counterfactual graph with more than two nodes, the so-called "zig-zag graphs" an example of which is shown in Fig. 13 (b).

Lemma 28 *Assume G is such that X is a parent of Y and Z, and Y and Z are connected by a bidirected path with observable nodes $W^1, \ldots, W^k$ on the path. Then $P_*, G \not\vdash_{id} P(y_x, w^1, \ldots, w^k, z_{x'})$, $P(y_x, w^1, \ldots, w^k, z)$ for any value assignments $y, w^1, \ldots, w^k, z$.*

The w-graph in Fig. 8 (b) and the zig-zag graph in Fig. 13 (b) have very special structure, so we don't expect our characterization to be complete with just these graphs. In order to continue, we must provide two lemmas which allow us to transform difficult graphs in various ways by adding nodes and edges, while retaining the non-identifiability of the underlying counterfactual from P_*.

Lemma 29 (downward extension lemma) *Assume $P_*, G \not\vdash_{id} P(\gamma)$. Let $\{y^1_{\mathbf{x}^1}, \ldots, y^n_{\mathbf{x}^m}\}$ be a subset of counterfactual events in γ. Let G' be a graph obtained from G by adding a new child W of $Y^1, \ldots, Y^n$, and let P'_* be the set of all interventional distributions in models inducing G'. Let $\gamma' = (\gamma \setminus \{y^1_{\mathbf{x}^1}, \ldots, y^n_{\mathbf{x}^m}\}) \cup \{w_{\mathbf{x}^1}, \ldots, w_{\mathbf{x}^m}\}$, where w is an arbitrary value of W. Then $P'_*, G' \not\vdash_{id} P(\gamma')$.*

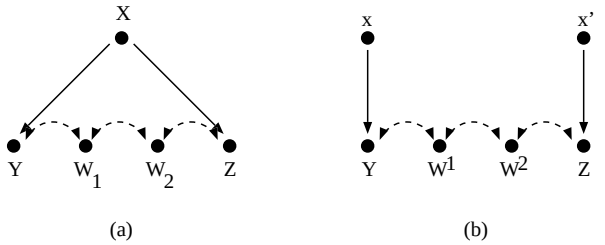

Figure 13: (a) Causal diagram (b) Corresponding counterfactual graph for the non-identifiable query $P(Y_x, W^1, W^2, Z_{x'})$.

The first result states that non-identification on a set of parents (causes) translates into non-identification on children (effects). The intuitive explanation for this is that it is possible to construct a one-to-one function from the space of distributions on causes to the space of distributions on effects. If a given $P(\gamma)$ cannot be identified from P_*, this implies that there exist two models which agree on P_*, but disagree on $P(\gamma)$, where γ is a set of counterfactual causes. It is then possible to augment these models using the one-to-one function in question to obtain disagreement on $P(\delta)$, where δ is a set of counterfactual effects of γ. A more detailed argument is found in the appendix.

Lemma 30 (contraction lemma) *Assume $P_*, G \not\vdash_{id} P(\gamma)$. Let G' be obtained from G by merging some two nodes X,Y into a new node Z where Z inherits all the parents and children of X,Y, subject to the following restrictions:*

- *The merge does not create cycles.*
- *If $(\exists w_{\mathbf{S}} \in \gamma)$ where $x \in \mathbf{s}$, $y \notin \mathbf{s}$, and $X \in An(W)_G$, then $Y \notin An(W)_G$.*
- *If $(\exists y_{\mathbf{S}} \in \gamma)$ where $x \in \mathbf{s}$, then $An(X)_G = \emptyset$.*
- *If $(Y_{\mathbf{w}}, X_{\mathbf{S}} \in \gamma)$, then $\mathbf{w}$ and $\mathbf{s}$ agree on all variable settings.*

Assume $|X| \times |Y| = |Z|$ and there's some isomorphism f assigning value pairs x,y to a value $f(x,y) = z$. Let γ' be obtained from γ as follows. For any $w_{\mathbf{S}} \in \gamma$:

- *If $W \notin \{X,Y\}$, and values x,y occur in $\mathbf{s}$, replace them by $f(x,y)$.*
- *If $W \notin \{X,Y\}$, and the value of one of X,Y occur in $\mathbf{s}$, replace it by some z consistent with the value of X or Y.*
- *If X,Y do not occur in γ, leave γ as is.*
- *If $W = Y$ and $x \in \mathbf{s}$, replace $w_{\mathbf{S}}$ by $f(x,y)_{\mathbf{S}\setminus\{x\}}$.*
- *otherwise, replace every variable pair of the form $Y_{\mathbf{r}} = y, X_{\mathbf{S}} = x$ by $Z_{\mathbf{r},\mathbf{S}} = f(x,y)$.*

Then $P_*, G' \not\vdash_{id} P(\gamma')$.

This lemma has a rather complicated statement, but the basic idea is very simple. If we have a causal model with a graph G where some counterfactual $P(\gamma)$ is not identifiable, then a coarser, more "near-sighted" view of G which merges two distinct variables with their own mechanisms into a single variable with a single mechanism will not render $P(\gamma)$ identifiable. This is because merging nodes in the graph does not alter the model, but only our state of knowledge of the model. Therefore, whatever model pair was used to prove $P(\gamma)$ non-identifiable will remain the same in the new, coarser graph. The complicated statement of the lemma is due to the fact that we cannot allow arbitrary node merges, we must satisfy certain coherence conditions. For instance, the merge cannot create directed cycles in the graph.

It turns out that whenever **ID*** fails on $P(\gamma)$, the corresponding counterfactual graph contains a subgraph which can be obtained by a set of applications of the previous two lemmas to the w-graph and the zig-zag graphs. This allows an argument that shows $P(\gamma)$ cannot be identified from P_*.

Theorem 31 (completeness) *If **ID*** or **IDC*** fail, then the corresponding query is not identifiable from P_*.*

Since **ID*** is complete for $P(\gamma)$ queries, we can give a graphical characterization of counterfactual graphs where $P(\gamma)$ cannot be identified from P_*.

Theorem 32 *Let G_γ, γ' be obtained from **make-cg**(G,γ). Then $P_*, G \not\vdash_{id} P(\gamma)$ if and only if there exists a C-component $S \subseteq An(\gamma')_{G_\gamma}$ where some $X \in Pa(S)$ is set to x while at the same time either X is also a parent of another node in S and is set to another value x', or S contains a variable derived from X which is observed to be x'.*

Proof This follows from Theorem 31 and the construction of **ID***. ■

5. Conclusions

This paper considers a hierarchy of queries about relationships among variables in graphical causal models: associational relationships which can be obtained from observational studies, cause-effect relationships obtained by experimental studies, and counterfactuals, which are derived from parallel worlds resulting from hypothetical actions, possibly conflicting with available evidence. We consider the identification problem for this hierarchy, the task of computing a query from the given causal diagram and available information lower in the hierarchy.

We provide sound and complete algorithms for this identification problem, and a graphical characterization of non-identifiable queries where these algorithms must fail. Specifically, we provide complete algorithms for identifying causal effects and conditional causal effects from observational studies, and show that a graphical structure called a *hedge* completely characterizes all cases where causal effects are non-identifiable. As a corollary, we show that the three rules of do-calculus are complete for identifying effects. We also provide complete algorithms for identifying counterfactual queries (possibly conditional) from experimental studies. If we view the structure of the causal graph as experimentally testable, as is often the case in practice, this result can be viewed as giving a full characterization of testable counterfactuals assuming structural semantics.

These results settle important questions in causal inference, and pave the way for computing more intricate causal queries which involve nested counterfactuals, such as those defining direct

and indirect effects (Pearl, 2001), and path-specific effects (Avin et al., 2005). The characterization of non-identifiable queries we provide defines precisely the situations when such queries cannot be computed precisely, and must instead by approximated using methods such as bounding (Balke and Pearl, 1994a), instrumental variables (Pearl, 2000), or additional assumptions, such as linearity, which can make identification simpler.

Acknowledgments

Appendix A.

Here, we augment the intuitive proof outlines we gave in the main body of the paper with more formal arguments. We start with a set of results which were used to classify graphs with non-identifiable effects. In the proofs presented here, we will construct the distributions which make up our set of premises to be positive. This is because non-positive distributions present a number of technical difficulties, for instance d-separation and independence are not related in a straightforward way in such distributions, and conditional distributions may not be defined. We should mention, however, that distributions which span multiple hypothetical worlds which we discussed in Section 4 may be non-positive by definition.

Theorem 5 *If sets $\boldsymbol{X}$ and $\boldsymbol{Y}$ are d-separated by $\boldsymbol{Z}$ in G, then $\boldsymbol{X}$ is independent of $\boldsymbol{Y}$ given $\boldsymbol{Z}$ in every P for which G is an I-map. Furthermore, the causal diagram induced by any semi-Markovian PCM M is a semi-Markovian I-map of the distribution $P(\boldsymbol{v},\boldsymbol{u})$ induced by M.*

Proof It is not difficult to see that if we restrict d-separation queries to a subset of variables $\mathbf{W}$ in some graph G, the corresponding independencies in $P(\mathbf{w})$ will only hold whenever the d-separation statements hold. Furthermore, if we replace G by a latent projection L (Pearl, 2000), where we view variables $\mathbf{V} \setminus \mathbf{W}$ as hidden, independencies in $P(\mathbf{w})$ will only hold whenever the corresponding d-separation statement (extended to include bidirected arcs) holds in L. ■

Theorem 10 *$P(\boldsymbol{v}), G \not\vdash_{id} P(y|do(x))$ in G shown in Fig. 1 (a).*

Proof We construct two causal models M^1 and M^2 such that $P^1(X,Y) = P^2(X,Y)$, and $P^1_x(Y) \neq P^2_x(Y)$. The two models agree on the following: all 3 variables are boolean, U is a fair coin, and $f_X(u) = u$. Let $\oplus$ denote the exclusive or (XOR) function. Then the value of Y is determined by the function $u \oplus x$ in M^1, while Y is set to 0 in M^2. Then $P^1(Y=0) = P^2(Y=0) = 1$, $P^1(X=0) = P^2(X=0) = 0.5$. Therefore, $P^1(X,Y) = P^2(X,Y)$, while $P^2_x(Y=0) = 1 \neq P^1_x(Y=0) = 0.5$. Note that while P is non-positive, it is straightforward to modify the proof for the positive case by letting f_Y functions in both models return 1 half the time, and the values outlined above half the time. ■

Theorem 12 *Let G be a Y-rooted C-tree. Let $\boldsymbol{X}$ be any subset of observable nodes in G which does not contain Y. Then $P(\boldsymbol{v}), G \not\vdash_{id} P(y|do(\boldsymbol{x}))$.*

Proof We generalize the proof for the bow arc graph. We can assume without loss of generality that each unobservable U in G has exactly two observable children. We construct two models with binary nodes. In the first model, the value of all observable nodes is set to the bit parity (sum modulo 2) of the parent values. In the second model, the same is true for all nodes except Y, with the latter being set to 0 explicitly. All $\mathbf{U}$ nodes in both models are fair coins. Since G is a tree, and since every $U \in \mathbf{U}$ has exactly two children in G, every $U \in \mathbf{U}$ has exactly two distinct downward paths to Y in G. It's then easy to establish that Y counts the bit parity of every node in $\mathbf{U}$ twice in the first model. But this implies $P^1(Y = 1) = 0$.

Because bidirected arcs form a spanning tree over observable nodes in G, for any set of nodes $\mathbf{X}$ such that $Y \notin \mathbf{X}$, there exists $U \in \mathbf{U}$ with one child in $An(\mathbf{X})_G$ and one child in $G \setminus An(\mathbf{X})_G$. Thus $P^1_{\mathbf{X}}(Y = 1) > 0$, but $P^2_{\mathbf{X}}(Y = 1) = 0$. It is straightforward to generalize this proof for the positive $P(\mathbf{v})$ in the same way as in Theorem 10. ■

Theorem 13 *$P(\boldsymbol{v}), G \not\vdash_{id} P(y|do(pa(y)))$ if and only if there exists a subgraph of G which is a Y-rooted C-tree.*

Proof From Tian (2002), we know that whenever there is no subgraph G' of G, such that all nodes in G' are ancestors of Y, and G' is a C-component, $P_{pa(Y)}(Y)$ is identifiable. From Theorem 12, we know that if there is a Y-rooted C-tree containing a non-empty subset S of parents of Y, then $P_s(Y)$ is not identifiable. But it is always possible to extend the counterexamples which prove non-identification of $P_s(Y)$ with additional variables which are independent. ■

Theorem 17 *Let F, F' be subgraphs of G which form a hedge for $P(\boldsymbol{y}|do(\boldsymbol{x}))$. Then $P(\boldsymbol{v}), G \not\vdash_{id} P(\boldsymbol{y}|do(\boldsymbol{x}))$.*

Proof We first show $P_{\mathbf{X}}(\mathbf{r})$ is not identifiable in F. As before, we assume each U has two observable children. We construct two models with binary nodes. In M^1 every variable in F is equal to the bit parity of its parents. In M^2 the same is true, except all nodes in F' disregard the parent values in $F \setminus F'$. All $\mathbf{U}$ are fair coins in both models.

As was the case with C-trees, for any C-forest F, every $U \in \mathbf{U} \cap F$ has exactly two downward paths to $\mathbf{R}$. It is now easy to establish that in M^1, $\mathbf{R}$ counts the bit parity of every node in $\mathbf{U}^1$ twice, while in M^2, $\mathbf{R}$ counts the bit parity of every node in $\mathbf{U}^2 \cap F'$ twice. Thus, in both models with no interventions, the bit parity of $\mathbf{R}$ is even.

Next, fix two distinct instantiations of $\mathbf{U}$ that differ by values of $\mathbf{U}^*$. Consider the topmost node $W \in F$ with an odd number of parents in $\mathbf{U}^*$ (which exists because bidirected edges in F form a spanning tree). Then flipping the values of $\mathbf{U}^*$ once will flip the value W once. Thus the function from $\mathbf{U}$ to $\mathbf{V}$ induced by a C-forest F in M^1 and M^2 is one to one.

The above results, coupled with the fact that in a C-forest, $|\mathbf{U}| + 1 = |\mathbf{V}|$ implies that any assignment where $\sum \mathbf{r} \pmod 2 = 0$ is equally likely, and all other node assignments are impossible in both F and F'. Since the two models agree on all functions and distributions in $F \setminus F'$, $\sum_{f'} P^1 = \sum_{f'} P^2$. It follows that the observational distributions are the same in both models.

As before, we can find $U \in \mathbf{U}$ with one child in $An(\mathbf{X})_F$, and one child in $F \setminus An(\mathbf{X})_F$, which implies the probability of odd bit parity of $\mathbf{R}$ is 0.5 in M^1, and 0 in M^2.

Next, we note that the construction so far results in a non-positive distribution P. To rid our proof of non-positivity, we "soften" our two models with new unobservable binary U_R for every $R \in \mathbf{R}$ which assumes value 1 with very small probability p. Whenever U_R is 1, the node R flips its value, otherwise it keeps the value as defined above. Note that $P(\mathbf{v})$ will remain the same in both models because our augmentation is the same, and the previous unsoftened models agreed on $P(\mathbf{v})$. It's easy to see that the bit parity of R in both models will be odd only when an odd number of U_R assume values of 1. Because p is arbitrarily small, the probability of an odd parity is far smaller than the probability of even parity. Now consider what happens after $do(\mathbf{x})$. In M^2, the probability of odd bit parity stays the same. In M^1 before the addition of U_R, the probability was 0.5. But it's easy to see that U_R nodes change the bit parity of $\mathbf{R}$ in a completely symmetric way, so the probability of even parity remains 0.5.

This implies $P_{\mathbf{x}}(\mathbf{r})$ is not identifiable. Finally, to see that $P_{\mathbf{x}}(\mathbf{y})$ is not identifiable, augment our counterexample by nodes in $\mathbf{I} = An(\mathbf{Y}) \cap De(\mathbf{R})$. Without loss of generality, assume every node in $\mathbf{I}$ has at most one child. Let each node I in $\mathbf{I}$ be equal to the bit parity of its parents. Moreover, each I has an exogenous parent U_I independent of the rest of $\mathbf{U}$ which, with small probability p causes it to flip it's value. Then the bit parity of $\mathbf{Y}$ is even if and only if an odd number of $\mathbf{U_I}$ turn on. Moreover, it's easy to see $P(\mathbf{I}|\mathbf{R})$ is positive by construction. We can now repeat the previous argument. ■

Next, we provide the proof of soundness of **ID** and **IDC** using do-calculus. This both simplifies the proofs and allows us to infer do-calculus is complete from completeness of our algorithms. We will invoke do-calculus rules by just using their number, for instance "by rule 2." First, we prove that a joint distribution in a causal model can be represented as a product of interventional distributions corresponding to the set of c-component in the graph induced by the model.

Lemma 33 (c-component factorization) *Let M be a causal model with graph G. Let $\boldsymbol{y}, \boldsymbol{x}$ be value assignments. Let $C(G \setminus \boldsymbol{X}) = \{S_1, ..., S_k\}$. Then $P_{\boldsymbol{x}}(\boldsymbol{y}) = \sum_{\boldsymbol{v} \setminus (\boldsymbol{y} \cup \boldsymbol{x})} \prod_i P_{\boldsymbol{v} \setminus s_i}(s_i)$.*

Proof A proof of this was derived by Tian (2002). Nevertheless, we reprove this result using do-calculus to help with our subsequent completeness results. Assume $\mathbf{X} = \emptyset$, $\mathbf{Y} = \mathbf{V}$, $C(G) = \{S_1, ..., S_k\}$, and let $A_i = An(S_i)_G \setminus S_i$. Then

$$\prod_i P_{\mathbf{v} \setminus s_i}(s_i) = \prod_i P_{a_i}(s_i) = \prod_i \prod_{V_j \in S_i} P_{a_i}(v_j | v_\pi^{(j-1)} \setminus a_i)$$

$$= \prod_i \prod_{V_j \in S_i} P(v_j | v_\pi^{(j-1)}) = \prod_i P(v_i | v_\pi^{(i-1)}) = P(\mathbf{v}).$$

The first identity is by rule 3, the second is by chain rule of probability. To prove the third identity, we consider two cases. If $A \in A_i \setminus V_\pi^{(j-1)}$, we can eliminate the intervention on A from the expression $P_{a_i}(v_j | v_\pi^{(j-1)})$ by rule 3, since $(V_j \perp\!\!\!\perp A | V_\pi^{(j-1)})_{G_{\overline{a_i}}}$.

If $A \in A_i \cap V_\pi^{(j-1)}$, consider any back-door path from A_i to V_j. Any such path with a node not in $V_\pi^{(j-1)}$ will be d-separated because, due to recursiveness, it must contain a blocked collider. Further, this path must contain bidirected arcs only, since all nodes on this path are conditioned or fixed.

Because $A_i \cap S_i = \emptyset$, all such paths are d-separated. The identity now follows from rule 2. The last two identities are just grouping of terms, and application of chain rule.

Having proven that c-component factorization holds for $P(\mathbf{v})$, we want to extend the result to $P_{\mathbf{x}}(\mathbf{y})$. First, let's consider $P_{\mathbf{x}}(\mathbf{v} \setminus \mathbf{x})$. This is just the distribution of the submodel $M_{\mathbf{x}}$. But $M_{\mathbf{x}}$ is just an ordinary causal model inducing $G \setminus \mathbf{X}$, so we can apply the same reasoning to obtain $P_{\mathbf{x}}(\mathbf{v} \setminus \mathbf{x}) = \prod_i P_{\mathbf{v} \setminus s_i}(s_i)$, where $C(G \setminus \mathbf{X}) = \{S_1, ..., S_k\}$. As a last step, it's easy to verify that $P_{\mathbf{x}}(\mathbf{y}) = \sum_{\mathbf{v} \setminus (\mathbf{x} \cup \mathbf{y})} P_{\mathbf{x}}(\mathbf{v} \setminus \mathbf{x})$. ■

Lemma 34 *Let $\boldsymbol{X}' = \boldsymbol{X} \cap An(\boldsymbol{Y})_G$. Then $P_{\boldsymbol{x}}(\boldsymbol{y})$ obtained from P in G is equal to $P'_{\boldsymbol{x}'}(\boldsymbol{y})$ obtained from $P' = P(An(\boldsymbol{Y}))$ in $An(\boldsymbol{Y})_G$.*

Proof Let $\mathbf{W} = \mathbf{V} \setminus An(\mathbf{Y})_G$. Then the submodel $M_{\mathbf{W}}$ induces the graph $G \setminus \mathbf{W} = An(\mathbf{Y})_G$, and its distribution is $P' = P_{\mathbf{W}}(An(\mathbf{Y})) = P(An(\mathbf{Y}))$ by rule 3. Now $P_{\mathbf{x}}(\mathbf{y}) = P_{\mathbf{x}'}(\mathbf{y}) = P_{\mathbf{x}', \mathbf{W}}(\mathbf{y}) = P'_{\mathbf{x}'}(\mathbf{y})$ by rule 3. ■

Lemma 35 *Let $\boldsymbol{W} = (\boldsymbol{V} \setminus \boldsymbol{X}) \setminus An(\boldsymbol{Y})_{G_{\overline{\boldsymbol{X}}}}$. Then $P_{\boldsymbol{x}}(\boldsymbol{y}) = P_{\boldsymbol{x}, \boldsymbol{w}}(\boldsymbol{y})$, where $\boldsymbol{w}$ are arbitrary values of $\boldsymbol{W}$.*

Proof Note that by assumption, $\mathbf{Y} \perp\!\!\!\perp \mathbf{W} | \mathbf{X}$ in $G_{\overline{\mathbf{X}}, \overline{\mathbf{W}}}$. The conclusion follows by rule 3. ■

Lemma 36 *When the conditions of line 6 are satisfied, $P_{\boldsymbol{x}}(\boldsymbol{y}) = \sum_{s \setminus \boldsymbol{y}} \prod_{V_i \in S} P(v_i | v_\pi^{(i-1)})$.*

Proof If line 6 preconditions are met, then G local to that recursive call is partitioned into S and $\mathbf{X}$, and there are no bidirected arcs from $\mathbf{X}$ to S. The conclusion now follows from the proof of Lemma 33. ■

Lemma 37 *Whenever the conditions of the last recursive call of **ID** are satisfied, $P_{\boldsymbol{x}}$ obtained from P in the graph G is equal to $P'_{\boldsymbol{x} \cap S'}$ obtained from $P' = \prod_{V_i \in S'} P(V_i | V_\pi^{(i-1)} \cap S', v_\pi^{(i-1)} \setminus S')$ in the graph S'.*

Proof It is easy to see that when the last recursive call executes, $\mathbf{X}$ and S partition G, and $\mathbf{X} \subset An(S)_G$. This implies that the submodel $M_{\mathbf{x} \setminus S'}$ induces the graph $G \setminus (\mathbf{X} \setminus S') = S'$. The distribution $P_{\mathbf{x} \setminus S'}$ of $M_{\mathbf{x} \setminus S'}$ is equal to P' by the proof of Lemma 33. It now follows that $P_{\mathbf{x}} = P_{\mathbf{x} \cap S', \mathbf{x} \setminus S'} = P'_{\mathbf{x} \cap S'}$. ■

Theorem 38 (soundness) *Whenever **ID** returns an expression for $P_{\boldsymbol{x}}(\boldsymbol{y})$, it is correct.*

Proof If $\mathbf{x} = \emptyset$, the desired effect can be obtained from P by marginalization, thus this base case is clearly correct. The soundness of all other lines except the failing line 5 has already been established. ■

Having established soundness, we show that whenever **ID** fails, we can recover a hedge for an effect involving a subset of variables involved in the original effect expression $P(\mathbf{y}|do(\mathbf{x}))$. This in turn implies completeness.

Theorem 39 *Assume **ID** fails to identify $P_{\boldsymbol{X}}(\boldsymbol{y})$ (executes line 5). Then there exist $\boldsymbol{X}' \subseteq \boldsymbol{X}$, $\boldsymbol{Y}' \subseteq \boldsymbol{Y}$ such that the graph pair G, S returned by the fail condition of **ID** contain as edge subgraphs C-forests F, F' that form a hedge for $P_{\boldsymbol{X}'}(\boldsymbol{y}')$.*

Proof Consider line 5, and G and $\mathbf{y}$ local to that recursive call. Let $\mathbf{R}$ be the root set of G. Since G is a single C-component, it is possible to remove a set of directed arrows from G while preserving the root set $\mathbf{R}$ such that the resulting graph F is an $\mathbf{R}$-rooted C-forest.

Moreover, since $F' = F \cap S$ is closed under descendants, and since only single directed arrows were removed from S to obtain F', F' is also a C-forest. $F' \cap \mathbf{X} = \emptyset$, and $F \cap \mathbf{X} \neq \emptyset$ by construction. $\mathbf{R} \subseteq An(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$ by lines 2 and 3 of the algorithm. It's also clear that $\mathbf{y}, \mathbf{x}$ local to the recursive call in question are subsets of the original input. ■

Theorem 18 ***ID** is complete.*

Proof By the previous theorem, if **ID** fails, then $P_{\mathbf{X}'}(\mathbf{y}')$ is not identifiable in a subgraph $H = G_{An(\mathbf{Y})_{\cap De(F)}}$ of G. Moreover, $\mathbf{X} \cap H = \mathbf{X}'$, by construction of H. As such, it is easy to extend the counterexamples in Theorem 39 with variables independent of H, with the resulting models inducing G, and witnessing the non-identifiability of $P_{\mathbf{X}}(\mathbf{y})$. ■

Next, we prove the results necessary to establish completeness of **IDC**.

Lemma 40 *If rule 2 of do-calculus applies to a set $\boldsymbol{Z}$ in G for $P_{\boldsymbol{X}}(\boldsymbol{y}|\boldsymbol{w})$ then there are no d-connected paths to $\boldsymbol{Y}$ that pass through $\boldsymbol{Z}$ in neither $G_1 = G \setminus \boldsymbol{X}$ given $\boldsymbol{Z}, \boldsymbol{W}$ nor in $G_2 = G \setminus (\boldsymbol{X} \cup \boldsymbol{Z})$ given $\boldsymbol{W}$.*

Proof Clearly, there are no d-connected paths through $\mathbf{Z}$ in G_2 given $\mathbf{W}$. Consider a d-connected path through $Z \in \mathbf{Z}$ to $\mathbf{Y}$ in G_1, given $\mathbf{Z}, \mathbf{W}$. Note that this path must either form a collider at Z or a collider which is an ancestor of Z. But this must mean there is a back-door path from $\mathbf{Z}$ to $\mathbf{Y}$, which is impossible, since rule 2 is applicable to $\mathbf{Z}$ in G for $P_{\mathbf{X}}(\mathbf{y}|\mathbf{w})$. Contradiction. ■

Theorem 20 *For any G and any conditional effect $P_{\boldsymbol{X}}(\boldsymbol{y}|\boldsymbol{w})$ there exists a unique maximal set $\boldsymbol{Z} = \{Z \in \boldsymbol{W} | P_{\boldsymbol{X}}(\boldsymbol{y}|\boldsymbol{w}) = P_{\boldsymbol{X},z}(\boldsymbol{y}|\boldsymbol{w} \setminus \{z\})\}$ such that rule 2 applies to $\boldsymbol{Z}$ in G for $P_{\boldsymbol{X}}(\boldsymbol{y}|\boldsymbol{w})$. In other words, $P_{\boldsymbol{X}}(\boldsymbol{y}|\boldsymbol{w}) = P_{\boldsymbol{X},\boldsymbol{Z}}(\boldsymbol{y}|\boldsymbol{w} \setminus \boldsymbol{z})$.*

Proof Fix two maximal sets $\mathbf{Z}_1, \mathbf{Z}_2 \subseteq \mathbf{W}$ such that rule 2 applies to $\mathbf{Z}_1, \mathbf{Z}_2$ in G for $P_{\mathbf{X}}(\mathbf{y}|\mathbf{w})$. If $\mathbf{Z}_1 \neq \mathbf{Z}_2$, fix $Z \in \mathbf{Z}_1 \setminus \mathbf{Z}_2$. By Lemma 40, rule 2 applies for $\{Z\} \cup \mathbf{Z}_2$ in G for $P_{\mathbf{X}}(\mathbf{y}|\mathbf{w})$, contradicting our assumption.

Thus if we fix G and $P_{\mathbf{X}}(\mathbf{y}|\mathbf{w})$, any set to which rule 2 applies must be a subset of the unique maximal set $\mathbf{Z}$. It follows that $\mathbf{Z} = \{Z \in \mathbf{W} | P_{\mathbf{X}}(\mathbf{y}|\mathbf{w}) = P_{\mathbf{X},z}(\mathbf{y}|\mathbf{w} \setminus \{z\})\}$. ■

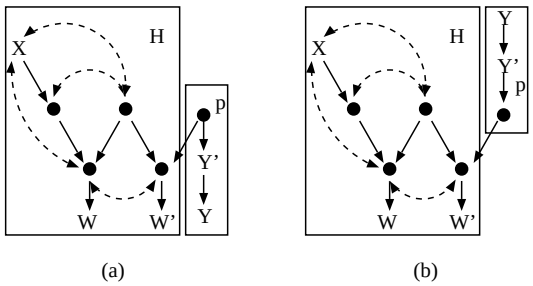

Figure 14: Inductive cases for proving non-identifiability of $P_x(y|w,w')$.

Lemma 41 *Let F, F' form a hedge for $P_{\boldsymbol{X}}(\boldsymbol{y})$. Then $F \subseteq F' \cup \boldsymbol{X}$.*

Proof It has been shown that **ID** fails on $P_{\mathbf{X}}(\mathbf{y})$ in G and returns a hedge if and only if $P_{\mathbf{X}}(\mathbf{y})$ is not identifiable in G. In particular, edge subgraphs of the graphs G and S returned by line 5 of **ID** form the C-forests of the hedge in question. It is easy to check that a subset of $\mathbf{X}$ and S partition G. ■

We rephrase the statement of Theorem 21 somewhat, to reduce "algebraic clutter."

Theorem 21 *Let $P_{\boldsymbol{X}}(\boldsymbol{y}|\boldsymbol{w})$ be such that every $W \in \boldsymbol{W}$ has a back-door path to $\boldsymbol{Y}$ in $G \setminus \boldsymbol{X}$ given $\boldsymbol{W} \setminus \{W\}$. Then $P_{\boldsymbol{X}}(\boldsymbol{y}|\boldsymbol{w})$ is identifiable in G if and only if $P_{\boldsymbol{X}}(\boldsymbol{y},\boldsymbol{w})$ is identifiable in G.*

Proof If $P_{\mathbf{X}}(\mathbf{y},\mathbf{w})$ is identifiable in G, then we can certainly identify $P_{\mathbf{X}}(\mathbf{y}|\mathbf{w})$ by marginalization and division. The difficult part is to prove that if $P_{\mathbf{X}}(\mathbf{y},\mathbf{w})$ is not identifiable then neither is $P_{\mathbf{X}}(\mathbf{y}|\mathbf{w})$.

Assume $P_{\mathbf{X}}(\mathbf{w})$ is identifiable. Then if $P_{\mathbf{X}}(\mathbf{y}|\mathbf{w})$ were identifiable, we would be able to compute $P_{\mathbf{X}}(\mathbf{y},\mathbf{w})$ by the chain rule. Thus our conclusion follows.

Assume $P_{\mathbf{X}}(\mathbf{w})$ is not identifiable. We also know that every $W \in \mathbf{W}$ contains a back-door path to some $Y \in \mathbf{Y}$ in $G \setminus \mathbf{X}$ given $\mathbf{W} \setminus \{W\}$. Fix such W and Y, along with a subgraph p of G which forms the witnessing back-door path. Consider also the hedge F, F' which witnesses the non-identifiability of $P_{\mathbf{X}'}(\mathbf{w}')$, where $\mathbf{X}' \subseteq \mathbf{X}, \mathbf{W}' \subseteq \mathbf{W}$.

Let $H = G_{De(F)\cup An(\mathbf{W}')_{G_{\overline{\mathbf{X}'}}}}$. We will attempt to show that $P_{\mathbf{X}'}(Y|\mathbf{w})$ is not identifiable in $H \cup p$. Without loss of generality, we make the following three assumptions. First, we restrict our attention to $\mathbf{W}'' \subseteq \mathbf{W}$ that occurs in $H \cup p$. Second, we assume p is a path segment which starts at H and ends at Y, and does not intersect H. Third, we assume all observable nodes in H have at most one child.

Consider the models M^1, M^2 from the proof of Theorem 17 which induce H. We extend the models by adding to them binary variables in p. Each variable $X \in p$ is equal to the bit parity of its parents, if it has any. If not, X behaves as a fair coin. If $Y \in H$ has a parent $X \in p$, the value of X is added to the bit parity computation Y makes.

Call the resulting models M^1_*, M^2_*. Because M^1, M^2 agreed on $P(H)$, and variables and functions in p are the same in both models, $P^1_* = P^2_*$. We will assume $\mathbf{w}''$ assigns 0 to every variable in $\mathbf{W}''$. What remains to be shown is that $P^1_{*\mathbf{X}}(y|\mathbf{w}'') \neq P^2_{*\mathbf{X}}(y|\mathbf{w}'')$. We will prove this by induction on the path structure of p. We handle the inductive cases first. In all these cases, we fix a node Y' that is between Y and H on the path p, and prove that if $P_{\mathbf{X}'}(y'|\mathbf{w}'')$ is not identifiable, then neither is $P_{\mathbf{X}'}(y|\mathbf{w}'')$.

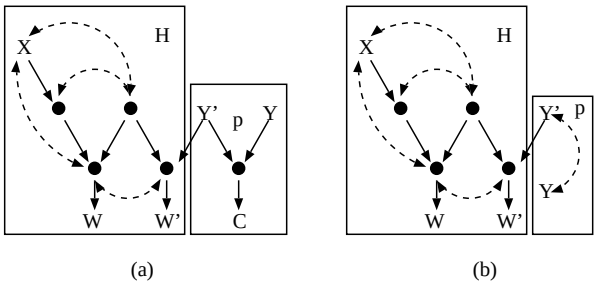

Figure 15: Inductive cases for proving non-identifiability of $P_x(y|w,w')$.

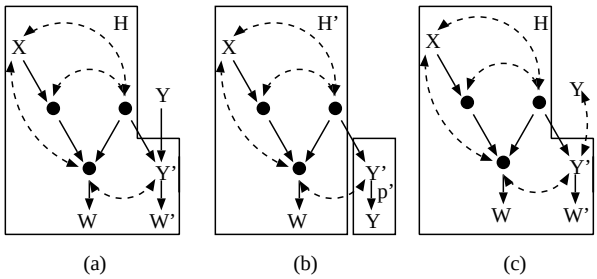

Figure 16: Base cases for proving non-identifiability of $P_x(y|w,w')$.

Assume neither Y nor Y' have descendants in $\mathbf{W}''$. If Y' is a parent of Y as in Fig. 14 (a), then $P_{\mathbf{X}'}(y|\mathbf{w}'') = \sum_{y'} P(y|y')P_{\mathbf{X}'}(y'|\mathbf{w}'')$. If Y is a parent of Y', as in Fig. 14 (b) then the next node in p must be a child of Y'. Therefore, $P_{\mathbf{X}'}(y|\mathbf{w}'') = \sum_{y'} P(y|y')P_{\mathbf{X}'}(y'|\mathbf{w}'')$. In either case, by construction $P(Y|Y')$ is a 2 by 2 identity matrix. This implies that the mapping from $P_{\mathbf{X}'}(y'|\mathbf{w}'')$ to $P_{\mathbf{X}'}(y|\mathbf{w}'')$ is one to one. If Y' and Y share a hidden common parent U as in Fig. 15 (b), then our result follows by combining the previous two cases.

The next case is if Y and Y have a common child C which is either in $\mathbf{W}''$ or has a descendant in $\mathbf{W}''$, as in Fig. 15 (a). Now $P_{\mathbf{X}'}(y|\mathbf{w}'') = \sum_{y'} P(y|y',c)P_{\mathbf{X}'}(y'|\mathbf{w}'')$. Because all nodes in $\mathbf{W}''$ were observed to be 0, $P(y|y',c)$ is again a 2 by 2 identity matrix.

Finally, we handle the base cases of our induction. In all such cases, Y is the first node not in H on the path p. Let Y' be the last node in H on the path p.

Assume Y is a parent of Y', as shown in Fig. 16 (a). By Lemma 41, we can assume $Y \notin An(F \setminus F')_H$. By construction, $(\sum \mathbf{W}'' = Y + 2 * \sum \mathbf{U}) \pmod 2$ in M^1_*, and $(\sum \mathbf{W}'' = Y + 2 * \sum(\mathbf{U} \cap F')) \pmod 2$ in M^2_*. If every variable in $\mathbf{W}''$ is observed to be 0, then $Y = (2 * \sum \mathbf{U}) \pmod 2$ in M^1_*, and $Y = (2 * \sum(\mathbf{U} \cap F')) \pmod 2$ in M^2_*. If an intervention $do(\mathbf{x})$ is performed, $(\sum \mathbf{W}'' = Y + 2 * \sum(\mathbf{U} \cap F')) \pmod 2$ in $M^2_{*\mathbf{X}}$, by construction. Thus if $\mathbf{W}''$ are all observed to be zero, $Y = 0$ with probability 1. Note that in $M^1_{\mathbf{X}}$ as constructed in the proof of Theorem 17, $(\sum \mathbf{w}'' = \mathbf{x} + \sum \mathbf{U}') \pmod 2$, where $\mathbf{U}' \subseteq \mathbf{U}$ consists of unobservable nodes with one child in $An(\mathbf{X})_F$ and one child in $F \setminus An(\mathbf{X})_F$.

Because $Y \notin An(F \setminus F')_H$, we can conclude that if $\mathbf{W}''$ are observed to be 0, $Y = (\mathbf{x} + \sum \mathbf{U}') \pmod 2$ in $M^1_{*\mathbf{X}'}$. Thus, $Y = 0$ with probability 0.5. Therefore, $P^1_{*\mathbf{X}'}(y|\mathbf{w}'') \neq P^2_{*\mathbf{X}'}(y|\mathbf{w}'')$ in this case.

Assume Y is a child of Y'. Now consider a graph G' which is obtained from $H \cup p$ by removing the (unique) outgoing arrow from Y' in H. If $P_{\mathbf{X}'}(Y|\mathbf{w}'')$ is not identifiable in G', we are done.

Assume $P_{\mathbf{X}'}(Y|\mathbf{w}'')$ is identifiable in G'. If $Y' \in F$, and $\mathbf{R}$ is the root set of F, then removing the Y'-outgoing directed arrow from F results in a new C-forest, with a root set $\mathbf{R} \cup \{Y'\}$. Because Y is a child of Y', the new C-forests form a hedge for $P_{\mathbf{X}'}(y, \mathbf{w}'')$. If $Y' \in H \setminus F$, then removing the Y'-outgoing directed arrow results in substituting Y for $W \in \mathbf{W}'' \cap De(Y')_H$. Thus in G', F, F' form a hedge for $P_{\mathbf{X}'}(y, \mathbf{w}'' \setminus \{w\})$. In either case, $P_{\mathbf{X}'}(y, \mathbf{w}'')$ is not identifiable in G'.

If $P_{\mathbf{X}'}(\mathbf{w}'')$ is identifiable in G', we are done. If not, consider a smaller hedge $H' \subset H$ witnessing this fact. Now consider the segment p' of p between Y and H'. We can repeat the inductive argument for H', p' and Y. See Fig. 16 (b).

If $P_{\mathbf{X}'}(\mathbf{w}'')$ is identifiable in G', we are done. If not, consider a smaller hedge $H' \subset H$ witnessing this fact. Now consider the segment p' of p between Y and H'. We can repeat the inductive argument for H', p' and Y. See Fig. 16 (b). If Y and Y' have a hidden common parent, as is the case in Fig. 16 (c), we can combine the first inductive case, and the first base case to prove our result.

We conclude the proof by introducing a slight change to rid us of non-positivity in the distributions P^1, P^2 in our counterexamples. Specifically, for every node I in $p \cup (De(\mathbf{R}) \cap An(\mathbf{Y}))$, add a new binary exogenous parent U_I which is independent of other nodes in $\mathbf{U}$, and has an arbitrarily small probability of assuming the value 1, and causing its child to flip its current value. We let P_{odd} be the probability an odd number of U_I nodes assume the value 1. Because $P(U_I = 1)$ is vanishingly small for every I, P_{odd} is much smaller than 0.5. It's easy to see that P is positive in counterexamples augmented in this way. In the base case when Y is a parent of Y', we modify our equations to account for the addition of U_I. Specifically, $(\sum \mathbf{W}'' = Y + 2 * \sum \mathbf{U} + \sum \mathbf{U_I} \pmod 2)$ in M^1_*, and $(\sum \mathbf{W}'' = Y + 2 * \sum (\mathbf{U} \cap F') + \sum \mathbf{U_I} \pmod 2)$ in M^2_*, where $U_{\mathbf{U}}$ is the set of nodes added. If every variable in $\mathbf{W}''$ is observed to be 0, then $Y = (2 * \sum \mathbf{U} + \sum \mathbf{U_I} \pmod 2)$ in M^1_*, and $Y = (2 * \sum (\mathbf{U} \cap F') + \sum \mathbf{U_I} \pmod 2)$ in M^2_*. So prior to the intervention, $P(Y = 1|\mathbf{w}'') = P_{odd}$. But because $P^1_{\mathbf{X}'}(Y = 1|\mathbf{w}'') = 0.5$, adding U_I nodes to the model does not change this probability. Because $P^2(Y = 1|\mathbf{w}'') = P^2_{\mathbf{X}}(Y = 1|\mathbf{w}'')$, our conclusion follows.

In the inductive cases above, we showed that $P_{\mathbf{X}}(Y' = Y|\mathbf{W}'') = 1$ in our counterexamples. It's easy to see that with the addition of U_I, $P_{\mathbf{X}}(Y' = Y|\mathbf{W}'') = P_{odd}$. This implies that if $P^1_{\mathbf{X}}(Y'|\mathbf{W}'') \neq P^2_{\mathbf{X}}(Y'|\mathbf{W}'')$, then $P^1_{\mathbf{X}}(Y|\mathbf{W}'') \neq P^2_{\mathbf{X}}(Y|\mathbf{W}'')$.

This completes the proof. ■

What remains for us to show are the theorems which imply the soundness and completeness results in Section 4. The most important point in these proofs is that counterfactual graphs are generally no different from causal diagrams discussed in Sections 2 and 3, with their only special feature being that by construction, some nodes in the graph happen to share functions. This means that a lot of results we already proved for Section 3 can be reused without change.

Lemma 42 *If the preconditions of line 7 are met,* $P(S) = P_{\boldsymbol{x}}(\boldsymbol{var}(S))$, *where* $\boldsymbol{x} = \bigcup \boldsymbol{sub}(S)$.

Proof Let $\mathbf{x} = \bigcup \mathbf{sub}(S)$. Since the preconditions are met, $\mathbf{x}$ does not contain conflicting assignments to the same variable, which means $do(\mathbf{x})$ is a sound action in the original causal model. Note that for any variable $Y_{\mathbf{W}}$ in S, any variable in $(Pa(S) \setminus S) \cap An(Y_{\mathbf{W}})_S$ is already in $\mathbf{w}$, while any variable in $(Pa(S) \setminus S) \setminus An(Y_{\mathbf{W}})_S$ can be added to the subscript of $Y_{\mathbf{W}}$ without changing the variable. Since $Y \cap \mathbf{X} = \emptyset$ by assumption, $Y_{\mathbf{W}} = Y_{\mathbf{X}}$. Since $Y_{\mathbf{W}}$ was arbitrary, our result follows. ■

For convenience, we show the soundness of **ID*** and **IDC*** asserted in Theorem 26 separately.

Theorem 26 (a) *If **ID*** succeeds, the expression it returns is equal to $P(\gamma)$ in a given causal graph.*

Proof The proof outline in Section 3 is sufficient for everything except the base cases. In particular, line 6 follows by Lemma 33. For soundness, we only need to handle the positive base case, which follows from Lemma 42. ■

The soundness of **IDC*** is also fairly straightforward.

Theorem 26 (b) *If **IDC*** does not output **FAIL**, the expression it returns is equal to $P(\gamma|\delta)$ in a given causal graph, if that expression is defined, and **UNDEFINED** otherwise.*

Proof Theorem 20 shows how an operation similar to line 4 is sound by rule 2 of do-calculus (Pearl, 1995) when applied in a causal diagram. But we know that the counterfactual graph is just a causal diagram for a model where some nodes share functions, so the same reasoning applies. The rest is straightforward. ■

To show completeness of **ID*** and **IDC***, we first prove a utility lemma which will make it easier to construct counterexamples which agree on P_* but disagree on a given counterfactual query.

Lemma 43 *Let G be a causal graph partitioned into a set $\{S_1,...,S_k\}$ of C-components. Then two models M_1, M_2 which induce G agree on P_* if and only if their submodels $M^1_{\mathbf{v}\setminus s_i}$, $M^2_{\mathbf{v}\setminus s_i}$ agree on P_* for every C-component S_i, and value assignment $\mathbf{v}\setminus s_i$.*

Proof This follows from C-component factorization: $P(\mathbf{v}) = \prod_i P_{\mathbf{V}\setminus s_i}(s_i)$. This implies that for every $do(\mathbf{x})$, $P_{\mathbf{X}}(\mathbf{v})$ can be expressed as a product of terms $P_{\mathbf{V}\setminus(s_i\setminus\mathbf{X})}(s_i\setminus\mathbf{x})$, which implies the result. ■

The next result generalizes Lemma 27 to a wider set of counterfactual graphs which result from non-identifiable queries.

Lemma 28 *Assume G is such that X is a parent of Y and Z, and Y and Z are connected by a bidirected path with observable nodes $W^1,...,W^k$ on the path. Then $P_*, G \not\vdash_{id} P(y_x, w^1,...,w^k, z_{x'})$, $P(y_x, w^1,...,w^k, z)$ for any value assignments $y, w^1,...,w^k, z$.*

Proof We construct two models with graph G as follows. In both models, all variables are binary, and $P(\mathbf{u})$ is uniform. In M^1, each variable is set to the bit parity of its parents. In M^2, the same is true except Y and Z ignore the values of X. To prove that the two models agree on P_*, we use Lemma 43. Clearly the two models agree on $P(X)$. To show that the models also agree on $P_x(\mathbf{V}\setminus X)$ for all values of x, note that in M_2 each value assignment over $\mathbf{V}\setminus X$ with even bit parity is equally likely, while no assignment with odd bit parity is possible. But the same is true in M^1 because any value of x contributes to the bit parity of $\mathbf{V}\setminus X$ exactly twice. The agreement of M^1_x, M^2_x on P_* follows by the graph structure of G.

To see that the result is true, we note firstly that $P(\Sigma_i W^i + Y_x + Z_{x'} \pmod 2 = 1) = P(\Sigma_i W^i + Y_x + Z \pmod 2 = 1) = 0$ in M^2, while the same probabilities are positive in M^1, and secondly that in both models distributions $P(y_x, w^1,...,w^k, z_{x'})$ and $P(y_x, w^1,..,w^k, z)$ assign equal probabilities to

outcomes with positive probabilities, while we just established that the set of these possible outcomes differs in M_1 and M_2. Note that the proof is easy to generalize for positive P_* by adding a small probability for Y to flip its normal value. ■

To obtain a full characterization of non-identifiable counterfactual graphs, we augment the difficult graphs we obtained from the previous two results using certain graph transformation rules which preserve non-identifiability. These rules are given in the following two lemmas.

Lemma 29 *Assume $P_*, G \not\vdash_{id} P(\gamma)$. Let $\{y^1_{\mathbf{x}^1}, ..., y^n_{\mathbf{x}^m}\}$ be a subset of counterfactual events in γ. Let G' be a graph obtained from G by adding a new child W of $Y^1, ..., Y^n$, and let P'_* be the set of all interventional distributions in models inducing G'. Let $\gamma' = (\gamma \setminus \{y^1_{\mathbf{x}^1}, ..., y^n_{\mathbf{x}^m}\}) \cup \{w_{\mathbf{x}^1}, ..., w_{\mathbf{x}^m}\}$, where w is an arbitrary value of W. Then $P'_*, G' \not\vdash_{id} P(\gamma')$.*

Proof Let M^1, M^2 witness $P_*, G \not\vdash_{id} P(\gamma)$. We will extend these models to witness $P'_*, G' \not\vdash_{id} P(\gamma')$. Since the function of a newly added W will be shared, and M^1, M^2 agree on P_* in G, the extensions will agree on P'_* by Lemma 43. We have two cases.

Assume there is a variable Y^i such that $y^i_{\mathbf{x}^j}, y^i_{\mathbf{x}^k}$ are in γ. By Lemma 27, $P_*, G \not\vdash_{id} P(y^i_{\mathbf{x}^j}, y^i_{\mathbf{x}^k})$. Then let W be a child of just Y^i, and assume $|W| = |Y^i| = c$. Let W be set to the value of Y^i with probability $1-\varepsilon$, and otherwise it is set to a uniformly chosen random value of Y^i among the other $c-1$ values. Since ε is arbitrarily small, and since $W_{\mathbf{x}^j}$ and $W_{\mathbf{x}^k}$ pay attention to the same U variable, it is possible to set ε in such a way that if $P^1(Y^i_{\mathbf{x}^j}, Y^i_{\mathbf{x}^k}) \neq P^2(Y^i_{\mathbf{x}^j}, Y^i_{\mathbf{x}^k})$, however minutely, then $P^1(W_{\mathbf{x}^j}, W_{\mathbf{x}^k}) \neq P^2(W_{\mathbf{x}^j}, W_{\mathbf{x}^k})$.

Otherwise, let $|W| = \prod_i |Y^i|$, and let $P(W|Y^1, ..., Y^n)$ be an invertible stochastic matrix. Our result follows. ■

Lemma 30 *Assume $P_*, G \not\vdash_{id} P(\gamma)$. Let G' be obtained from G by merging some two nodes X, Y into a new node Z where Z inherits all the parents and children of X, Y, subject to the following restrictions:*

- *The merge does not create cycles.*
- *If $(\exists w_{\mathbf{s}} \in \gamma)$ where $x \in \mathbf{s}$, $y \notin \mathbf{s}$, and $X \in An(W)_G$, then $Y \notin An(W)_G$.*
- *If $(\exists y_{\mathbf{s}} \in \gamma)$ where $x \in \mathbf{s}$, then $An(X)_G = \emptyset$.*
- *If $(Y_{\mathbf{w}}, X_{\mathbf{s}} \in \gamma)$, then $\mathbf{w}$ and $\mathbf{s}$ agree on all variable settings.*

Assume $|X| \times |Y| = |Z|$ and there's some isomorphism f assigning value pairs x, y to a value $f(x,y) = z$. Let γ' be obtained from γ as follows. For any $w_{\mathbf{s}} \in \gamma$:

- *If $W \notin \{X, Y\}$, and values x, y occur in $\mathbf{s}$, replace them by $f(x,y)$.*
- *If $W \notin \{X, Y\}$, and the value of one of X, Y occur in $\mathbf{s}$, replace it by some z consistent with the value of X or Y.*
- *If X, Y do not occur in γ, leave γ as is.*
- *If $W = Y$ and $x \in \mathbf{s}$, replace $w_{\mathbf{s}}$ by $f(x,y)_{\mathbf{s} \setminus \{x\}}$.*

- *otherwise, replace every variable pair of the form* $Y_{\mathbf{r}} = y, X_{\mathbf{s}} = x$ *by* $Z_{\mathbf{r},\mathbf{s}} = f(x,y)$.

Then $P_*, G' \not\vdash_{id} P(\gamma')$.

Proof Let Z be the Cartesian product of X, Y, and fix f. We want to show that the proof of non-identification of $P(\gamma)$ in G carries over to $P(\gamma')$ in G'.

We have five modification conditions which can apply to a variable $w_{\mathbf{s}} \in \gamma$. However, since γ is left alone if X, Y do not occur in γ (the third condition), only the remaining four of these conditions result in an actual modification of a counterfactual variable in γ.

We go through these remaining conditions one by one. The first clearly results in the same counterfactual variable. For the second, due to the restrictions we imposed, $w_{\mathbf{z}} = w_{\mathbf{z},y,x}$, which means we can apply the first modification.

For the fourth, we have $P(\gamma) = P(\delta, y_{x,\mathbf{z}})$. By our restrictions, and rule 2 of do-calculus (Pearl, 1995), this is equal to $P(\delta, y_{\mathbf{z}} | x_{\mathbf{z}})$. Since this is not identifiable, then neither is $P(\delta, y_{\mathbf{z}}, x_{\mathbf{z}})$. Now it's clear that our modification is equivalent to one applied after the fifth condition.

The fifth modification is simply a merge of events consistent with a single causal world into a conjunctive event, which does not change the overall expression. ■

We are now ready to show the main completeness results for counterfactual identification algorithms. Again, we prove this results separately for **ID*** and **IDC*** for convenience.

Theorem 31 (a) ***ID**** *is complete.*

Proof We want to show that if line 8 fails, the original $P(\gamma)$ cannot be identified. There are two broad cases to consider. If G_γ contains the w-graph, the result follows by Lemmas 27 and 29. If not, we argue as follows.

Fix some X which witnesses the precondition on line 8. We can assume X is a parent of some nodes in S. Assume no other node in $\mathbf{sub}(S)$ affects S (effectively we delete all edges from parents of S to S except from X). Because the w-graph is not a part of G_γ, this has no ramifications on edges in S. Further, we assume X has two values in S.

If $X \notin S$, fix $Y, W \in S \cap Ch(X)$. Assume S has no directed edges at all. Then $P_*, G \not\vdash_{id} P(S)$ by Lemma 28. The result now follows by Lemma 29, and by construction of G_γ, which implies all nodes in S have some descendant in γ.

If S has directed edges, we want to show $P_*, G \not\vdash_{id} P(R(S))$, where $R(S)$ is the subset of S with no children in S. We can recover this from the previous case as follows. Assume S has no edges as before. For a node $Y \in S$, fix a set of childless nodes $\mathbf{X} \in S$ which are to be their parents. Add a virtual node Y' which is a child of all nodes in $\mathbf{X}$. Then $P_*, G \not\vdash_{id} P((S \setminus \mathbf{X}) \cup Y')$ by Lemma 29. Then $P_*, G \not\vdash_{id} P(R(S'))$, where S' is obtained from S by adding edges from $\mathbf{X}$ to Y by Lemma 30, which applies because no w-graph exists in G_γ. We can apply this step inductively to obtain the desired forest (all nodes have at most one child) S while making sure $P_*, G \not\vdash_{id} P(R(S))$.

If S is not a forest, we can simply disregard extra edges so effectively it is a forest. Since the w-graph is not in G_γ this does not affect edges from X to S.

If $X \in S$, fix $Y \in S \cap Ch(X)$. If S has no directed edges at all, replace X by a new virtual node Y, and make X be the parent of Y. By Lemma 28, $P_*, G \not\vdash_{id} P((S \setminus x) \cup y_x)$. We now repeat the same steps as before, to obtain that $P_*, G \not\vdash_{id} P((R(S) \setminus x) \cup y_x)$ for general S. Now we use Lemma 30 to

obtain $P_*, G \not\vdash_{id} P(R(S))$. Having shown $P_*, G \not\vdash_{id} P(R(S))$, we conclude our result by inductively applying Lemma 29. ■

Theorem 31 (b) ***IDC**** *is complete.*

Proof The difficult step is to show that after line 5 is reached, if $P_*, G \not\vdash_{id} P(\gamma, \delta)$ then $P_*, G \not\vdash_{id} P(\gamma|\delta)$. If $P_*, G \vdash_{id} P(\delta)$, this is obvious. Assume $P_*, G \not\vdash_{id} P(\delta)$. Fix the S which witnesses that for $\delta' \subseteq \delta$, $P_*, G \not\vdash_{id} P(\delta')$. Fix some Y such that a back-door, that is, starting with an incoming arrow, path exists from δ' to Y in $G_{\gamma,\delta}$. We want to show that $P_*, G \not\vdash_{id} P(Y|\delta')$. Let $G' = G_{An(\delta') \cap De(S)}$.

Assume Y is a parent of a node $D \in \delta'$, and $D \in G'$. Augment the counterexample models which induce counterfactual graph G' with an additional binary node for Y, and let the value of D be set as the old value plus Y modulo $|D|$. Let Y attain value 1 with vanishing probability ε. That the new models agree on P_* is easy to establish. To see that $P_*, G \not\vdash_{id} P(\delta')$ in the new model, note that $P(\delta')$ in the new model is equal to $P(\delta' \setminus D, D = d) * (1-\varepsilon) + P(\delta' \setminus D, D = (d-1) \pmod{|D|}) * \varepsilon$. Because ε is arbitrarily small, this implies our result. To show that $P_*, G \not\vdash_{id} P(Y = 1|\delta')$, we must show that the models disagree on $P(\delta'|Y = 1)/P(\delta')$. But to do this, we must simply find two consecutive values of D, $d, d+1 \pmod{|D|}$ such that $P(\delta' \setminus D, d+1 \pmod{|D|})/P(\delta' \setminus D, d)$ is different in the two models. But this follows from non-identification of $P(\delta')$.

If Y is not a parent of $D \in G'$, then either it is further along on the back-door path or it's a child of some node in G'. In case 1, we must construct the distributions along the back-door path in such a way that if $P_*, G \not\vdash_{id} P(Y'|\delta')$ then $P_*, G \not\vdash_{id} P(Y|\delta')$, where Y' is a node preceding Y on the path. The proof follows closely the one in Theorem 21. In case 2, we duplicate the nodes in G' which lead from Y to δ', and note that we can show non-identification in the resulting graph using reasoning in case 1. We obtain our result by applying Lemma 30. ■

Abstract

Consider data consisting of pairwise measurements, such as presence or absence of links between pairs of objects. These data arise, for instance, in the analysis of protein interactions and gene regulatory networks, collections of author-recipient email, and social networks. Analyzing pairwise measurements with probabilistic models requires special assumptions, since the usual independence or exchangeability assumptions no longer hold. Here we introduce a class of variance allocation models for pairwise measurements: mixed membership stochastic blockmodels. These models combine global parameters that instantiate dense patches of connectivity (blockmodel) with local parameters that instantiate node-specific variability in the connections (mixed membership). We develop a general variational inference algorithm for fast approximate posterior inference. We demonstrate the advantages of mixed membership stochastic blockmodels with applications to social networks and protein interaction networks.

Keywords: hierarchical Bayes, latent variables, mean-field approximation, statistical network analysis, social networks, protein interaction networks

1. Introduction

The problem of modeling relational information among objects, such as pairwise relations represented as graphs, arises in a number of settings in machine learning. For example, scientific literature connects papers by citations, the Web connects pages by links, and protein-protein interaction data connects proteins by physical binding records. In these settings, we often wish to infer hidden attributes of the objects from the observed measurements on pairwise properties. For example, we might want to compute a clustering of the web-pages, predict the functions of a protein, or assess

the degree of relevance of a scientific abstract to a scholar's query. Unlike traditional data collected from individual objects, *relational data* violate the classical independence or exchangeability assumptions made in machine learning and statistics. The observations are dependent because of the way they are connected. This interdependence suggests that a different set of assumptions is more appropriate.

There is a history of research devoted to analyzing relational data. One well-studied problem is *clustering*, grouping the objects to uncover a structure based on the observed patterns of interactions. Standard model-based clustering methods, for example, mixture models, are not immediately applicable to relational data because they assume that the objects are conditionally independent given their cluster assignments. Rather, the latent stochastic blockmodel (Wang and Wong, 1987; Snijders and Nowicki, 1997) is an adaptation of mixture modeling to relational data. In that model, each object belongs to a cluster and the relationships between objects are governed by the corresponding pair of clusters. With posterior inference, one identifies a set of latent roles which govern the objects relationships with each other. A recent extension of this model relaxed the finite-cardinality assumption on the latent clusters with a nonparametric hierarchical Bayesian model based on the Dirichlet process prior (Kemp et al., 2004, 2006; Xu et al., 2006).

The latent stochastic blockmodel suffers from a limitation that each object can only belong to one cluster, or in other words, play a single latent role. However, many relational data sets are multi-facet. For example, when a protein or a social actor interacts with different partners, different functional or social contexts may apply and thus the protein or the actor may be acting according to different latent roles they can possible play. In this paper, we relax the assumption of single-latent-role for actors, and develop a *mixed membership model* for relational data. Mixed membership models, such as latent Dirichlet allocation (Blei et al., 2003), have re-emerged in recent years as a flexible modeling tool for data where the single cluster assumption is violated by the heterogeneity within of a data point. For almost two decades, these models have been successfully applied in many domains, such as surveys (Berkman et al., 1989; Erosheva, 2002), population genetics (Pritchard et al., 2000), document analysis (Minka and Lafferty, 2002; Blei et al., 2003; Buntine and Jakulin, 2006), image processing (Li and Perona, 2005), and transcriptional regulation (Airoldi et al., 2007).

The mixed membership model associates each unit of observation with multiple clusters rather than a single cluster, via a membership probability-like vector. The concurrent membership of a data in different clusters can capture its different aspects, such as different underlying topics for words constituting each document. This is also a natural idea for relational data, where the objects can bear multiple latent roles or cluster-memberships that influence their relationships to others. As we will demonstrate, a mixed membership approach to relational data lets us describe the interaction between objects playing multiple roles. For example, some of a protein's interactions may be governed by one function; other interactions may be governed by another function.

Existing mixed membership models are not appropriate for relational data because they assume that the data are conditionally independent given their latent membership vectors. In relational data, where each object is described by its relationships to others, we would like to assume that the ensemble of mixed membership vectors help govern the relationships of each object. The conditional independence assumptions of modern mixed membership models do not apply.

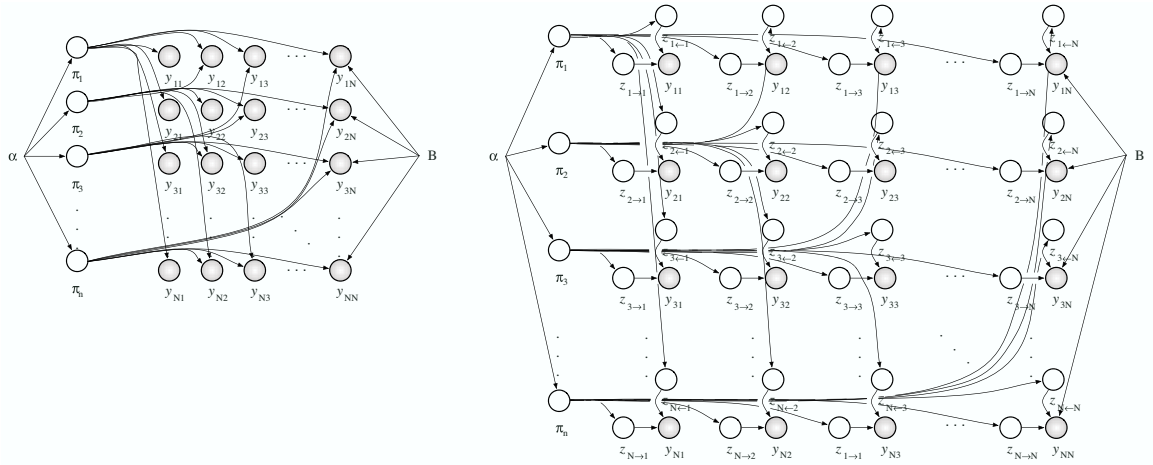

Figure 1: Two graphical model representations of the mixed membership stochastic blockmodel (MMB). Intuitively, the MMB summarized the variability of a graph with the blockmodel B and node-specific mixed membership vectors (left). In detail, a mixed membership, $\pi_n(k)$, quantifies the expected proportion of times node n instantiates the connectivity pattern of group k, according to the blockmodel. In any given interaction, $Y(n,m)$, however, node n instantiates the connectivity pattern of a single group, $z_{n\to m}(k)$. (right). We did not draw all the arrows out of the block model B for clarity; all interactions depend on it.

In this paper, we develop mixed membership models for relational data.[1] Models in this family include parameters to reduce bias due to sparsity, and can be used to analyze multiple collections of paired measurements, and collections of non-binary and multivariate paired measurements. We develop a fast nested variational inference algorithm that performs well in the relational setting and is parallelizable. We demonstrate the application of our technique to large-scale protein interaction networks and social networks. Our model captures the multiple roles that objects exhibit in interaction with others, and the relationships between those roles in determining the observed interaction matrix.

Mixed membership and the latent block structure can be recovered from relational data (Section 4.1). The application to a friendship network among students tests the model on a real data set where a well-defined latent block structure exists (Section 4.2). The application to a protein interaction network tests to what extent our model can reduce the dimensionality of the data, while revealing substantive information about the functionality of proteins that can be used to inform subsequent analyses (Section 4.3).

2. The Mixed Membership Stochastic Blockmodel

In this section, we describe the modeling assumptions if the mixed membership model of relational data. We represent observed relational data as a graph $G = (\mathcal{N}, Y)$, where $Y(p,q)$ maps pairs of nodes to values, that is, edge weights. We consider binary matrices, where $Y(p,q) \in \{0,1\}$. The data can be thought of as a directed graph.

As a running example, we consider the monk data of Sampson (1968). Sampson measured a collection of sociometric relations among a group of monks by repeatedly asking questions such as "whom do you like?" and "whom do you dislike?" to determine asymmetric social relationships within the group. The questionnaire was repeated at four subsequent epochs. Information about these repeated, asymmetric relations was collapsed into a square binary table that encodes the directed connections between monks by Breiger et al. (1975). In analyzing this data, the goal is to determine the social structure within the monastery.

In the context of the monastery example, we assume K factions, that is, latent groups, exist in the monastery, and the observed network is generated according to distributions of group-membership for each monk and a matrix of group-group interaction strength. The per-monk distributions are specified by latent simplicial vectors. Each monk is associated with a randomly drawn vector $\vec{\pi}_i$ for monk i, where $\pi_{i,g}$ denotes the probability of monk i belonging to group g. That is, each monk can simultaneously belong to multiple groups with different degrees of affiliation strength. The probabilities of interactions between different groups are defined by a matrix of Bernoulli rates $B_{(K\times K)}$, where $B(g,h)$ represents the probability of having a link between a monk from group g and a monk from group h.

For each monk, the indicator vector $\vec{z}_{p\to q}$ denotes the group membership of monk p when he responds to survey questions about monk q and $\vec{z}_{p\leftarrow q}$ denotes the group membership of monk q when he responds to survey questions about node p.[2] N denotes the number of monks in the monastery, and recall that K denotes the number of distinct groups a monk can belong to.

More in general, monks can be represented by nodes in a graph, where directed (binary) edges represent positive responses to survey questions about a specific sociometric relation. In this abstract setting, the mixed membership stochastic blockmodel (MMB) posits that a graph $G = (\mathcal{N}, Y)$ is drawn from the following procedure.

- For each node $p \in \mathcal{N}$:
  - Draw a K dimensional mixed membership vector $\vec{\pi}_p \sim$ Dirichlet ($\vec{\alpha}$).
- For each pair of nodes $(p,q) \in \mathcal{N} \times \mathcal{N}$:
  - Draw membership indicator for the initiator, $\vec{z}_{p\to q} \sim$ Multinomial ($\vec{\pi}_p$).
  - Draw membership indicator for the receiver, $\vec{z}_{q\to p} \sim$ Multinomial ($\vec{\pi}_q$).
  - Sample the value of their interaction, $Y(p,q) \sim$ Bernoulli ($\vec{z}_{p\to q}^{\top} B\, \vec{z}_{p\leftarrow q}$).

1. In previous work we combined mixed membership and blockmodels to perform analyses of a single collection of binary, paired measurements; namely, hypothesis testing, predicting and de-noising interactions within an unsupervised learning setting (Airoldi et al., 2005).
2. An indicator vector is used to denote membership in one of the K groups. Such a membership-indicator vector is specified as a K-dimensional vector of which only one element equals to one, whose index corresponds to the group to be indicated, and all other elements equal to zero.

This process is illustrated as a graphical model in Figure 1. Note that the group membership of each node is *context dependent*. That is, each node may assume different membership when interacting to or being interacted by different peers. Statistically, each node is an admixture of group-specific interactions. The two sets of latent group indicators are denoted by $\{\vec{z}_{p\to q} : p,q \in \mathcal{N}\} =: Z_{\to}$ and $\{\vec{z}_{p\leftarrow q} : p,q \in \mathcal{N}\} =: Z_{\leftarrow}$. Also note that the pairs of group memberships that underlie interactions need not be equal; this fact is useful for characterizing asymmetric interaction networks. Equality may be enforced when modeling symmetric interactions.

Under the MMB, the joint probability of the data Y and the latent variables $\{\vec{\pi}_{1:N}, Z_{\to}, Z_{\leftarrow}\}$ can be written in the following factored form,

$$p(Y,\vec{\pi}_{1:N},Z_{\to},Z_{\leftarrow}|\vec{\alpha},B) = \prod_{p,q} P(Y(p,q)|\vec{z}_{p\to q},\vec{z}_{p\leftarrow q},B)P(\vec{z}_{p\to q}|\vec{\pi}_p)P(\vec{z}_{p\leftarrow q}|\vec{\pi}_q)\prod_p P(\vec{\pi}_p|\vec{\alpha}). \quad (1)$$

This model generalizes to two important cases. First, multiple networks among the same actors can be generated by the same latent vectors. This may be useful, for instance, to analyze multivariate sociometric relations. Second, in the MMB the data generating distribution is a Bernoulli, but B can be a matrix that parameterizes any kind of distribution. This may be useful, for instance, to analyze collections of paired measurements, Y, that take values in an arbitrary metric space. We elaborate on this in Section 5.

2.1 Modeling Sparsity

Adjacency matrices encoding binary pairwise measurements are often sparse, that is, they contain many zeros or non-interactions. It is useful to distinguish two sources of non-interaction: they may be the result of the rarity of interactions in general, or they may be an indication that the pair of relevant blocks rarely interact. In applications to social sciences, for instance, nodes may represent people and blocks may represent social communities. It is reasonable to expect that a large portion of the non-interactions is due to limited opportunities of contact between people rather than due to deliberate choices, the structure of which the blockmodel is trying to estimate. It is useful to account for these two sources of sparsity at the model level. A good estimate of the portion of zeros that should not be explained by the blockmodel B reduces the bias of the estimates of its elements.

Thus, we introduce a sparsity parameter $\rho \in [0,1]$ in the MMB to characterize the source of non-interaction. Instead of sampling a relation $Y(p.q)$ directly the Bernoulli with parameter specified as above, we down-weight the probability of successful interaction to $(1-\rho)\cdot \vec{z}_{p\to q}^{\top} B\, \vec{z}_{p\leftarrow q}$. This is the result of assuming that the probability of a non-interaction comes from a mixture, $1-\sigma_{pq} = (1-\rho)\cdot \vec{z}_{p\to q}^{\top}(1-B)\, \vec{z}_{p\leftarrow q} + \rho$, where the weight ρ capture the portion zeros that should not be explained by the blockmodel B. A large value of ρ will cause the interactions in the matrix to be weighted more than non-interactions, in determining plausible values for $\{\vec{\alpha}, B, \vec{\pi}_{1:N}\}$.

The sparsity parameter ρ can be estimated. Its maximum likelihood estimate provides the best data-driven guess about the proportion of zeros that the blockmodel can explain. Introducing ρ provides a strategy to rescale B, by separating zeros in the adjacency matrix into those that are likely to be due to the blockmodel and those that are not.

2.2 Summarizing and De-Noising Pairwise Measurements

It is useful to distinguish two types of data analysis that can be performed with the mixed-membership blockmodel. First, MMB can be used to summarize the data, Y, in terms of the global blockmodel, B, and the node-specific mixed memberships, Πs. Second, MMB can be used to de-noise the data, Y, in terms of the global blockmodel, B, and interaction-specific single memberships, Zs. In both cases the model depends on a small set of unknown constants to be estimated: α, and B. The likelihood is the same in both cases, although, the rationale for including the set of latent variables Zs differs. When summarizing data, we could integrate out the Zs analytically; this leads to numerical optimization of a smaller set of variational parameters, Γs. We choose to keep the Zs to simplify inference. When de-noising, the Zs are instrumental in estimating posterior expectations of each interactions individually—a network analog to the Kalman Filter. The posterior expectations of an interaction is computed as follows, in the two cases,

$$\mathbb{E}\,[\,Y(p,q)=1\,] \approx \widehat{\vec{\pi}}_p{}' \widehat{B}\, \widehat{\vec{\pi}}_q \qquad \text{and} \qquad \mathbb{E}\,[\,Y(p,q)=1\,] \approx \widehat{\vec{\phi}}_{p\to q}{}' \widehat{B}\, \widehat{\vec{\phi}}_{p\leftarrow q}.$$

2.3 An Illustration: Crisis in a Cloister

To illustrate the MMB, we return to an analysis of the monk data described above. Sampson (1968) surveyed 18 novice monks in a monastery and asked them to rank the other novices in terms of four sociometric relations: like/dislike, esteem, personal influence, and alignment with the monastic credo. We consider Breiger's collation of Sampson's data (Breiger et al., 1975). The original graph of monk-monk interaction is illustrated in Figure 2 (left).

Sampson spent several months in a monastery in New England, where novice monks were preparing to join a monastic order. Sampson's original analysis was rooted in direct anthropological observations. He suggested the existence of tight factions among the novices: the loyal opposition (whose members joined the monastery first), the young turks (who joined later on), the outcasts (who were not accepted in the two main factions), and the waverers (who did not take sides). The events that took place during Sampson's stay at the monastery supported his observations—members of the young turks resigned or were expelled over religious differences (John and Gregory). We shall

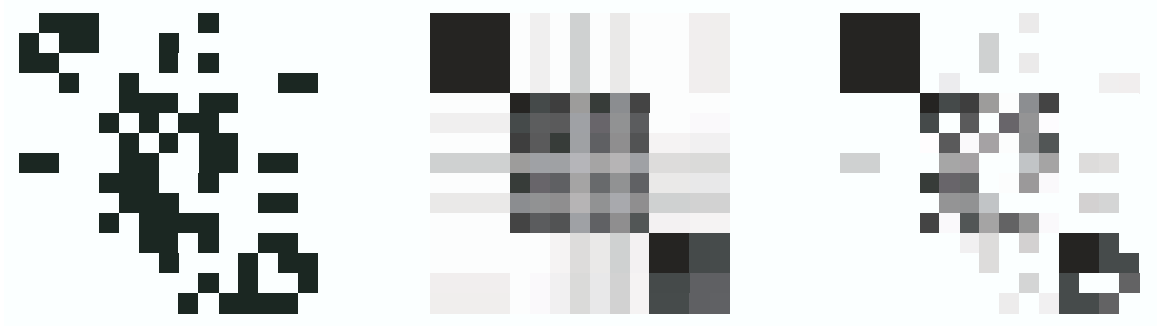

Figure 2: Original adjacency matrix of whom-do-like sociometric relations (left), relations predicted using approximate MLEs for $\vec{\pi}_{1:N}$ and B (center), and relations de-noised using the model including Zs indicators (right).

refer to the labels assigned by Sampson to the novices in the analysis below. For more analyses, we refer to Fienberg et al. (1985), Davis and Carley (2006) and Handcock et al. (2007).

Using the algorithms presented in Section 3, we fit the monks to MMB models for different numbers of groups, providing model estimates $\{\hat{\alpha}, \hat{B}\}$ and posterior mixed membership vectors $\vec{\pi}_n$ for each monk. Here, we use the following approximation to BIC to choose the number of groups in the MMB:

$$BIC = 2 \cdot \log p(Y) \approx 2 \cdot \log p(Y|\widehat{\vec{\pi}}, \widehat{Z}, \widehat{\vec{\alpha}}, \widehat{B}) - |\vec{\alpha}, B| \cdot \log |Y|,$$

which selects three groups, where $|\vec{\alpha}, B|$ is the number of hyper-parameters in the model, and $|Y|$ is the number of positive relations observed (Volinsky and Raftery, 2000; Handcock et al., 2007). Note that this is the same number of groups that Sampson identified. We illustrate the fit of model fit via the predicted network in Figure 2 (Right). The three panels contrast the different resolution of the original adjacency matrix of whom-do-like sociometric relations (left panel) obtained in different uses of MMB. If the goal of the analysis if to find a parsimonious summary of the data, the amount of relational information that is captured by in $\hat{\alpha}, \hat{B}$, and $\mathbb{E}[\vec{\pi}|Y]$ leads to a coarse reconstruction of the original sociomatrix (central panel). If the goal of the analysis if to de-noising a collection of pairwise measurements, the amount of relational information that is revealed by $\hat{\alpha}, \hat{B}, \mathbb{E}[\vec{\pi}|Y]$ and $\mathbb{E}[Z_{\rightarrow}, Z_{\leftarrow}|Y]$ leads to a finer reconstruction of the original sociomatrix, Y—relations in Y are re-weighted according to how much they *make sense* to the model (right panel).

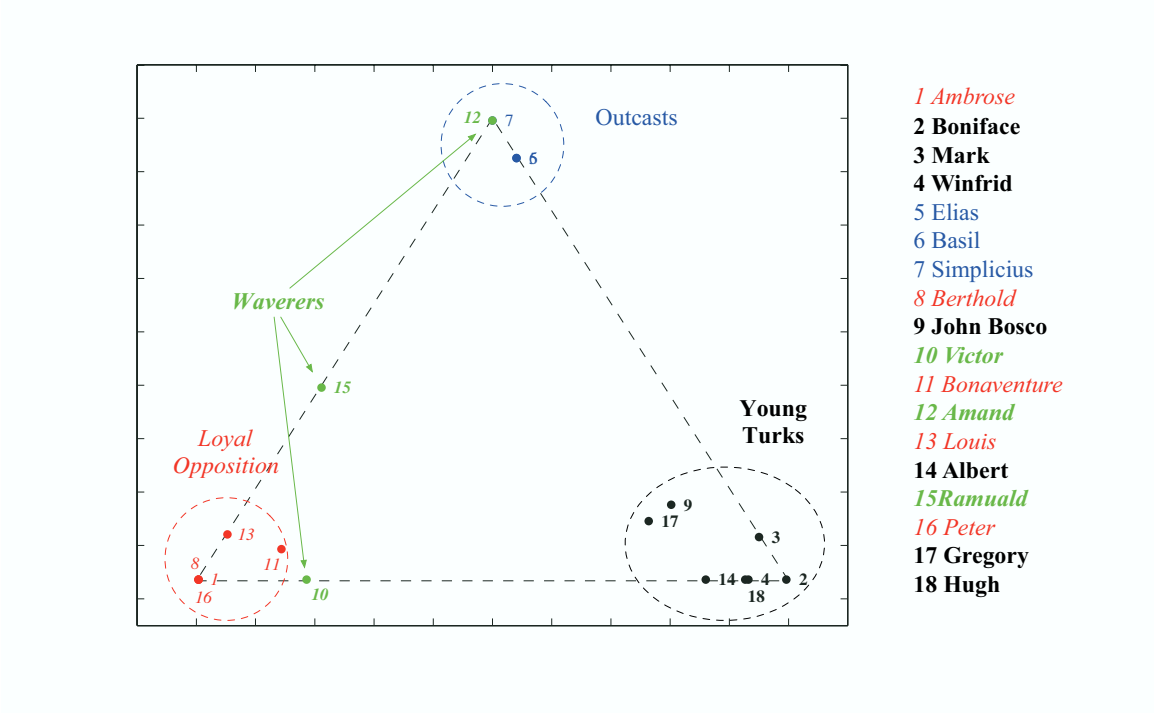

Figure 3: Posterior mixed membership vectors, $\vec{\pi}_{1:18}$, projected in the simplex. Numbered points can be mapped to monks' names using the legend on the right. The colors identify the four factions defined by Sampson's anthropological observations.

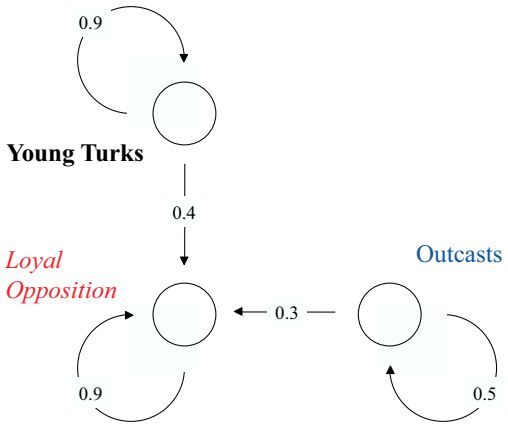

Figure 4: Estimated blockmodel in the monk data, $\hat{B}$.

The MMB provides interesting descriptive statistics about the actors in the observed graph. In Figure 3 we illustrate the the posterior means of the mixed membership scores, $\mathbb{E}[\vec{\pi}|Y]$, for the 18 monks in the monastery. Note that the monks cluster according to Sampson's classification, with Young Turks, Loyal Opposition, and Outcasts dominating each corner respectively. We can see the central role played by John Bosco and Gregory, who exhibit relations in all three groups, as well as the uncertain affiliations of Ramuald and Victor. (Amand's uncertain affiliation, however, is not captured.) The estimated blockmodel is shown in Figure 4.

3. Parameter Estimation and Posterior Inference

Two computational problems are central to the MMB: posterior inference of the per-node mixed membership vectors and per-pair roles, and parameter estimation of the Dirichlet parameters and Bernoulli rate matrix. We derive empirical Bayes estimates of the parameters $(\vec{\alpha}, B)$, and employ a mean-field approximation scheme for posterior inference.

3.1 Posterior Inference

The posterior inference problem is to compute the posterior distribution of the latent variables given a collection of observations. The normalizing constant of the posterior distribution is the marginal probability of the data, which requires an integral over the simplicial vectors $\vec{\pi}_p$,

$$p(Y|\vec{\alpha}, B) = \int_{\Pi} \sum_{Zs} \left(\prod_{p,q} P(Y(p,q)|\vec{z}_{p\to q}, \vec{z}_{p\leftarrow q}, B) P(\vec{z}_{p\to q}|\vec{\pi}_p) P(\vec{z}_{p\leftarrow q}|\vec{\pi}_q) \prod_{p} P(\vec{\pi}_p|\vec{\alpha}) \right) d\vec{\pi},$$

which is not solvable in closed form (Blei et al., 2003). A number of approximate inference algorithms for mixed membership models have appeared in recent years, including mean-field variational methods (Blei et al., 2003; Teh et al., 2007), expectation propagation (Minka and Lafferty, 2002), and Monte Carlo Markov chain sampling (MCMC) (Erosheva and Fienberg, 2005; Griffiths and Steyvers, 2004).

We appeal to variational methods (Jordan et al., 1999; Wainwright and Jordan, 2003). The main idea behind variational methods is to first posit a distribution of the latent variables with free parameters, and then fit those parameters such that the distribution is close in Kullback-Leibler divergence to the true posterior. The variational distribution is simpler than the true posterior so that the optimization problem can be approximately solved. Good reviews of variational methods can be found in Wainwright and Jordan (2003), Xing et al. (2003), Bishop et al. (2003) and Airoldi (2007).

In the MMB, we begin by bounding the log of the marginal probability of the data with Jensen's inequality,

$$\log p(Y \mid \alpha, B) \geq \mathbb{E}_q \left[\log p(Y, \vec{\pi}_{1:N}, Z_{\rightarrow}, Z_{\leftarrow} | \alpha, B) \right] - \mathbb{E}_q \left[\log q(\vec{\pi}_{1:N}, Z_{\rightarrow}, Z_{\leftarrow}) \right].$$

We have introduced a distribution of the latent variables q that depends on a set of free parameters. We specify q as the mean-field fully-factorized family,

$$q(\vec{\pi}_{1:N}, Z_{\rightarrow}, Z_{\leftarrow} | \vec{\gamma}_{1:N}, \Phi_{\rightarrow}, \Phi_{\leftarrow}) = \prod_p q_1(\vec{\pi}_p | \vec{\gamma}_p) \prod_{p,q} \left(q_2(\vec{z}_{p \rightarrow q} | \vec{\phi}_{p \rightarrow q}) \, q_2(\vec{z}_{p \leftarrow q} | \vec{\phi}_{p \leftarrow q}) \right),$$

where q_1 is a Dirichlet, q_2 is a multinomial, and $\{\vec{\gamma}_{1:N}, \Phi_{\rightarrow}, \Phi_{\leftarrow}\}$ are the set of free *variational parameters* that are optimized to tighten the bound.

Tightening the bound with respect to the variational parameters is equivalent to minimizing the KL divergence between q and the true posterior. When all the nodes in the graphical model are conjugate pairs or mixtures of conjugate pairs, we can directly write down a coordinate ascent algorithm for this optimization to reach a local maximum of the bound. The updates for the variational multinomial parameters are

$$\hat{\phi}_{p \rightarrow q, g} \propto e^{\mathbb{E}_q[\log \pi_{p,g}]} \cdot \prod_h \left(B(g,h)^{Y(p,q)} \cdot (1 - B(g,h))^{1 - Y(p,q)} \right)^{\phi_{p \leftarrow q, h}} \tag{2}$$

$$\hat{\phi}_{p \leftarrow q, h} \propto e^{\mathbb{E}_q[\log \pi_{q,h}]} \cdot \prod_g \left(B(g,h)^{Y(p,q)} \cdot (1 - B(g,h))^{1 - Y(p,q)} \right)^{\phi_{p \rightarrow q, g}}, \tag{3}$$

for $g, h = 1, \ldots, K$. The update for the variational Dirichlet parameters $\gamma_{p,k}$ is

$$\hat{\gamma}_{p,k} = \alpha_k + \sum_q \phi_{p \rightarrow q, k} + \sum_q \phi_{p \leftarrow q, k}, \tag{4}$$

for all nodes $p = 1, \ldots, N$ and $k = 1, \ldots, K$. The complete coordinate ascent algorithm is described in Figure 5.

To improve convergence, we employed a nested variational inference scheme based on an alternative schedule of updates to the traditional ordering. In a typical schedule for coordinate ascent (which we call "naïve variational inference"), one initializes the variational Dirichlet parameters $\vec{\gamma}_{1:N}$ and the variational multinomial parameters $(\vec{\phi}_{p \rightarrow q}, \vec{\phi}_{p \leftarrow q})$ to non-informative values, and then iterates the following two steps until convergence: (i) update $\vec{\phi}_{p \rightarrow q}$ and $\phi_{p \leftarrow q}$ for all edges (p,q), and (ii) update $\vec{\gamma}_p$ for all nodes $p \in \mathcal{N}$. In such algorithm, at each variational inference cycle we need to allocate $NK + 2N^2K$ scalars.

In our experiments, the naïve variational algorithm often converged only after many iterations. We attribute this behavior to the dependence between $\vec{\gamma}_{1:N}$ and B, which is not satisfied by the naïve algorithm. Some intuition about why this may happen follows. From a purely algorithmic

1. initialize $\vec{\gamma}^0_{pk} = \frac{2N}{K}$ for all p,k
2. **repeat**
3. **for** $p = 1$ to N
4. **for** $q = 1$ to N
5. get **variational** $\vec{\phi}^{t+1}_{p\to q}$ and $\vec{\phi}^{t+1}_{p\leftarrow q} = f\ (\ Y(p,q), \vec{\gamma}^t_p, \vec{\gamma}^t_q, B^t\ )$
6. partially update $\vec{\gamma}^{t+1}_p$, $\vec{\gamma}^{t+1}_q$ and B^{t+1}
7. **until** convergence

5.1. initialize $\phi^0_{p\to q,g} = \phi^0_{p\leftarrow q,h} = \frac{1}{K}$ for all g,h
5.2. **repeat**
5.3. **for** $g = 1$ to K
5.4. update $\phi^{s+1}_{p\to q} \propto f_1\ (\ \vec{\phi}^s_{p\leftarrow q}, \vec{\gamma}_p, B\ )$
5.5. normalize $\vec{\phi}^{s+1}_{p\to q}$ to sum to 1
5.6. **for** $h = 1$ to K
5.7. update $\phi^{s+1}_{p\leftarrow q} \propto f_2\ (\ \vec{\phi}^s_{p\to q}, \vec{\gamma}_q, B\ )$
5.8. normalize $\vec{\phi}^{s+1}_{p\leftarrow q}$ to sum to 1
5.9. **until** convergence

Figure 5: **Top:** The two-layered variational inference for $(\vec{\gamma}, \phi_{p\to q,g}, \phi_{p\leftarrow q,h})$ and $M = 1$. The inner algorithm consists of Step 5. The function f is described in details in the bottom panel. The partial updates in Step 6 for $\vec{\gamma}$ and B refer to Equation 4 of Section B.4 and Equation 5 of Section B.5, respectively. **Bottom:** Inference for the variational parameters $(\vec{\phi}_{p\to q}, \vec{\phi}_{p\leftarrow q})$ corresponding to the basic observation $Y(p,q)$. This nested algorithm details Step 5 in the top panel. The functions f_1 and f_2 are the updates for $\phi_{p\to q,g}$ and $\phi_{p\leftarrow q,h}$ described in Equations 2 and 3 of Section B.4.

perspective, the naïve variational EM algorithm instantiates a large coordinate ascent algorithm, where the parameters can be divided into blocks. Blocks are processed in a specific order, and the parameters within each block get all updated each time.[3] At every new iteration the naïve algorithm sets all the elements of $\vec{\gamma}^{t+1}_{1:N}$ equal to the same constant. This dampens the likelihood by suddenly breaking the dependence between the estimates of parameters in $\hat{\vec{\gamma}}^t_{1:N}$ and in $\hat{B}^t$ that was being inferred from the data during the previous iteration.

Instead, the nested variational inference algorithm maintains some of this dependence that is being inferred from the data across the various iterations. This is achieved mainly through a different

3. Within a block, the order according to which (scalar) parameters get updated is not expected to affect convergence.

scheduling of the parameter updates in the various blocks. To a minor extent, the dependence is maintained by always keeping the block of free parameters, $(\vec{\phi}_{p\to q}, \vec{\phi}_{p\leftarrow q})$, optimized given the other variational parameters. Note that these parameters are involved in the updates of parameters in $\vec{\gamma}_{1:N}$ and in B, thus providing us with a channel to maintain some of the dependence among them, that is, by keeping them at their optimal value given the data.

Furthermore, the nested algorithm has the advantage that it trades time for space thus allowing us to deal with large graphs; at each variational cycle we need to allocate $NK+2K$ scalars only. The increased running time is partially offset by the fact that the algorithm can be parallelized and leads to empirically observed faster convergence rates.

An alternative strategy to perform inference is given by Monte Carlo Markov chain (e.g., see Griffiths and Steyvers, 2004; Kemp et al., 2004). While powerful in some settings, MCMC is impractical here. There are too many variables to sample. The proposed nested variational EM algorithm outperforms MCMC variations (i.e., blocked and collapsed Gibbs samplers) in terms of memory requirements and convergence rates.

3.2 Parameter Estimation

We compute the empirical Bayes estimates of the model hyper-parameters $\{\vec{\alpha}, B\}$ with a variational expectation-maximization (EM) algorithm. Alternatives to empirical Bayes have been proposed to fix the hyper-parameters and reduce the computation. The results, however, are not always satisfactory and often times cause of concern, since the inference is sensitive to the choice of the hyper-parameters (Joutard et al., 2007). Empirical Bayes, on the other hand, guides the posterior inference towards a region of the hyper-parameter space that is supported by the data.

Variational EM uses the lower bound in Equation 5 as a surrogate for the likelihood. To find a local optimum of the bound, we iterate between fitting the variational distribution q to approximate the posterior and maximizing the corresponding bound with respect to the parameters. The latter M-step is equivalent to finding the MLE using expected sufficient statistics under the variational distribution. We consider the maximization step for each parameter in turn.

A closed form solution for the approximate maximum likelihood estimate of $\vec{\alpha}$ does not exist (Minka, 2003). We use a linear-time Newton-Raphson method, where the gradient and Hessian are

$$\begin{aligned}
\frac{\partial \mathcal{L}_{\vec{\alpha}}}{\partial \alpha_k} &= N\left(\psi\left(\sum_k \alpha_k\right) - \psi(\alpha_k)\right) + \sum_p \left(\psi(\gamma_{p,k}) - \psi\left(\sum_k \gamma_{p,k}\right)\right), \\
\frac{\partial \mathcal{L}_{\vec{\alpha}}}{\partial \alpha_{k_1}\alpha_{k_2}} &= N\left(\mathbb{I}_{(k_1=k_2)} \cdot \psi'(\alpha_{k_1}) - \psi'\left(\sum_k \alpha_k\right)\right).
\end{aligned}$$

The approximate MLE of B is

$$\hat{B}(g,h) = \frac{\sum_{p,q} Y(p,q) \cdot \phi_{p\to qg}\, \phi_{p\leftarrow qh}}{(1-\rho) \cdot \sum_{p,q} \phi_{p\to qg}\, \phi_{p\leftarrow qh}},$$

for every index pair $(g,h) \in [1,K] \times [1,K]$. Finally, the approximate MLE of the sparsity parameter ρ is

$$\hat{\rho} = \frac{\sum_{p,q} \left(1 - Y(p,q)\right) \cdot \left(\sum_{g,h} \phi_{p\to qg}\, \phi_{p\leftarrow qh}\right)}{\sum_{p,q} \sum_{g,h} \phi_{p\to qg}\, \phi_{p\leftarrow qh}}.$$

Alternatively, we can fix ρ prior to the analysis; the density of the interaction matrix is estimated with $\hat{d} = \sum_{p,q} Y(p,q)/N^2$, and the sparsity parameter is set to $\tilde{\rho} = (1 - \hat{d})$. This latter estimator attributes all the information in the non-interactions to the point mass, that is, to latent sources other than the block model B or the mixed membership vectors $\vec{\pi}_{1:N}$. It does however provide a quick recipe to reduce the computational burden during exploratory analyses.[4]

Several model selection strategies are available for complex hierarchical models (Joutard et al., 2007). In our setting, model selection translates into the determination of a plausible value of the number of groups K. In the various analyses presented, we selected the optimal value of K according to two strategies. On large networks, we selected K corresponding to the highest averaged held-out likelihood in a cross-validation experiment. On small networks—where cross-validation cannot be expected to work well, as we discuss in Section 5—we selected K using an approximation to BIC.

4. Experiments and Results

We present a study of simulated data and applications to social and protein interaction networks.

Simulations are performed in Section 4.1 to show that both mixed membership, $\vec{\pi}_{1:N}$, and the latent block structure, B, can be recovered from data, when they exist, and that the nested variational inference algorithm is faster than the naïve implementation while reaching the same peak in the likelihood—all other things being equal.

The application to a friendship network among students in Section 4.2 tests the model on a real data set where we expect a well-defined latent block structure to inform the observed connectivity patterns in the network. In this application, the blocks are interpretable in terms of grades. We compare our results with those that were recently obtained with a simple mixture of blocks (Doreian et al., 2007) and with a latent space model (Handcock et al., 2007) on the same data.

The application to a protein interaction network in Section 4.3 tests the model on a real data set where we expect a noisy, vague latent block structure to inform the observed connectivity patterns in the network to some degree. In this application, the blocks are interpretable in terms functional biological contexts. This application tests to what extent our model can reduce the dimensionality of the data, while revealing substantive information about the functionality of proteins that can be used to inform subsequent analyses.

4.1 Exploring Expected Model Behavior with Simulations

In developing the MMB and the corresponding computation, our hope is the the model can recover both the mixed membership of nodes to clusters and the latent block structure among clusters in situations where a block structure exists and the relations are measured with some error. To substantiate this claim, we sampled graphs of $100, 300,$ and 600 nodes from blockmodels with $4, 10,$ and 20 clusters, respectively, using the MMB. We used different values of α to simulate a range of settings in terms of membership of nodes to clusters—from unique $(\alpha = 0.05)$ to mixed $(\alpha = 0.25)$.

Recovering the truth. The variational EM algorithm successfully recovers both the latent block model B and the latent mixed membership vectors $\vec{\pi}_{1:N}$. In Figure 6 we show the adjacency matrices of binary interactions where rows, that is, nodes, are reordered according to their most likely membership. The estimated reordering reveals the block model that was originally used to simulate

4. Note that $\tilde{\rho} = \hat{\rho}$ in the case of single membership. In fact, that implies $\phi^m_{p \to qg} = \phi^m_{p \leftarrow qh} = 1$ for some (g,h) pair, for any (p,q) pair.

the interactions. As α increases, each node is likely to belong to more clusters. As a consequence, they express interaction patterns of clusters. This phenomenon reflects in the reordered interaction matrices as the block structure is less evident.

Nested variational inference. The nested variational algorithm drives the log-likelihood to converge faster to its peak than the naïve algorithm. In Figure 7 (left panel) we compare the running times of the nested variational-EM algorithm versus the naïve implementation. The nested algorithm, which is more efficient in terms of space, converged faster. Furthermore, the nested variational algorithm can be parallelized given that the updates for each interaction (i, j) are independent of one another.

Choosing the number of blocks. The right panel of Figure 7 shows an example where cross-validation is sufficient to perform model selection for the MMB. The example shown corresponds to a network among 300 nodes with $K = 10$ clusters. We measure the number of latent clusters

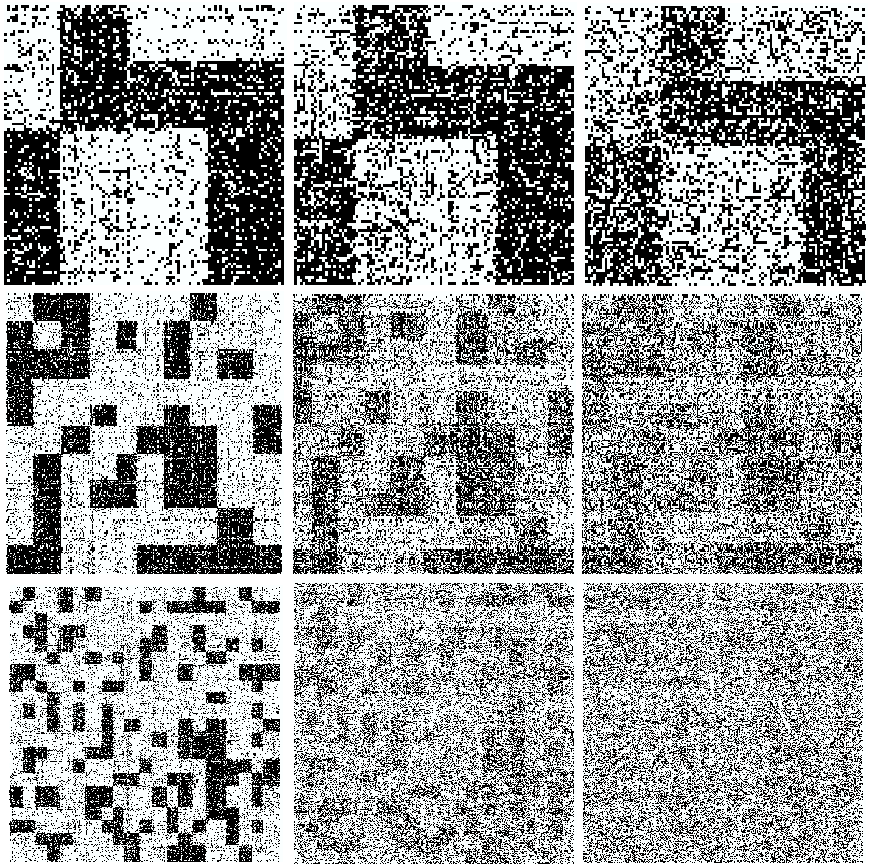

Figure 6: Adjacency matrices of corresponding to simulated interaction graphs with 100 nodes and 4 clusters, 300 nodes and 10 clusters, 600 nodes and 20 clusters (top to bottom) and α equal to $0.05, 0.1$ and 0.25 (left to right). Rows, which corresponds to nodes, are reordered according to their most likely membership. The estimated reordering accurately reveals the original blockmodel.

on the X axis and the average held-out log-likelihood, corresponding to five-fold cross-validation experiments, on the Y axis. The nested variational EM algorithm was xrun until convergence, for each value of K we tested, with a tolerance of $\varepsilon = 10^{-5}$. Our estimate for K occurs at the peak in the average held-out log-likelihood, and equals the correct number of clusters, $K^* = 10$

4.2 Application to Social Network Analysis

We considered a friendship network among a group of 69 students in grades 7–12. The analysis here directly compares clustering results obtained by MMB to published clustering results obtained by competing models, in a setting where a fair amount of social segregation is expected (Doreian et al., 2007; Handcock et al., 2007).

The National Longitudinal Study of Adolescent Health is nationally representative study that explores the how social contexts such as families, friends, peers, schools, neighborhoods, and communities influence health and risk behaviors of adolescents, and their outcomes in young adulthood (Harris et al., 2003; Udry, 2003). As part of the survey, a questionnaire was administered to a sample of students in each school, who were allowed to nominate up to 10 friends. We analyzed a friendship network among the students, at the same school that was considered by Handcock et al. (2007) and discussants. Friendship nominations were collected among 71 students in grades 7 to 12; two students did not nominate any friends. The network of binary, asymmetric friendship relations among the remaining 69 students that constitutes our data is shown in Figure 9 (left).

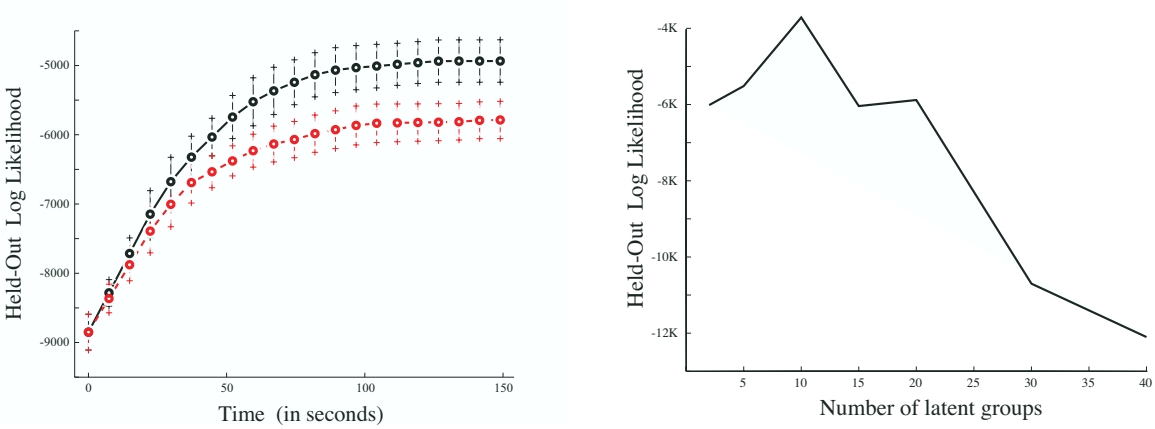

Figure 7: **Left:** The running time of the naïve variational inference (dashed, red line) against the running time of our enhanced (nested) variational inference algorithm (solid, black line), on a graph with 100 nodes and 4 clusters. We measure the number of seconds on the X axis and the log-likelihood on the Y axis. The two curves are averages over 26 experiments, and the error bars are at three standard deviations. Each of the 26 pairs of experiments was initialized with the same values for the parameters. **Right:** The held-out log-likelihood is indicative of the true number of latent clusters, on simulated data. We measure the number of latent clusters on the X axis and the log-likelihood on a test set on the Y axis. In the example shown, the peak identifies the correct number of clusters, $K^* = 10$

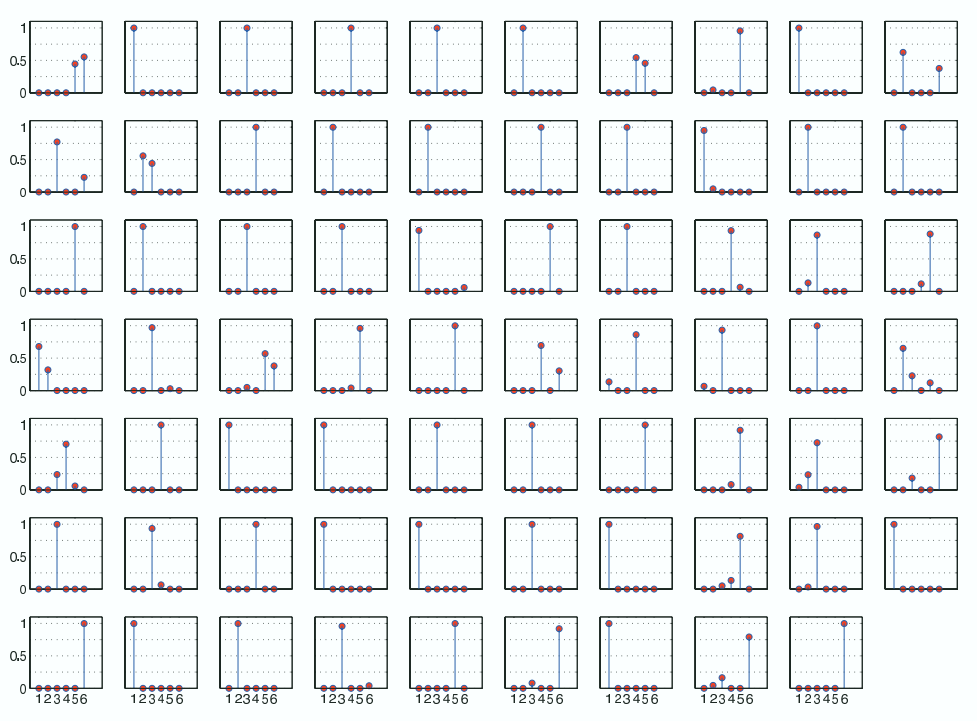

Figure 8: The posterior mixed membership scores, $\vec{\pi}$, for the 69 students. Each panel correspond to a student; we order the clusters 1 to 6 on the X axis, and we measure the student's grade of membership to these clusters on the Y axis.

Given the size of the network we used BIC to perform model selection, as in the monks example of Section 2.3. The results suggest a model with $K^* = 6$ groups. (We fix $K^* = 6$ in the analyses that follow.) The hyper-parameters estimated with the nested variational EM. They are $\hat{\alpha} = 0.0487$, $\hat{\rho} = 0.936$, and a fairly diagonal blockmodel,

$$\hat{B} = \begin{bmatrix} 0.3235 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \\ 0.0 & 0.3614 & 0.0002 & 0.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.2607 & 0.0 & 0.0 & 0.0002 \\ 0.0 & 0.0 & 0.0 & 0.3751 & 0.0009 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0002 & 0.3795 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.3719 \end{bmatrix}.$$

Figure 8 shows the expected posterior mixed membership scores for the 69 students in the sample; few students display mixed membership. The rarity of mixed membership in this context is expected, while mixed membership may signal unexpected social situations for further investigation. For instance, it may signal a family bond such as brotherhood, or a student that is repeating a grade and is thus part of a broader social clique. In Figure 9, we contrast the friendship relation data (left) to the estimates obtained by thresholding the estimated probabilities of a relation, using the blockmodel and the node-specific latent variables (center) and the interactions-specific latent variables (right). The model provides a good summary of the social structure in the school; students

tend to befriend other students in the same grade, with a few exceptions. The low degree of mixed membership explains the absence of obvious differences between the model-based reconstructions of the friendship relations with the two model variants (center and right).

Figure 9: Original matrix of friensdhip relations among 69 students in grades 7 to 12 (left), and friendship estimated relations obtained by thresholding the posterior expectations $\vec{\pi}_p{}' B \vec{\pi}_q | Y$ (center), and $\vec{\phi}_p{}' B \vec{\phi}_q | Y$ (right).

Next, we attempted a quantitative evaluation of the goodness of fit. In this data, the blocks are clearly interpretable a-posteriori in terms of grades. The mixed membership vectors provide a mapping between grades and blocks. Conditionally on such a mapping, we assign students to the grade they are most associated with, according to their posterior-mean mixed membership vectors, $\mathbb{E}[\vec{\pi}_n | Y]$. To be fair in the comparison with competing models, we assign students to a unique grade—despite MMB allows for mixed membership. Table 1 computes the correspondence of grades to blocks by quoting the number of students in each grade-block pair, for MMB versus the mixture blockmodel (MB) in Doreian et al. (2007), and the latent space cluster model (LSCM) in Handcock et al. (2007). The higher the sum of counts on diagonal elements is the better is the correspondence, while the higher the sum of counts off diagonal elements is the worse is the correspondence. MMB performs best by allocating 63 students to their grades, versus 57 of MB, and 37 of LSCM. Correspondence only partially captures goodness of fit, however, it is a good metric in the setting we consider, where a fair amount of clustering is present. The results suggest that the extra-flexibility MMB offers over MB and LSCM reduces bias in the prediction of the membership of students to blocks. In other words, mixed membership does not absorb noise in this example; rather it accommodates variability in the friendship relation that is instrumental in producing better predictions.

Concluding this example, we note how the model decouples the observed friendship patterns into two complementary sources of variability. On the one hand, the connectivity matrix B is a global, unconstrained set of hyper-parameters. On the other hand, the mixed membership vectors $\vec{\pi}_{1:N}$ provide a collection of node-specific latent vectors, which inform the directed connections in the graph in a symmetric fashion.

4.3 Application to Protein Interactions in *Saccharomyces Cerevisiae*

We considered physical interactions among 871 proteins in yeast. The analysis allows us to evaluate the utility of MMB in summarizing and de-noising complex connectivity patterns quantitatively, using an independent set of functional annotations. For instance, between two models that sug-

	MMB Clusters						MSB Clusters						LSCM Clusters					
Grade	1	2	3	4	5	6	1	2	3	4	5	6	1	2	3	4	5	6
7	13	1	0	0	0	0	13	1	0	0	0	0	13	1	0	0	0	0
8	0	9	2	0	0	1	0	10	2	0	0	0	0	11	1	0	0	0
9	0	0	16	0	0	0	0	0	10	0	0	6	0	0	7	6	3	0
10	0	0	0	10	0	0	0	0	0	10	0	0	0	0	0	0	3	7
11	0	0	1	0	11	1	0	0	1	0	11	1	0	0	0	0	3	10
12	0	0	0	0	0	4	0	0	0	0	0	4	0	0	0	0	0	4

Table 1: Grade levels versus (highest) expected posterior membership for the 69 students, according to three alternative models. MMB is the proposed mixed membership stochastic blockmodel, MSB is a simpler stochastic block mixture model (Doreian et al., 2007), and LSCM is the latent space cluster model (Handcock et al., 2007).

gest different sets of interactions as reliable, we prefer the model that reveals *functionally relevant* interactions—as measured using the annotations.

Protein interactions (PPI) form the physical basis for the formation of stable protein complexes (i.e., protein clusters) and signaling pathways (i.e., cascades of protein interaction events) that carry out all major biological processes in the cell. A number of high-throughput experimental technologies have been devised to determine the set of interacting proteins on a global scale in yeast. These include two-hybrid (Y2H) screens and mass spectrometry methods (Gavin et al., 2002; Ho et al., 2002; Krogan et al., 2006). High-throughput technologies, however, often miss to identify interactions that are not present under the given conditions. Specific wet-lab methods employed by a certain technology, such as tagging, may disturb the formation of a stable protein complex, and weakly associated components may dissociate and escape detection. Statistical models that encode information about functional processes with high precision are an essential tool for carrying out probabilistic de-noising of biological signals from high-throughput experiments.

The goal of the analysis of protein interactions with MMB is to reveal the proteins' diverse functional roles by analyzing their local and global patterns of interaction. The biochemical composition of individual proteins make them suitable for carrying out a specific set of cellular operations, or *functions*. The main intuition behind our methodology is that pairs of protein interact because they participate in the same cellular process, as part of the same stable protein complex, that is, co-location, or because they are part of interacting protein complexes, as they carry out compatible cellular operations (Alberts et al., 2002). Below, we describe the MIPS protein interactions data and the possible interpretations of the blocks in MMB in terms of biological functions, and we report results of two experiments.

4.3.1 PROTEIN INTERACTION DATA AND FUNCTIONAL ANNOTATION DATA

The Munich Institute for Protein Sequencing (MIPS) database was created in 1998 based on evidence derived from a variety of experimental techniques (Mewes et al., 2004). It includes a hand-curated collection of protein interactions that does not include interactions obtained with high-throughput technologies. The collection covers about 8000 protein complex associations in yeast.

We analyzed a subset of this collection containing 871 proteins, the interactions amongst which were hand-curated.

The MIPS institute also provides a set of functional annotations for each protein. These annotations are organized in a tree, with 15 nodes (i.e., high-level functions) at the first level, 72 nodes (i.e., the mid-level functions) at the second level, and 255 nodes (i.e., the low-level functions) at the the leaf level. We mapped the 871 proteins in our collections to the high-level functions of the MIPS annotation tree. Table 2 quotes the number of proteins annotated to each of these 15 functions. Most proteins participate in more than one functional category, with an average of ≈ 2.4 functional annotations for each protein.. The relative importance of functional categories in our collection, in terms of the number of proteins involved, is similar to the relative importance of functional categories over the entire MIPS collection. We can also represent each protein in terms of its MIPS functional annotations. This leads to a 15-dimensional, binary representation for each protein, $\vec{b}_p$, where a component $\vec{b}_p(k) = 1$ indicates that protein p is annotated with function k in Table 2. Figure 10 shows the binary representations, $\vec{b}_{1:871}$, of the proteins in our collections; each panel corresponds to a protein; the 15 functional categories are ordered as in Table 2 on the X axis, whereas the presence or absence of the corresponding functional annotation is displayed on the Y axis. In Section 4.3.2, we fit a mixed membership blockmodel with $K = 15$, and we explore the direct correspondence between protein-specific mixed memberships to blocks, $\vec{\pi}_{1:871}$, and MIPS-derived functional annotations, $\vec{b}_{1:871}$.

An alternative source of functional annotations is the gene ontology (GO), distributed as part of the Saccharomyces genome database (Ashburner et al., 2000). GO provides vocabularies for describing the molecular function, biological process, and cellular component of gene products—such as proteins. Terms are organized in a directed acyclic graph. Terms at the top represent broader, more general concepts, terms lower down represent more specific concepts. There are two different relationship types between (parent-child) terms: "is a" and "part of". Proteins are annotated to terms, and, most importantly, a protein is typically annotated to multiple terms, in different portions of the GO annotation graph. We restrict our evaluations to a collection of GO terms that is specific enough for a co-annotation (i.e., two proteins annotated to the same term) to be functionally relevant to molecular biologists (Myers et al., 2006). In Section 4.3.3, we select the mixed membership blockmodel best for predicting out-of-sample interactions, corresponding to

#	Category	Count	#	Category	Count
1	Metabolism	125	9	Interaction w/ cell. environment	18
2	Energy	56	10	Cellular regulation	37
3	Cell cycle & DNA processing	162	11	Cellular other	78
4	Transcription (tRNA)	258	12	Control of cell organization	36
5	Protein synthesis	220	13	Sub-cellular activities	789
6	Protein fate	170	14	Protein regulators	1
7	Cellular transportation	122	15	Transport facilitation	41
8	Cell rescue, defence & virulence	6			

Table 2: The 15 high-level functional categories obtained by cutting the MIPS annotation tree at the first level and how many proteins (out of 871) participate in each.

$K^* = 50$, and we explore its goodness-of-fit indirectly—rather than attempting a direct interpretation of the model's parameters—, in terms of the number of predicted interactions that are functionally relevant according to GO functional annotations.

4.3.2 DIRECT EVALUATION: THE MODEL CAPTURES SUBSTANTIVE BIOLOGY

In the first experiment, we fit a model with $K = 15$ blocks, and we attempt a direct interpretation of the blocks in terms of the 15 high-level functional categories in the MIPS annotation tree—separate from the MIPS protein interaction data, and independently conceived. We discuss results

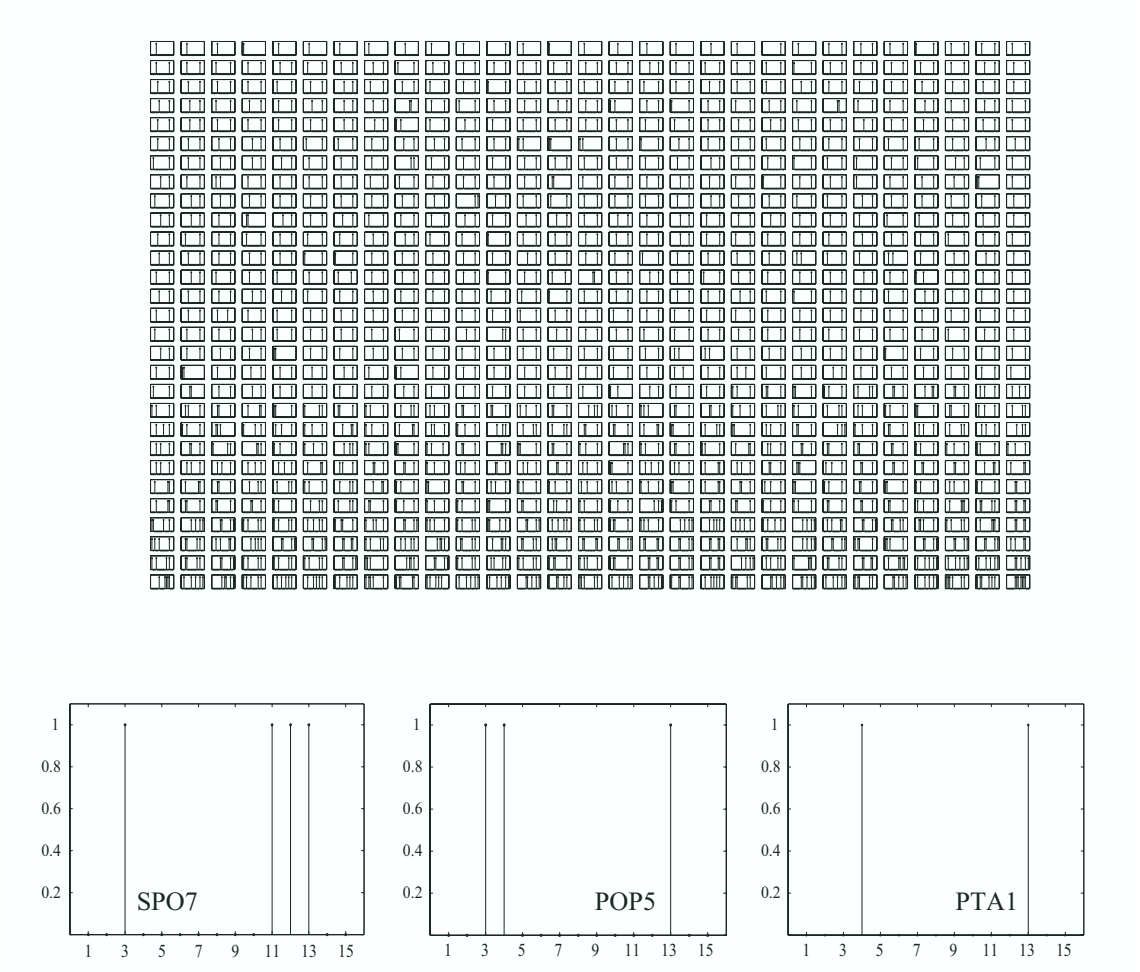

Figure 10: By mapping individual proteins to the 15 general functions in Table 2, we obtain a 15-dimensional representation for each protein. Here, each panel corresponds to a protein; the 15 functional categories are displayed on the X axis, whereas the presence or absence of the corresponding functional annotation is displayed on the Y axis. The plots at the bottom zoom into three example panels (proteins).

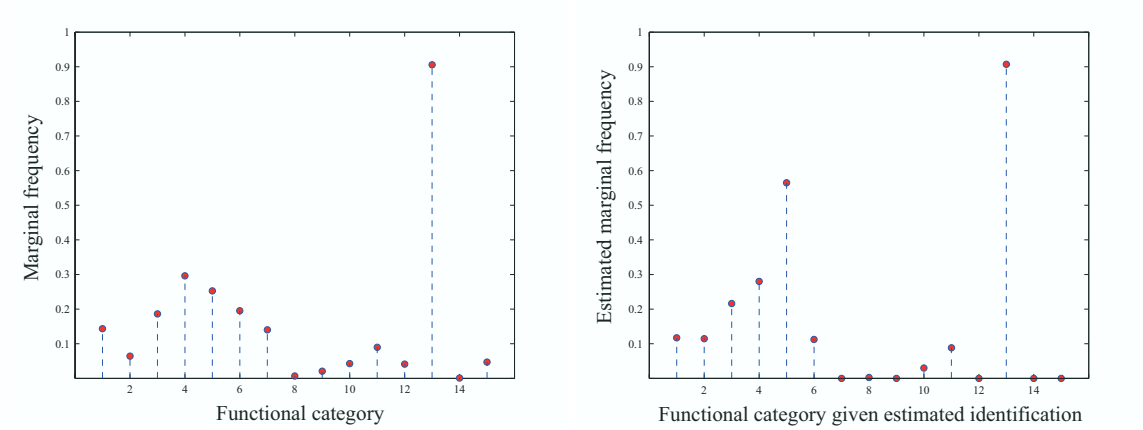

Figure 11: The mapping of blocks to functions is estimated by maximizing the accuracy of the predicted annotations of 87 proteins. We plot marginal frequencies of proteins' membership to true functions (left) and to predicted functions (right).

that portray the relevance of mixed membership, the resolution of the identification of blocks with functional categories, and selected predictions.

We want to compute the correspondence between protein-specific mixed memberships to blocks, $\vec{\pi}_{1:871}$, and MIPS-derived functional annotations, $\vec{b}_{1:871}$. The $K = 15$ blocks in the blockmodel B are not directly identifiable in terms of functional categories. In other words, we need to estimate a permutation of the components of $\vec{\pi}_n$ in order to be able to interpret $E[\pi_n(k)|Y]$ as the expected degree of membership of protein n in function k of Table 2—rather than simply the expected degree of membership of protein n in block k, out of 15. To estimate the permutation that best identifies blocks to functions, we proceeded as follows. We sampled 87 proteins and their corresponding MIPS annotations, $\vec{b}_{1:87}$. We predicted membership of the 87 proteins by thresholding their mixed membership representations,

$$\hat{b}_n(k) = \begin{cases} 1 & \text{if } \pi_n(k) > \tau \\ 0 & \text{otherwise,} \end{cases}$$

where τ is the 95th percentile of the ensemble of elements of $\vec{\pi}_{1:87}$, corresponding to the 87 proteins in the training set. We then greedily identified the mapping that maximizing the accuracy of the predicted annotations of 87 proteins. We used this mapping to compare predicted versus known functional annotations for all proteins; in Figure 11 we plot marginal frequencies of proteins' membership to true functions (left panel) and to predicted functions (right panel). The accuracy on the 90% testing set is about 87%. An algorithm that randomly guesses annotations, knowing the right proportions of annotations in each category, leads to a baseline accuracy of about 70%. Figure 12 shows predicted mixed memberships (dashed, red lines) versus the true annotations (solid, black lines), given the estimated mapping of blocks to functions, for six example proteins.

4.3.3 INDIRECT EVALUATION: FUNCTIONAL CONTENT OF PREDICTED INTERACTIONS

In the second experiment, we selected the mixed membership blockmodel best for predicting out-of-sample interactions, and we explored its goodness-of-fit indirectly, in terms of the number of

predicted interactions that are functionally relevant according to GO present in estimated protein interaction networks obtained with the two types of analyses that MMB supports; summarization and de-noising.

We fit models with K ranging between 2 and 255. We selected the best model ($K = 50$) using cross-validated held-out log likelihood, as in Figure 7. This finding supports the hypothesis that proteins derived from the MIPS data are interpretable in terms functional biological contexts. Alternatively, the blocks might encode signal at a finer resolution, such as that of protein complexes.

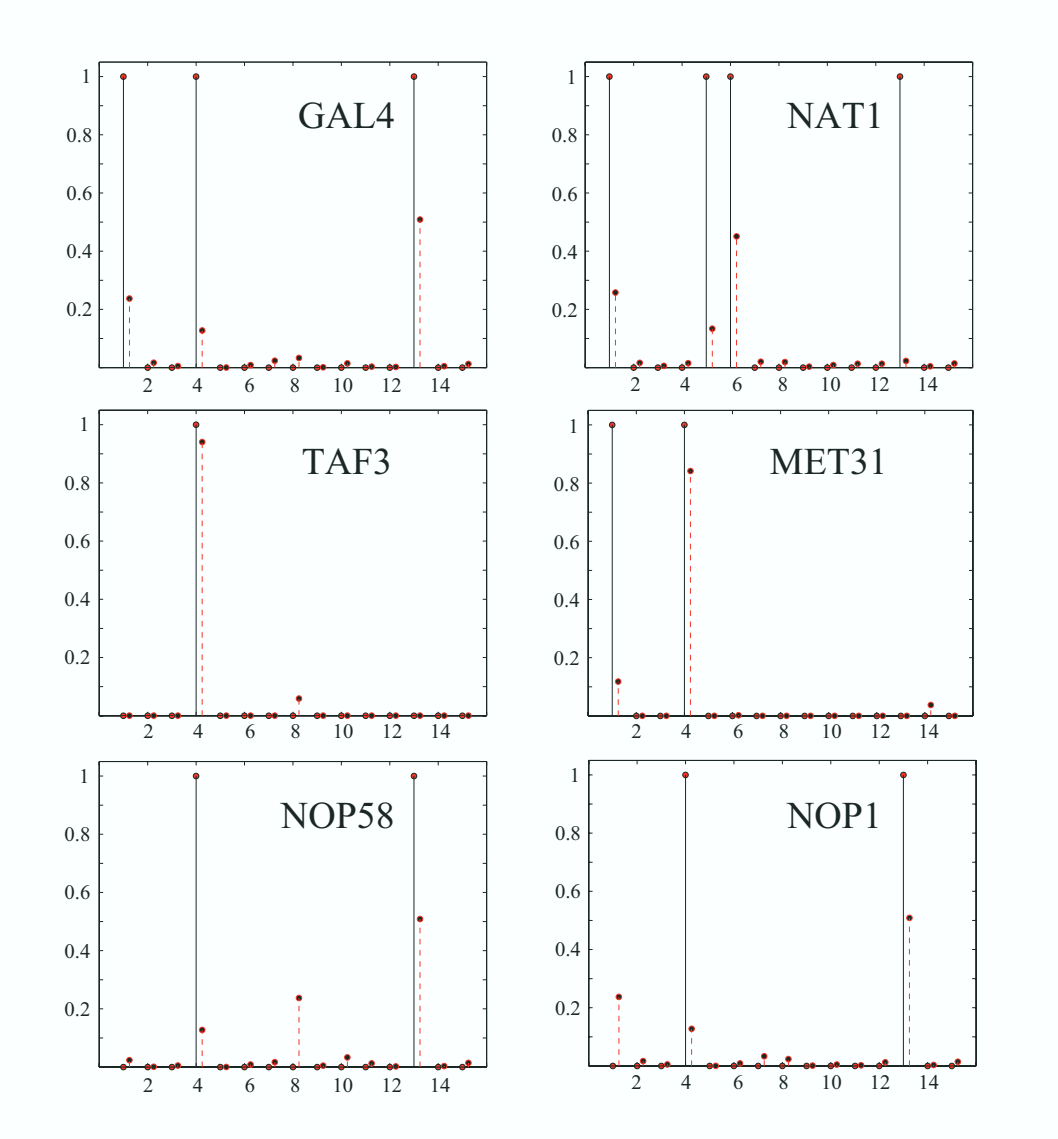

Figure 12: Predicted mixed-memberships (dashed, red lines) versus binary manually curated functional annotations (solid, black lines) for six example proteins, given the estimated mapping of blocks to functions in Figure 11.

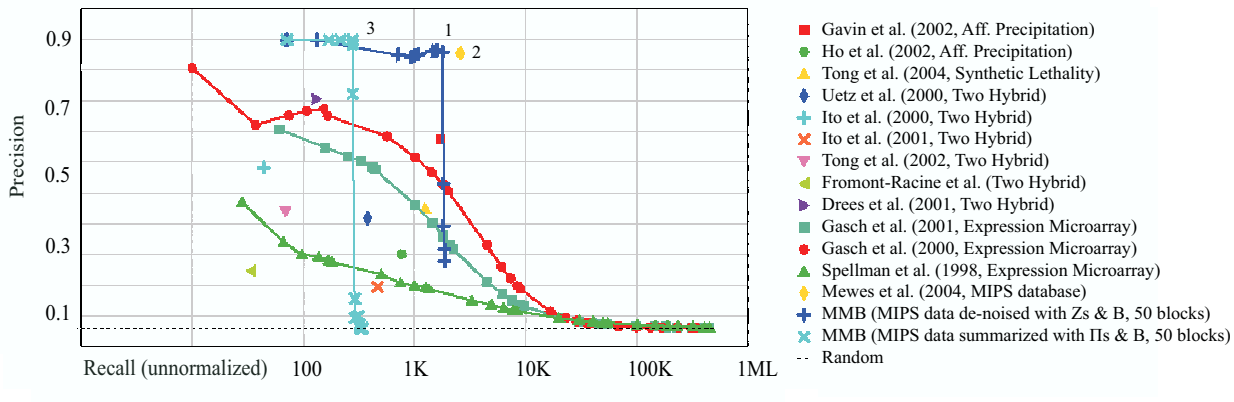

Figure 13: In the top panel we measure the functional content of the the MIPS collection of protein interactions (yellow diamond), and compare it against other published collections of interactions and microarray data, and to the posterior estimates of the MMB models—computed as described in Section 4.3.3. A breakdown of three estimated interaction networks (the points annotated 1, 2, and 3) into most represented gene ontology categories is detailed in Table 3.

If that was the case, however, we would expect the optimal number of blocks to be significantly higher; $871/5 \approx 175$, given an average size of five proteins in a complex (Krogan et al., 2006).

Using this model, we computed posterior model-based expectations of each interaction as follows,

$$\mathbb{E}\,[\,Y(p,q)\,] \approx \widehat{\vec{\pi}}_p{}' \widehat{B}\, \widehat{\vec{\pi}}_q \qquad \text{and} \qquad \mathbb{E}\,[\,Y(p,q)\,] \approx \widehat{\vec{\phi}}_{p\to q}{}' \widehat{B}\, \widehat{\vec{\phi}}_{p\leftarrow q}.$$

These computations lead to two estimated protein interaction networks with expected probabilities of interactions taking values in $[0,1]$. We obtained binary protein interaction networks by thresholding these expected probabilities at ten different values. In terms of the two analyses described in Section 2.2, this amount to either (i)predicting physical interactions by thresholding the posterior expectations computed using blockmodel B and mixed membership map $\vec{\pi}s$, essentially a prediction task, or (ii) we de-noise the observed interactions Y using the blockmodel B and interaction-specific membership indicators Zs, essentially a de-noising task. We use the independent set of functional annotations from the gene ontology to decide which interactions are functionally meaningful; namely those between pairs of proteins that share at least one functional annotation (Myers et al., 2006). In this sense, between two models that suggest different sets of interactions as reliable, our evaluation assigns a higher score to the model that reveals *functionally relevant* interactions. Figure 13 shows the functional content of the original MIPS collection of physical interactions (point no.2), and of the collections of interactions computed using $(B,\Pi s)$, the light blue $(-\times)$ line, and using (B,Zs), the dark blue $(-+)$ line, thresholded at ten different levels—precision-recall curves. The posterior means of Πs provide a parsimonious representation for the MIPS collection, and lead to precise interaction estimates, in moderate amount ($-\times$ line). The posterior means of Zs provide a richer representation for the data, and describe most of the functional content of the MIPS collection with high precision ($-+$ line). Figure 13 also shows the functional content of the original MIPS collection (the yellow diamond). Most importantly, notice the estimated protein interaction

networks, that is, ex-es and crosses, corresponding to lower levels of recall feature a more precise functional content than the original. This means that the proposed latent block structure is helpful in summarizing the collection of interactions—by ranking them properly. On closer inspection, dense blocks of predicted interactions contain known functional predictions that were not in the MIPS collection, thus effectively improving the quality of the data that instantiate activity specific to few biological contexts, such as biopolymer catabolism and homeostasis. In conclusion, results suggest that MMB successfully reduces the dimensionality of the data, while revealing substantive information about the multiple functionality of proteins that can be used to inform subsequent analyses.

Table 3 provides more information about three instances of predicted interaction networks displayed in Figure 13; those corresponding the points annotated 1, 2, and 3. Specifically, the table shows a breakdown of the predicted (posterior) collections of interactions in each example network into the gene ontology categories. A count in the table corresponds to the fact that both proteins are annotated with the same GO functional category.[5]

In this application, the MMB learned information about (i) the mixed membership of objects to latent groups, and (ii) the connectivity patterns among latent groups. These estimates were useful in describing and summarizing the functional content of the MIPS collection of protein interactions. This suggests the use of MMB as a dimensionality reduction approach that may be useful for performing model-driven de-noising of new collections of interactions, such as those measured via high-throughput experiments.

5. Discussion

Modern probabilistic models for relational data analysis are rooted in the stochastic blockmodels for psychometric and sociological analysis, pioneered by Lorrain and White (1971) and by Holland and Leinhardt (1975). In statistics, this line of research has been extended in various contexts over the years (Fienberg et al., 1985; Wasserman and Pattison, 1996; Snijders, 2002; Hoff et al., 2002; Doreian et al., 2004). In machine learning, the related technique of Markov random networks (Frank and Strauss, 1986) have been used for link prediction (Taskar et al., 2003) and the traditional blockmodels have been extended to include nonparametric Bayesian priors (Kemp et al., 2004, 2006; Xu et al., 2006) and to integrate relations and text (McCallum et al., 2007).

There is a close relationship between the MMB and the latent space models (Hoff et al., 2002; Handcock et al., 2007). In the latent space models, the latent vectors are drawn from Gaussian distributions and the interaction data is drawn from a Gaussian with mean $\vec{\pi}_p{}' \mathbb{I} \vec{\pi}_q$. In the MMB, the marginal probability of an interaction takes a similar form, $\vec{\pi}_p{}' B \vec{\pi}_q$, where B is the matrix of probabilities of interactions for each pair of latent groups. Two major differences exist between these approaches. In MMB, the distribution over the latent vectors is a Dirichlet and the underlying data distribution is arbitrary—we have chosen Bernoulli. The posterior inference in latent space models (Hoff et al., 2002; Handcock et al., 2007) is carried out via MCMC sampling, while we have developed a scalable variational inference algorithm to analyze large network structures. (It would be interesting to develop a variational algorithm for the latent space models as well.) A number of well-designed numerical investigations and comparisons between variational EM and variants of MCMC have been performed in existing literature; for instance, see Buntine and Jakulin (2006),[6]

5. Note that, in GO, proteins are typically annotated to multiple functional categories.

Table 3: Breakdown of three example interaction networks into most represented gene ontology categories—see text for more details. The digit in the first column indicates the example network in Figure 13 that any given line refers to. The last two columns quote the number of predicted, and possible pairs for each GO term.

and Braun and McAuliffe (2007). We refer readers interested in the comparison between variational vs. MCMC to these resources.

The model decouples the observed connectivity patterns into two sources of variability, B, Πs, that are apparently in competition for explaining the data, possibly raising an identifiability issue. This is not the case, however, as the blockmodel B captures global/asymmetric relations, while the mixed membership vectors Πs capture local/symmetric relations. This difference practically eliminates the issue, unless there is no signal in the data to begin with.

A recurring question, which bears relevance to mixed membership models in general, is why we do not integrate out the single membership indicators—$(\vec{z}_{p\to q}, \vec{z}_{p\leftarrow q})$. While this may lead to computational efficiencies we would often lose interpretable quantities that are useful for making predictions, for de-noising new measurements, or for performing other tasks. In fact, the posterior distributions of such quantities typically carry substantive information about elements of the appli-

cation at hand. In the application to protein interaction networks of Section 4.3, for example, they encode the interaction-specific memberships of individual proteins to protein complexes.

In the relational setting, cross-validation is feasible if the blockmodel estimated on training data can be expected to hold on test data; for this to happen the network must be of reasonable size, so that we can expect members of each block to be in both training and test sets. In this setting, scheduling of variational updates is important; nested variational scheduling leads to efficient and parallelizable inference.

A limitation of our model can be best appreciated in a simulation setting. If we consider structural properties of the network MMB is capable of generating, we count a wide array of local and global connectivity patterns. But the model does not readily generate *hubs*, that is, nodes connected with a large number of directed or undirected connections, or networks with skewed degree distributions.

From a data analysis perspective, we speculate that the value of MMB in capturing substantive information about a problem will increase in semi-supervised setting—where, for example, information about the membership of genes to functional contexts is included in the form of prior distributions. In such a setting we may be interested in looking at the change between prior and posterior membership; a sharp change may signal biological phenomena worth investigating. We need not assume that the number of groups/blocks, K, is finite. It is possible, for example, to posit that the mixed-membership vectors are sampled form a stochastic process, in the nonparametric setting. To maintain mixed membership of nodes to groups/blocks in such setting, we need to sample them from a hierarchical Dirichlet process (Teh et al., 2006), rather than from a Dirichlet Process (Escobar and West, 1995).

MMB generalizes to two important cases. First, multiple data collections $Y_{1:M}$ on the same objects can be generated by the same latent vectors. This might be useful, for example, for simultaneously analyzing the relational measurements about esteem and disesteem, liking and disliking, positive influence and negative influence, praise and blame, for example, see Sampson (1968), or those about the collection of 17 relations measured by Bradley (1987). Second, in the MMB the data generating distribution is a Bernoulli, but B can be a matrix that parameterizes any kind of distribution. For example, technologies for measuring interactions between pairs of proteins such as mass spectrometry (Ho et al., 2002) and tandem affinity purification (Gavin et al., 2002) return a probabilistic assessment about the presence of interactions, thus setting the range of $Y(p,q)$ to $[0,1]$. This is not the case for the manually curated collection of interactions we analyze in Section 4.3.

6. Conclusions

In this paper we introduced mixed membership stochastic blockmodels, a novel class of latent variable models for relational data. These models provide exploratory tools for scientific analyses in applications where the observations can be represented as a collection of unipartite graphs. The nested variational inference algorithm is parallelizable and allows fast approximate inference on large graphs.

Appendix A. General Model Formulation

In general, mixed membership stochastic blockmodels can be specified in terms of assumptions at four levels: population, node, latent variable, and sampling scheme level.

A.1 Population Level

Assume that there are K classes or sub-populations in the population of interest. We denote by $f\ (\ Y(p,q) \mid B(g,h)\ )$ the probability distribution of the relation measured on the pair of nodes (p,q), where the *p-th* node is in the *h-th* sub-population, the *q-th* node is in the *h-th* sub-population, and $B(g,h)$ contains the relevant parameters. The indices i, j run in $1,\ldots,N$, and the indices g,h run in $1,\ldots,K$.

A.2 Node Level

The components of the membership vector $\vec{\pi}_p = [\vec{\pi}_p(1),\ldots,\vec{\pi}_p(k)]'$ encodes the mixed membership of the *n-th* node to the various sub-populations. The distribution of the observed response $Y(p,q)$ given the relevant, node-specific memberships, $(\vec{\pi}_p,\vec{\pi}_q)$, is then

$$Pr\ (\ Y(p,q) \mid \vec{\pi}_p,\vec{\pi}_q,B\ )\ \ =\ \ \sum_{g,h=1}^{K} \vec{\pi}_p(g)\ f(Y(p,q) \mid B(g,h))\ \vec{\pi}_q(h).$$

Conditional on the mixed memberships, the response edges y_{jnm} are independent of one another, both across distinct graphs and pairs of nodes.

A.3 Latent Variable Level

Assume that the mixed membership vectors $\vec{\pi}_{1:N}$ are realizations of a latent variable with distribution $D_{\vec{\alpha}}$, with parameter vector $\vec{\alpha}$. The probability of observing $Y(p,q)$, given the parameters, is then

$$Pr\ (\ Y(p,q) \mid \vec{\alpha},B\ )\ \ =\ \ \int Pr\ (\ Y(p,q) \mid \vec{\pi}_p,\vec{\pi}_q,B\ )\ D_{\vec{\alpha}}(d\vec{\pi}).$$

A.4 Sampling Scheme Level

Assume that the M independent replications of the relations measured on the population of nodes are independent of one another. The probability of observing the whole collection of graphs, $Y_{1:M}$, given the parameters, is then given by the following equation.

$$Pr\ (\ Y_{1:M} \mid \vec{\alpha},B\ ) = \prod_{m=1}^{M} \prod_{p,q=1}^{N} Pr\ (\ Y_m(p,q) \mid \vec{\alpha},B\ )\ .$$

Full model specifications immediately adapt to the different kinds of data, for example, multiple data types through the choice of f, or parametric or semi-parametric specifications of the prior on the number of clusters through the choice of a distribution for the πs, D_α.

Appendix B. Details of the Variational Approximation

Here we present more details about the derivation of the variational EM algorithm presented in Section 3. Furthermore, we address a setting where M replicates are available about the paired measurements, $G_{1:M} = (N, Y_{1:M})$, and relations $Y_m(p,q)$ take values into an arbitrary metric space according to $f\ (\ Y_m(p,q) \mid .. \ )$. An extension of the inference algorithm to address the case or multivariate relations, say J-dimensional, and multiple blockmodels $B_{1:J}$ each corresponding to a distinct relational response, can be derived with minor modifications of the derivations that follow.

B.1 Variational Expectation-Maximization

We begin by briefly summarizing the general strategy we intend to use. The approximate variant of EM we describe here is often referred to as *Variational EM* (Beal and Ghahramani, 2003). Recall that Y denotes the data. Rewrite $X = (\vec{\pi}_{1:N}, Z_{\rightarrow}, Z_{\leftarrow})$ for the latent variables, and $\Theta = (\vec{\alpha}, B)$ for the model's parameters. Briefly, it is possible to lower bound the likelihood, $p(Y|\Theta)$, making use of Jensen's inequality and of any distribution on the latent variables $q(X)$,

$$\begin{aligned} p(Y|\Theta) &= \log \int_{\mathcal{X}} p(Y,X|\Theta)\, dX \\ &= \log \int_{\mathcal{X}} q(X)\, \frac{p(Y,X|\Theta)}{q(X)}\, dX \qquad \text{(for any } q\text{)} \\ &\geq \int_{\mathcal{X}} q(X)\, \log \frac{p(Y,X|\Theta)}{q(X)}\, dX \qquad \text{(Jensen's)} \\ &= \mathbb{E}_q\, [\, \log p(Y,X|\Theta) - \log q(X)\,] \ =:\ \mathcal{L}(q,\Theta) \end{aligned}$$

In EM, the lower bound $\mathcal{L}(q,\Theta)$ is then iteratively maximized with respect to Θ, in the M step, and q in the E step (Dempster et al., 1977). In particular, at the *t-th* iteration of the E step we set

$$q^{(t)} = p(X|Y, \Theta^{(t-1)}), \tag{5}$$

that is, equal to the posterior distribution of the latent variables given the data and the estimates of the parameters at the previous iteration.

Unfortunately, we cannot compute the posterior in Equation 5 for the admixture of latent blocks model. Rather, we define a direct parametric approximation to it, $\tilde{q} = q_\Delta(X)$, which involves an extra set of *variational parameters*, Δ, and entails an approximate lower bound for the likelihood $\mathcal{L}_\Delta(q,\Theta)$. At the *t-th* iteration of the E step, we then minimize the Kullback-Leibler divergence between $q^{(t)}$ and $q^{(t)}_\Delta$, with respect to Δ, using the data.[7] The optimal parametric approximation is, in fact, a proper posterior as it depends on the data Y, although indirectly, $q^{(t)} \approx q^{(t)}_{\Delta^*(Y)}(X) = p(X|Y)$.

B.2 Lower Bound for the Likelihood

According to the mean-field theory (Jordan et al., 1999), one can approximate an intractable distribution such as the one defined by Equation (1) by a fully factored distribution $q(\vec{\pi}_{1:N}, Z^{\rightarrow}_{1:M}, Z^{\leftarrow}_{1:M})$

7. This is equivalent to maximizing the approximate lower bound for the likelihood, $\mathcal{L}_\Delta(q,\Theta)$, with respect to Δ.

defined as follows:

$$\begin{aligned} & q(\vec{\pi}_{1:N}, Z^{\rightarrow}_{1:M}, Z^{\leftarrow}_{1:M} | \vec{\gamma}_{1:N}, \Phi^{\rightarrow}_{1:M}, \Phi^{\leftarrow}_{1:M}) \\ = & \prod_p q_1(\vec{\pi}_p|\vec{\gamma}_p) \prod_m \prod_{p,q} \Big(q_2(\vec{z}^m_{p\rightarrow q}|\vec{\phi}^m_{p\rightarrow q}, 1)\; q_2(\vec{z}^m_{p\leftarrow q}|\vec{\phi}^m_{p\leftarrow q}, 1) \Big), \end{aligned}$$

where q_1 is a Dirichlet, q_2 is a multinomial, and $\Delta = (\vec{\gamma}_{1:N}, \Phi^{\rightarrow}_{1:M}, \Phi^{\leftarrow}_{1:M})$ represent the set of free *variational parameters* need to be estimated in the approximate distribution.

Minimizing the Kulback-Leibler divergence between this $q(\vec{\pi}_{1:N}, Z^{\rightarrow}_{1:M}, Z^{\leftarrow}_{1:M}|\Delta)$ and the original $p(\vec{\pi}_{1:N}, Z^{\rightarrow}_{1:M}, Z^{\leftarrow}_{1:M}$ defined by Equation (1) leads to the following approximate lower bound for the likelihood.

$$\begin{aligned} \mathcal{L}_\Delta(q,\Theta) &= \mathbb{E}_q\left[\log \prod_m \prod_{p,q} p_1(Y_m(p,q)|\vec{z}^m_{p\rightarrow q}, \vec{z}^m_{p\leftarrow q}, B)\right] \\ &+ \mathbb{E}_q\left[\log \prod_m \prod_{p,q} p_2(\vec{z}^m_{p\rightarrow q}|\vec{\pi}_p, 1)\right] + \mathbb{E}_q\left[\log \prod_m \prod_{p,q} p_2(\vec{z}^m_{p\leftarrow q}|\vec{\pi}_q, 1)\right] \\ &+ \mathbb{E}_q\left[\log \prod_p p_3(\vec{\pi}_p|\vec{\alpha})\right] - \mathbb{E}_q\left[\prod_p q_1(\vec{\pi}_p|\vec{\gamma}_p)\right] \\ &- \mathbb{E}_q\left[\log \prod_m \prod_{p,q} q_2(\vec{z}^m_{p\rightarrow q}|\vec{\phi}^m_{p\rightarrow q}, 1)\right] - \mathbb{E}_q\left[\log \prod_m \prod_{p,q} q_2(\vec{z}^m_{p\leftarrow q}|\vec{\phi}^m_{p\leftarrow q}, 1)\right]. \end{aligned}$$

Working on the single expectations leads to

$$\begin{aligned} \mathcal{L}_\Delta(q,\Theta) &= \sum_m \sum_{p,q} \sum_{g,h} \phi^m_{p\rightarrow q,g} \phi^m_{p\leftarrow q,h} \cdot f\left(Y_m(p,q), B(g,h)\right) \\ &+ \sum_m \sum_{p,q} \sum_g \phi^m_{p\rightarrow q,g}\left[\psi(\gamma_{p,g}) - \psi(\sum_g \gamma_{p,g})\right] \\ &+ \sum_m \sum_{p,q} \sum_h \phi^m_{p\leftarrow q,h}\left[\psi(\gamma_{p,h}) - \psi(\sum_h \gamma_{p,h})\right] \\ &+ \sum_p \log\Gamma(\sum_k \alpha_k) - \sum_{p,k} \log\Gamma(\alpha_k) + \sum_{p,k} (\alpha_k - 1)\left[\psi(\gamma_{p,k}) - \psi(\sum_k \gamma_{p,k})\right] \\ &- \sum_p \log\Gamma(\sum_k \gamma_{p,k}) + \sum_{p,k} \log\Gamma(\gamma_{p,k}) - \sum_{p,k} (\gamma_{p,k} - 1)\left[\psi(\gamma_{p,k}) - \psi(\sum_k \gamma_{p,k})\right] \\ &- \sum_m \sum_{p,q} \sum_g \phi^m_{p\rightarrow q,g} \log \phi^m_{p\rightarrow q,g} - \sum_m \sum_{p,q} \sum_h \phi^m_{p\leftarrow q,h} \log \phi^m_{p\leftarrow q,h} \end{aligned}$$

where

$$f\left(Y_m(p,q), B(g,h)\right) = Y_m(p,q) \log B(g,h) + \left(1 - Y_m(p,q)\right) \log\left(1 - B(g,h)\right);$$

m runs over $1,\ldots,M$; p,q run over $1,\ldots,N$; g,h,k run over $1,\ldots,K$; and $\psi(x)$ is the derivative of the log-gamma function, $\frac{d\log\Gamma(x)}{dx}$.

B.3 The Expected Value of the Log of a Dirichlet Random Vector

The computation of the lower bound for the likelihood requires us to evaluate $\mathbb{E}_q\left[\log \vec{\pi}_p\right]$ for $p = 1,\ldots,N$. Recall that the density of an exponential family distribution with natural parameter $\vec{\theta}$ can be written as

$$\begin{aligned} p(x|\alpha) &= h(x) \cdot c(\alpha) \cdot \exp\left\{\sum_k \theta_k(\alpha) \cdot t_k(x)\right\} \\ &= h(x) \cdot \exp\left\{\sum_k \theta_k(\alpha) \cdot t_k(x) - \log c(\alpha)\right\}. \end{aligned}$$

Omitting the node index p for convenience, we can rewrite the density of the Dirichlet distribution p_3 as an exponential family distribution,

$$p_3(\vec{\pi}|\vec{\alpha}) = \exp\left\{ \sum_k (\alpha_k - 1)\log(\pi_k) - \log\frac{\prod_k \Gamma(\alpha_k)}{\Gamma(\sum_k \alpha_k)} \right\},$$

with natural parameters $\theta_k(\vec{\alpha}) = (\alpha_k - 1)$ and natural sufficient statistics $t_k(\vec{\pi}) = \log(\pi_k)$. Let $c'(\vec{\theta}) = c(\alpha_1(\vec{\theta}), \ldots, \alpha_K(\vec{\theta}))$; using a well known property of the exponential family distributions (Schervish, 1995) we find that

$$\mathbb{E}_q\left[\log\pi_k\right] \;=\; \mathbb{E}_{\vec{\theta}}\left[\log t_k(x)\right] = \psi\left(\alpha_k\right) - \psi\left(\sum_k \alpha_k\right),$$

where $\psi(x)$ is the derivative of the log-gamma function, $\frac{d\log\Gamma(x)}{dx}$.

B.4 Variational E Step

The approximate lower bound for the likelihood $\mathcal{L}_\Delta(q,\Theta)$ can be maximized using exponential family arguments and coordinate ascent (Wainwright and Jordan, 2003).

Isolating terms containing $\phi^m_{p\to q,g}$ and $\phi^m_{p\leftarrow q,h}$ we obtain $\mathcal{L}_{\phi^m_{p\to q,g}}(q,\Theta)$ and $\mathcal{L}_{\phi^m_{p\to q,g}}(q,\Theta)$. The natural parameters $\vec{g}^m_{p\to q}$ and $\vec{g}^m_{p\leftarrow q}$ corresponding to the natural sufficient statistics $\log(\vec{z}^m_{p\to q})$ and $\log(\vec{z}^m_{p\leftarrow q})$ are functions of the other latent variables and the observations. We find that

$$\begin{aligned} g^m_{p\to q,g} &= \log\pi_{p,g} + \sum_h z^m_{p\leftarrow q,h}\cdot f\left(Y_m(p,q), B(g,h)\right), \\ g^m_{p\leftarrow q,h} &= \log\pi_{q,h} + \sum_g z^m_{p\to q,g}\cdot f\left(Y_m(p,q), B(g,h)\right), \end{aligned}$$

for all pairs of nodes (p,q) in the *m-th* network; where $g,h = 1,\ldots,K$, and

$$f\left(Y_m(p,q), B(g,h)\right) = Y_m(p,q)\log B(g,h) + \left(1 - Y_m(p,q)\right)\log\left(1 - B(g,h)\right).$$

This leads to the following updates for the variational parameters $(\vec{\phi}^m_{p\to q}, \vec{\phi}^m_{p\leftarrow q})$, for a pair of nodes (p,q) in the *m-th* network:

$$\begin{aligned} \hat{\phi}^m_{p\to q,g} &\propto e^{\,\mathbb{E}_q\left[g^m_{p\to q,g}\right]} \\ &= e^{\,\mathbb{E}_q\left[\log\pi_{p,g}\right]} \cdot e^{\,\sum_h \phi^m_{p\leftarrow q,h}\cdot\, \mathbb{E}_q\left[f\left(Y_m(p,q),B(g,h)\right)\right]} \\ &= e^{\,\mathbb{E}_q\left[\log\pi_{p,g}\right]} \cdot \prod_h \left(B(g,h)^{Y_m(p,q)} \cdot \left(1 - B(g,h)\right)^{1 - Y_m(p,q)} \right)^{\phi^m_{p\leftarrow q,h}}, \\ \hat{\phi}^m_{p\leftarrow q,h} &\propto e^{\,\mathbb{E}_q\left[g^m_{p\leftarrow q,h}\right]} \\ &= e^{\,\mathbb{E}_q\left[\log\pi_{q,h}\right]} \cdot e^{\,\sum_g \phi^m_{p\to q,g}\cdot\, \mathbb{E}_q\left[f\left(Y_m(p,q),B(g,h)\right)\right]} \\ &= e^{\,\mathbb{E}_q\left[\log\pi_{q,h}\right]} \cdot \prod_g \left(B(g,h)^{Y_m(p,q)} \cdot \left(1 - B(g,h)\right)^{1 - Y_m(p,q)} \right)^{\phi^m_{p\to q,g}}, \end{aligned}$$

for $g,h = 1,\ldots,K$. These estimates of the parameters underlying the distribution of the nodes' group indicators $\vec{\phi}^m_{p\to q}$ and $\vec{\phi}^m_{p\leftarrow q}$ need be normalized, to make sure $\sum_k \phi^m_{p\to q,k} = \sum_k \phi^m_{p\leftarrow q,k} = 1$.

Isolating terms containing $\gamma_{p,k}$ we obtain $\mathcal{L}_{\gamma_{p,k}}(q,\Theta)$. Setting $\frac{\partial \mathcal{L}_{\gamma_{p,k}}}{\partial \gamma_{p,k}}$ equal to zero and solving for $\gamma_{p,k}$ yields:

$$\hat{\gamma}_{p,k} = \alpha_k + \sum_m \sum_q \phi^m_{p\to q,k} + \sum_m \sum_q \phi^m_{p\leftarrow q,k},$$

for all nodes $p \in \mathcal{P}$ and $k = 1,\ldots,K$.

The *t-th* iteration of the variational E step is carried out for fixed values of $\Theta^{(t-1)} = (\vec{\alpha}^{(t-1)}, B^{(t-1)})$, and finds the optimal approximate lower bound for the likelihood $\mathcal{L}_{\Delta^*}(q,\Theta^{(t-1)})$.

B.5 Variational M Step

The optimal lower bound $\mathcal{L}_{\Delta^*}(q^{(t-1)},\Theta)$ provides a tractable surrogate for the likelihood at the *t-th* iteration of the variational M step. We derive empirical Bayes estimates for the hyper-parameters Θ that are based upon it.[8] That is, we maximize $\mathcal{L}_{\Delta^*}(q^{(t-1)},\Theta)$ with respect to Θ, given expected sufficient statistics computed using $\mathcal{L}_{\Delta^*}(q^{(t-1)},\Theta^{(t-1)})$.

Isolating terms containing $\vec{\alpha}$ we obtain $\mathcal{L}_{\vec{\alpha}}(q,\Theta)$. Unfortunately, a closed form solution for the approximate maximum likelihood estimate of $\vec{\alpha}$ does not exist (Blei et al., 2003). We can produce a Newton-Raphson method that is linear in time, where the gradient and Hessian for the bound $\mathcal{L}_{\vec{\alpha}}$ are

$$\begin{aligned}
\frac{\partial \mathcal{L}_{\vec{\alpha}}}{\partial \alpha_k} &= N\left(\psi\left(\sum_k \alpha_k\right) - \psi(\alpha_k)\right) + \sum_p \left(\psi(\gamma_{p,k}) - \psi\left(\sum_k \gamma_{p,k}\right)\right), \\
\frac{\partial \mathcal{L}_{\vec{\alpha}}}{\partial \alpha_{k_1}\alpha_{k_2}} &= N\left(\mathbb{I}_{(k_1=k_2)}\cdot\psi'(\alpha_{k_1}) - \psi'\left(\sum_k \alpha_k\right)\right).
\end{aligned}$$

Isolating terms containing B we obtain $\mathcal{L}_B$, whose approximate maximum is

$$\hat{B}(g,h) = \frac{1}{M}\sum_m \left(\frac{\sum_{p,q} Y_m(p,q)\cdot \phi^m_{p\to qg}\phi^m_{p\leftarrow qh}}{(1-\rho)\cdot\sum_{p,q}\phi^m_{p\to qg}\phi^m_{p\leftarrow qh}}\right),$$

for every index pair $(g,h) \in [1,K]\times[1,K]$.

In Section 2.1 we introduced an extra parameter, ρ, to control the relative importance of presence and absence of interactions in likelihood, that is, the score that informs inference and estimation. Isolating terms containing ρ we obtain $\mathcal{L}_\rho$. We may then estimate the sparsity parameter ρ by

$$\hat{\rho} = \frac{1}{M}\sum_m \left(\frac{\sum_{p,q}\left(1 - Y_m(p,q)\right)\cdot\left(\sum_{g,h}\phi^m_{p\to qg}\phi^m_{p\leftarrow qh}\right)}{\sum_{p,q}\sum_{g,h}\phi^m_{p\to qg}\phi^m_{p\leftarrow qh}}\right).$$

Alternatively, we can fix ρ prior to the analysis; the density of the interaction matrix is estimated with $\hat{d} = \sum_{m,p,q} Y_m(p,q)/(N^2M)$, and the sparsity parameter is set to $\tilde{\rho} = (1-\hat{d})$. This latter estimator attributes all the information in the non-interactions to the point mass, that is, to latent sources other than the block model B or the mixed membership vectors $\vec{\pi}_{1:N}$. It does, however, provide a quick recipe to reduce the computational burden during exploratory analyses.[9]

8. We could term these estimates *pseudo* empirical Bayes estimates, since they maximize an approximate lower bound for the likelihood, $\mathcal{L}_{\Delta^*}$.

9. Note that $\tilde{\rho} = \hat{\rho}$ in the case of single membership. In fact, that implies $\phi^m_{p\to qg} = \phi^m_{p\leftarrow qh} = 1$ for some (g,h) pair, for any (p,q) pair.

Abstract

In the last years of his life, Leo Breiman promoted random forests for use in classification. He suggested using averaging as a means of obtaining good discrimination rules. The base classifiers used for averaging are simple and randomized, often based on random samples from the data. He left a few questions unanswered regarding the consistency of such rules. In this paper, we give a number of theorems that establish the universal consistency of averaging rules. We also show that some popular classifiers, including one suggested by Breiman, are not universally consistent.

Keywords: random forests, classification trees, consistency, bagging

This paper is dedicated to the memory of Leo Breiman.

1. Introduction

Ensemble methods, popular in machine learning, are learning algorithms that construct a set of many individual classifiers (called base learners) and combine them to classify new data points by taking a weighted or unweighted vote of their predictions. It is now well-known that ensembles are often much more accurate than the individual classifiers that make them up. The success of ensemble algorithms on many benchmark data sets has raised considerable interest in understanding why such methods succeed and identifying circumstances in which they can be expected to produce good results. These methods differ in the way the base learner is fit and combined. For example, bagging (Breiman, 1996) proceeds by generating bootstrap samples from the original data set, constructing a classifier from each bootstrap sample, and voting to combine. In boosting (Freund and Schapire, 1996) and arcing algorithms (Breiman, 1998) the successive classifiers are constructed by giving increased weight to those points that have been frequently misclassified, and the classifiers are combined using weighted voting. On the other hand, random split selection (Dietterich, 2000)

grows trees on the original data set. For a fixed number S, at each node, S best splits (in terms of minimizing deviance) are found and the actual split is randomly and uniformly selected from them. For a comprehensive review of ensemble methods, we refer the reader to Dietterich (2000a) and the references therein.

Breiman (2001) provides a general framework for tree ensembles called "random forests". Each tree depends on the values of a random vector sampled independently and with the same distribution for all trees. Thus, a random forest is a classifier that consists of many decision trees and outputs the class that is the mode of the classes output by individual trees. Algorithms for inducing a random forest were first developed by Breiman and Cutler, and "Random Forests" is their trademark. The web page

http://www.stat.berkeley.edu/users/breiman/RandomForests

provides a collection of downloadable technical reports, and gives an overview of random forests as well as comments on the features of the method.

Random forests have been shown to give excellent performance on a number of practical problems. They work fast, generally exhibit a substantial performance improvement over single tree classifiers such as CART, and yield generalization error rates that compare favorably to the best statistical and machine learning methods. In fact, random forests are among the most accurate general-purpose classifiers available (see, for example, Breiman, 2001).

Different random forests differ in how randomness is introduced in the tree building process, ranging from extreme random splitting strategies (Breiman, 2000; Cutler and Zhao, 2001) to more involved data-dependent strategies (Amit and Geman, 1997; Breiman, 2001; Dietterich, 2000). As a matter of fact, the statistical mechanism of random forests is not yet fully understood and is still under active investigation. Unlike single trees, where consistency is proved letting the number of observations in each terminal node become large (Devroye, Györfi, and Lugosi, 1996, Chapter 20), random forests are generally built to have a small number of cases in each terminal node. Although the mechanism of random forest algorithms appears simple, it is difficult to analyze and remains largely unknown. Some attempts to investigate the driving force behind consistency of random forests are by Breiman (2000, 2004) and Lin and Jeon (2006), who establish a connection between random forests and adaptive nearest neighbor methods. Meinshausen (2006) proved consistency of certain random forests in the context of so-called quantile regression.

In this paper we offer consistency theorems for various versions of random forests and other randomized ensemble classifiers. In Section 2 we introduce a general framework for studying classifiers based on averaging randomized base classifiers. We prove a simple but useful proposition showing that averaged classifiers are consistent whenever the base classifiers are.

In Section 3 we prove consistency of two simple random forest classifiers, the *purely random forest* (suggested by Breiman as a starting point for study) and the *scale-invariant random forest* classifiers.

In Section 4 it is shown that averaging may convert inconsistent rules into consistent ones.

In Section 5 we briefly investigate consistency of bagging rules. We show that, in general, bagging preserves consistency of the base rule and it may even create consistent rules from inconsistent ones. In particular, we show that if the bootstrap samples are sufficiently small, the bagged version of the 1-nearest neighbor classifier is consistent.

Finally, in Section 6 we consider random forest classifiers based on randomized, greedily grown tree classifiers. We argue that some greedy random forest classifiers, including Breiman's random forest classifier, are inconsistent and suggest a consistent greedy random forest classifier.

2. Voting and Averaged Classifiers

Let $(X,Y),(X_1,Y_1),\ldots,(X_n,Y_n)$ be i.i.d. pairs of random variables such that X (the so-called *feature vector*) takes its values in $\mathbb{R}^d$ while Y (the *label*) is a binary $\{0,1\}$-valued random variable. The joint distribution of (X,Y) is determined by the marginal distribution μ of X (i.e., $\mathbb{P}\{X \in A\} = \mu(A)$ for all Borel sets $A \subset \mathbb{R}^d$) and the *a posteriori* probability $\eta : \mathbb{R}^d \to [0,1]$ defined by

$$\eta(x) = \mathbb{P}\{Y = 1 | X = x\} \ .$$

The collection $(X_1,Y_1),\ldots,(X_n,Y_n)$ is called the *training data*, and is denoted by D_n. A classifier g_n is a binary-valued function of X and D_n whose probability of error is defined by

$$L(g_n) = \mathbb{P}_{(X,Y)}\{g_n(X,D_n) \neq Y\}$$

where $\mathbb{P}_{(X,Y)}$ denotes probability with respect to the pair (X,Y) (i.e., conditional probability, given D_n). For brevity, we write $g_n(X) = g_n(X,D_n)$. It is well-known (see, for example, Devroye, Györfi, and Lugosi, 1996) that the classifier that minimizes the probability of error, the so-called *Bayes classifier* is $g^*(x) = \mathbb{1}_{\{\eta(x) \geq 1/2\}}$. The risk of g^* is called the Bayes risk: $L^* = L(g^*)$.

A sequence $\{g_n\}$ of classifiers is *consistent* for a certain distribution of (X,Y) if $L(g_n) \to L^*$ in probability.

In this paper we investigate classifiers that calculate their decisions by taking a majority vote over *randomized classifiers*. A randomized classifier may use a random variable Z to calculate its decision. More precisely, let $\mathcal{Z}$ be some measurable space and let Z take its values in $\mathcal{Z}$. A randomized classifier is an arbitrary function of the form $g_n(X,Z,D_n)$, which we abbreviate by $g_n(X,Z)$. The probability of error of g_n becomes

$$L(g_n) = \mathbb{P}_{(X,Y),Z}\{g_n(X,Z,D_n) \neq Y\} = \mathbb{P}\{g_n(X,Z,D_n) \neq Y | D_n\} \ .$$

The definition of consistency remains the same by augmenting the probability space appropriately to include the randomization.

Given any randomized classifier, one may calculate the classifier for various draws of the randomizing variable Z. It is then a natural idea to define an averaged classifier by taking a majority vote among the obtained random classifiers. Assume that $Z_1,\ldots,Z_m$ are identically distributed draws of the randomizing variable, having the same distribution as Z. Throughout the paper, we assume that $Z_1,\ldots,Z_m$ are independent, conditionally on X, Y, and D_n. Letting $Z^m = (Z_1,\ldots,Z_m)$, one may define the corresponding *voting classifier* by

$$g_n^{(m)}(x,Z^m,D_n) = \begin{cases} 1 & \text{if } \frac{1}{m}\sum_{j=1}^m g_n(x,Z_j,D_n) \geq \frac{1}{2} \ , \\ 0 & \text{otherwise.} \end{cases}$$

By the strong law of large numbers, for any fixed x and D_n for which $\mathbb{P}_Z\{g_n(x,Z,D_n) = 1\} \neq 1/2$, we have almost surely $\lim_{m\to\infty} g_n^{(m)}(x,Z^m,D_n) = \bar{g}_n(x,D_n)$, where $\bar{g}_n(x,D_n) = \bar{g}_n(x) = \mathbb{1}_{\{\mathbb{E}_Z g_n(x,Z) \geq 1/2\}}$

is a (non-randomized) classifier that we call the *averaged classifier.* (Here $\mathbb{P}_Z$ and $\mathbb{E}_Z$ denote probability and expectation with respect to the randomizing variable Z, that is, conditionally on X, Y, and D_n.)

$\bar{g}_n$ may be interpreted as an idealized version of the classifier $g_n^{(m)}$ that draws many independent copies of the randomizing variable Z and takes a majority vote over the resulting classifiers.

Our first result states that consistency of a randomized classifier is preserved by averaging.

Proposition 1 *Assume that the sequence $\{g_n\}$ of randomized classifiers is consistent for a certain distribution of (X,Y). Then the voting classifier $g_n^{(m)}$ (for any value of m) and the averaged classifier $\bar{g}_n$ are also consistent.*

Proof Consistency of $\{g_n\}$ is equivalent to saying that $\mathbb{E}L(g_n) = \mathbb{P}\{g_n(X,Z) \neq Y\} \to L^*$. In fact, since $\mathbb{P}\{g_n(X,Z) \neq Y | X = x\} \geq \mathbb{P}\{g^*(X) \neq Y | X = x\}$ for all $x \in \mathbb{R}^d$, consistency of $\{g_n\}$ means that for μ-almost all x,

$$\mathbb{P}\{g_n(X,Z) \neq Y | X = x\} \to \mathbb{P}\{g^*(X) \neq Y | X = x\} = \min(\eta(x), 1-\eta(x)) \; .$$

Without loss of generality, assume that $\eta(x) > 1/2$. (In the case of $\eta(x) = 1/2$ any classifier has a conditional probability of error $1/2$ and there is nothing to prove.) Then $\mathbb{P}\{g_n(X,Z) \neq Y | X = x\} = (2\eta(x)-1)\mathbb{P}\{g_n(x,Z) = 0\} + 1 - \eta(x)$, and by consistency we have $\mathbb{P}\{g_n(x,Z) = 0\} \to 0$.

To prove consistency of the voting classifier $g_n^{(m)}$, it suffices to show that $\mathbb{P}\{g_n^{(m)}(x,Z^m) = 0\} \to 0$ for μ-almost all x for which $\eta(x) > 1/2$. However,

$$\begin{aligned}
\mathbb{P}\{g_n^{(m)}(x,Z^m) = 0\} &= \mathbb{P}\left\{ (1/m) \sum_{j=1}^m \mathbb{1}_{\{g_n(x,Z_j)=0\}} > 1/2 \right\} \\
&\leq 2\mathbb{E}\left[(1/m) \sum_{j=1}^m \mathbb{1}_{\{g_n(x,Z_j)=0\}} \right] \\
&\qquad \text{(by Markov's inequality)} \\
&= 2\mathbb{P}\{g_n(x,Z) = 0\} \to 0 \; .
\end{aligned}$$

Consistency of the averaged classifier is proved by a similar argument.

□

3. Random Forests

Random forests, introduced by Breiman, are averaged classifiers in the sense defined in Section 2.

Formally, a random forest with m trees is a classifier consisting of a collection of randomized base tree classifiers $g_n(x,Z_1), \ldots, g_n(x,Z_m)$ where $Z_1, \ldots, Z_m$ are identically distributed random vectors, independent conditionally on X, Y, and D_n.

The randomizing variable is typically used to determine how the successive cuts are performed when building the tree such as selection of the node and the coordinate to split, as well as the position of the split. The random forest classifier takes a majority vote among the random tree classifiers. If m is large, the random forest classifier is well approximated by the averaged classifier

$\overline{g}_n(x) = \mathbb{1}_{\{\mathbb{E}_Z g_n(x,Z) \geq 1/2\}}$. For brevity, we state most results of this paper for the averaged classifier only, though by Proposition 1 various results remain true for the voting classifier $g_n^{(m)}$ as well.

In this section we analyze a simple random forest already considered by Breiman (2000), which we call the *purely random forest*.

The random tree classifier $g_n(x,Z)$ is constructed as follows. Assume, for simplicity, that μ is supported on $[0,1]^d$. All nodes of the tree are associated with rectangular cells such that at each step of the construction of the tree, the collection of cells associated with the leaves of the tree (i.e., external nodes) forms a partition of $[0,1]^d$. The root of the random tree is $[0,1]^d$ itself. At each step of the construction of the tree, a leaf is chosen uniformly at random. The split variable J is then selected uniformly at random from the d candidates $x^{(1)},\ldots,x^{(d)}$. Finally, the selected cell is split along the randomly chosen variable at a random location, chosen according to a uniform random variable on the length of the chosen side of the selected cell. The procedure is repeated k times where $k \geq 1$ is a deterministic parameter, fixed beforehand by the user, and possibly depending on n.

The randomized classifier $g_n(x,Z)$ takes a majority vote among all Y_i for which the corresponding feature vector X_i falls in the same cell of the random partition as x. (For concreteness, break ties in favor of the label 1.)

The purely random forest classifier is a radically simplified version of random forest classifiers used in practice. The main simplification lies in the fact that recursive cell splits do not depend on the labels $Y_1,\ldots,Y_n$. The next theorem mainly serves as an illustration of how the consistency problem of random forest classifiers may be attacked. More involved versions of random forest classifiers are discussed in subsequent sections.

Theorem 2 *Assume that the distribution of X is supported on $[0,1]^d$. Then the purely random forest classifier $\overline{g}_n$ is consistent whenever $k \to \infty$ and $k/n \to 0$ as $k \to \infty$.*

Proof By Proposition 1 it suffices to prove consistency of the randomized base tree classifier g_n. To this end, we recall a general consistency theorem for partitioning classifiers proved in (Devroye, Györfi, and Lugosi, 1996, Theorem 6.1). According to this theorem, g_n is consistent if both $\mathrm{diam}(A_n(X,Z)) \to 0$ in probability and $N_n(X,Z) \to \infty$ in probability, where $A_n(x,Z)$ is the rectangular cell of the random partition containing x and

$$N_n(x,Z) = \sum_{i=1}^{n} \mathbb{1}_{\{X_i \in A_n(x,Z)\}}$$

is the number of data points falling in the same cell as x.

First we show that $N_n(X,Z) \to \infty$ in probability. Consider the random tree partition defined by Z. Observe that the partition has $k+1$ rectangular cells, say $A_1,\ldots,A_{k+1}$. Let $N_1,\ldots,N_{k+1}$ denote the number of points of $X,X_1,\ldots,X_n$ falling in these $k+1$ cells. Let $S = \{X,X_1,\ldots,X_n\}$ denote the set of positions of these $n+1$ points. Since these points are independent and identically distributed, fixing the *set* S (but not the order of the points) and Z, the conditional probability that X falls in the i-th cell equals $N_i/(n+1)$. Thus, for every fixed $t > 0$,

$$\begin{aligned}
\mathbb{P}\{N_n(X,Z) < t\} &= \mathbb{E}\left[\mathbb{P}\{N_n(X,Z) < t | S, Z\}\right] \\
&= \mathbb{E}\left[\sum_{i:N_i<t} \frac{N_i}{n+1}\right] \leq (t-1)\frac{k+1}{n+1}
\end{aligned}$$

which converges to zero by our assumption on k.

It remains to show that $\mathrm{diam}(A_n(X,Z)) \to 0$ in probability. To this aim, let $V_n = V_n(x,Z)$ be the size of the first dimension of the rectangle containing x. Let $T_n = T_n(x,Z)$ be the number of times that the box containing x is split when we construct the random tree partition.

Let K_n be binomial $(T_n, 1/d)$, representing the number of times the box containing x is split along the first coordinate.

Clearly, it suffices to show that $V_n(x,Z) \to 0$ in probability for μ-almost all x, so it is enough to show that for all x, $\mathbb{E}[V_n(x,Z)] \to 0$. Observe that if $U_1, U_2, \ldots$ are independent uniform $[0,1]$, then

$$\begin{aligned}
\mathbb{E}[V_n(x,Z)] &\leq \mathbb{E}\left[\mathbb{E}\left[\prod_{i=1}^{K_n} \max(U_i, 1-U_i) \,\middle|\, K_n\right]\right] \\
&= \mathbb{E}\left[\mathbb{E}[\max(U_1, 1-U_1)]^{K_n}\right] \\
&= \mathbb{E}\left[(3/4)^{K_n}\right] \\
&= \mathbb{E}\left[\left(1 - \frac{1}{d} + \frac{3}{4d}\right)^{T_n}\right] \\
&= \mathbb{E}\left[\left(1 - \frac{1}{4d}\right)^{T_n}\right].
\end{aligned}$$

Thus, it suffices to show that $T_n \to \infty$ in probability. To this end, note that the partition tree is statistically related to a random binary search tree with $k+1$ external nodes (and thus k internal nodes). Such a tree is obtained as follows. Initially, the root is the sole external node, and there are no internal nodes. Select an external node uniformly at random, make it an internal node and give it two children, both external. Repeat until we have precisely k internal nodes and $k+1$ external nodes. The resulting tree is the random binary search tree on k internal nodes (see Devroye 1988 and Mahmoud 1992 for more equivalent constructions of random binary search trees). It is known that all levels up to $\ell = \lfloor 0.37 \log k \rfloor$ are full with probability tending to one as $k \to \infty$ (Devroye, 1986). The last full level F_n is called the fill-up level. Clearly, the partition tree has this property. Therefore, we know that all final cells have been cut at least ℓ times and therefore $T_n \geq \ell$ with probability converging to 1. This concludes the proof of Theorem 3.1. □

Remark 3 *We observe that the largest first dimension among external nodes does not tend to zero in probability except for $d = 1$. For $d \geq 2$, it tends to a limit random variable that is not atomic at zero (this can be shown using the theory of branching processes). Thus the proof above could not have used the uniform smallness of all cells. Despite the fact that the random partition contains some cells of huge diameter of non-shrinking size, the rule based on it is consistent.*

Next we consider a scale-invariant version of the purely random forest classifier. In this variant the root cell is the entire feature space and the random tree is grown up to k cuts. The leaf cell to cut and the direction J in which the cell is cut are chosen uniformly at random, exactly as in the purely random forest classifier. The only difference is that the position of the cut is now chosen in a data-based manner: if the cell to be cut contains N of the data points $X, X_1, \ldots, X_n$, then a random index I is chosen uniformly from the set $\{0, 1, \ldots, N\}$ and the cell is cut so that, when ordered by their J-th components, the points with the I smallest values fall in one of the subcells and the rest in

the other. To avoid ties, we assume that the distribution of X has non-atomic marginals. In this case the random tree is well-defined with probability one. Just like before, the associated classifier takes a majority vote over the labels of the data points falling in the same cell as X. The *scale-invariant random forest* classifier is defined as the corresponding averaged classifier.

Theorem 4 *Assume that the distribution of X has non-atomic marginals in $\mathbb{R}^d$. Then the scale-invariant random forest classifier $\bar{g}_n$ is consistent whenever $k \to \infty$ and $k/n \to 0$ as $k \to \infty$.*

Proof Once again, we may use Proposition 1 and (Devroye, Györfi, and Lugosi, 1996, Theorem 6.1) to prove consistency of the randomized base tree classifier g_n. The proof of the fact that $N_n(X,Z) \to \infty$ in probability is the same as in Theorem 2.

To show that $\mathrm{diam}(A_n(X,Z)) \to 0$ in probability, we begin by noting that, just as in the case of the purely random forest classifier, the partition tree is equivalent to a binary search tree, and therefore with probability converging to one, all final cells have been cut at least $\ell = \lfloor 0.37 \log k \rfloor$ times.

Since the classification rule is scale-invariant, we may assume, without loss of generality, that the distribution of X is concentrated on the unit cube $[0,1]^d$.

Let n_i denote the cardinality of the i-th cell in the partition, $1 \le i \le k+1$, where the cardinality of a cell C is $|C \cap \{X, X_1, \ldots, X_n\}|$. Thus, $\sum_{i=1}^{k+1} n_i = n+1$. Let V_i be the first dimension of the i-th cell. Let $V(X)$ be the first dimension of the cell that contains X. Clearly, given the n_i's, $V(X) = V_i$ with probability $n_i/(n+1)$. We need to show that $\mathbb{E}[V(X)] \to 0$. But we have

$$\mathbb{E}[V(X)] = \mathbb{E}\left[\frac{\sum_{i=1}^{k+1} n_i V_i}{n+1}\right].$$

So, it suffices to show that $\mathbb{E}[\sum_i n_i V_i] = o(n)$.

It is worthy of mention that the random split of a box can be imagined as follows. Given that we split along the s-th coordinate axis, and that a box has m points, then we select one of the $m+1$ spacings defined by these m points uniformly at random, still for that s-th coordinate. We cut that spacing properly but are free to do so anywhere. We can cut in proportions $\lambda, 1-\lambda$ with $\lambda \in (0,1)$, and the value of λ may vary from cut to cut and even be data-dependent. In fact, then, each internal and external node of our partition tree has associated with it two important quantities, a cardinality, and its first dimension. If we keep using i to index cells, then we can use n_i and V_i for the i-th cell, even if it is an internal cell.

Let A be the collection of external nodes in the subtree of the i-th cell. Then trivially,

$$\sum_{j \in A} n_j V_j \le n_i V_i \le n.$$

Thus, if E is the collection of all external nodes of a partition tree, ℓ is at most the minimum path distance from any cell in E to the root, and L is the collection of all nodes at distance ℓ from the root, then, by the last inequality,

$$\sum_{i \in E} n_i V_i \le \sum_{i \in L} n_i V_i.$$

Thus, using the notion of fill-up level F_n of the binary search tree, and setting $\ell = \lfloor 0.37 \log k \rfloor$, we have

$$\mathbb{E}\left[\sum_{i \in E} n_i V_i\right] \le n\mathbb{P}\{F_n < \ell\} + \mathbb{E}\left[\sum_{i \in L} n_i V_i\right].$$

We have seen that the first term is $o(n)$. We argue that the second term is not more than $n(1-1/(8d))^{\ell}$, which is $o(n)$ since $k \to \infty$. That will conclude the proof.

It suffices now to argue recursively and fix one cell of cardinality n and first dimension V. Let C be the collection of its children. We will show that

$$\mathbb{E}\left[\sum_{i\in C} n_i V_i\right] \le \left(1-\frac{1}{8d}\right) nV.$$

Repeating this recursively ℓ times shows that

$$\mathbb{E}\left[\sum_{i\in L} n_i V_i\right] \le n\left(1-\frac{1}{8d}\right)^{\ell}$$

because $V = 1$ at the root.

Fix that cell of cardinality n, and assume without loss of generality that $V = 1$. Let the spacings along the first coordinate be $a_1, \ldots, a_{n+1}$, their sum being one. With probability $1-1/d$, there the first axis is not cut, and thus, $\sum_{i\in C} n_i V_i = n$. With probability $1/d$, the first axis is cut in two parts. We will show that conditional on the event that the first direction is cut,

$$\mathbb{E}\left[\sum_{i} n_i V_i\right] \le \frac{7n}{8}\ .$$

Unconditionally, we have

$$\mathbb{E}\left[\sum_{i} n_i V_i\right] \le \left(1-\frac{1}{d}\right) n + \frac{1}{d}\cdot\frac{7n}{8} = \left(1-\frac{1}{8d}\right) n\ ,$$

as required. So, let us prove the conditional result.

Using δ_j to denote numbers drawn from $(0,1)$, possibly random, we have

$$\begin{aligned}
&\mathbb{E}\left[\sum_i n_i V_i\right] \\
&= \frac{1}{n+1}\mathbb{E}\Big[\sum_{j=1}^{n+1}\big[(j-1)(a_1+\cdots+a_{j-1}+a_j\delta_j) \\
&\qquad +(n+1-j)(a_j(1-\delta_j)+a_{j+1}+\cdots+a_{n+1})\big]\Big] \\
&= \frac{1}{n+1}\mathbb{E}\left[\sum_{k=1}^{n+1} a_k\left(\sum_{k<j\le n+1}(j-1)\right.\right. \\
&\qquad \left.\left.+\sum_{1\le j<k}(n+1-j)+\delta_k(k-1)+(1-\delta_k)(n+1-k)\right)\right] \\
&\le \frac{1}{n+1}\left(\sum_{k=1}^{n+1} a_k\left(n(n+1)-\frac{k(k-1)}{2}\right.\right. \\
&\qquad \left.\left.-\frac{(n-k+1)(n-k+2)}{2}+\max(k-1,n+1-k)\right)\right)
\end{aligned}$$

$$

\end{aligned}
$$

□

Our definition of the scale-invariant random forest classifier permits cells to be cut such that one of the created cells becomes empty. One may easily prevent this by artificially forcing a minimum number of points in each cell. This may be done by restricting the random position of each cut so that both created subcells contain at least, say, m points. By a minor modification of the proof above it is easy to see that as long as m is bounded by a constant, the resulting random forest classifier remains consistent under the same conditions as in Theorem 4.

4. Creating Consistent Rules by Randomization

Proposition 1 shows that if a randomized classifier is consistent, then the corresponding averaged classifier remains consistent. The converse is not true. There exist inconsistent randomized classifiers such that their averaged version becomes consistent. Indeed, Breiman's (2001) original random forest classifier builds tree classifiers by successive randomized cuts until the cell of the point X to be classified contains only one data point, and classifies X as the label of this data point. Breiman's random forest classifier is just the averaged version of such randomized tree classifiers. The randomized base classifier $g_n(x,Z)$ is obviously not consistent for all distributions.

This does not imply that the averaged random forest classifier is not consistent. In fact, in this section we will see that averaging may "boost" inconsistent base classifiers into consistent ones. We point out in Section 6 that there are distributions of (X,Y) for which Breiman's random forest classifier is not consistent. The counterexample shown in Proposition 8 is such that the distribution of X doesn't have a density. It is possible, however, that Breiman's random forest classifier is consistent whenever the distribution of X has a density. Breiman's rule is difficult to analyze as each cut of the random tree is determined by a complicated function of the entire data set D_n (i.e., both feature vectors and labels). However, in Section 6 below we provide arguments suggesting that Breiman's random forest is not consistent when a density exists. Instead of Breiman's rule, next we analyze a stylized version by showing that inconsistent randomized rules that take the label of only one neighbor into account can be made consistent by averaging.

For simplicity, we consider the case $d = 1$, though the whole argument extends, in a straightforward way, to the multivariate case. To avoid complications introduced by ties, assume that X has a non-atomic distribution. Define a randomized nearest neighbor rule as follows: for a fixed $x \in \mathbb{R}$, let $X_{(1)}(x), X_{(2)}(x), \ldots, X_{(n)}(x)$ be the ordering of the data points $X_1, \ldots, X_n$ according to increasing distances from x. Let $U_1, \ldots, U_n$ be i.i.d. random variables, uniformly distributed over $[0,1]$. The vector of these random variables constitutes the randomization Z of the classifier. We define $g_n(x,Z)$

to be equal to the label $Y_{(i)}(x)$ of the data point $X_{(i)}(x)$ for which

$$\max(i, mU_i) \leq \max(j, mU_j) \quad \text{for all } j = 1, \ldots, n$$

where $m \leq n$ is a parameter of the rule. We call $X_{(i)}(x)$ the perturbed nearest neighbor of x. Note that $X_{(1)}(x)$ is the (unperturbed) nearest neighbor of x. To obtain the perturbed version, we artificially add a random uniform coordinate and select a data point with the randomized rule defined above. Since ties occur with probability zero, the perturbed nearest neighbor classifier is well defined almost surely. It is clearly not, in general, a consistent classifier.

Call the corresponding averaged classifier $\bar{g}_n(x) = \mathbb{1}_{\{\mathbb{E}_Z g_n(x,Z) \geq 1/2\}}$ the *averaged perturbed nearest neighbor classifier.*

In the proof of the consistency result below, we use Stone's (1977) general consistency theorem for locally weighted average classifiers, see also (Devroye, Györfi, and Lugosi, 1996, Theorem 6.3). Stone's theorem concerns classifiers that take the form

$$g_n(x) = \mathbb{1}_{\{\sum_{i=1}^n Y_i W_{ni}(x) \geq \sum_{i=1}^n (1-Y_i) W_{ni}(x)\}}$$

where the weights $W_{ni}(x) = W_{ni}(x, X_1, \ldots, X_n)$ are non-negative and sum to one. According to Stone's theorem, consistency holds if the following three conditions are satisfied:

(i)
$$\lim_{n\to\infty} \mathbb{E}\left[\max_{1\leq i\leq n} W_{ni}(X)\right] = 0.$$

(ii) For all $a > 0$,
$$\lim_{n\to\infty} \mathbb{E}\left[\sum_{i=1}^n W_{ni}(X)\, \mathbb{1}_{\{\|X_i - X\| > a\}}\right] = 0.$$

(iii) There is a constant c such that, for every non-negative measurable function f satisfying $\mathbb{E}f(X) < \infty$,
$$\mathbb{E}\left[\sum_{i=1}^n W_{ni}(X) f(X_i)\right] \leq c\mathbb{E}f(X).$$

Theorem 5 *The averaged perturbed nearest neighbor classifier $\bar{g}_n$ is consistent whenever the parameter m is such that $m \to \infty$ and $m/n \to 0$.*

Proof If we define

$$W_{ni}(x) = \mathbb{P}_Z\{X_i \text{ is the perturbed nearest neighbor of } x\}$$

then it is clear that the averaged perturbed nearest neighbor classifier is a locally weighted average classifier and Stone's theorem may be applied. It is convenient to introduce the notation

$$p_{ni}(x) = \mathbb{P}_Z\{X_{(i)}(x) \text{ is the perturbed nearest neighbor of } x\}$$

and write $W_{ni}(x) = \sum_{j=1}^n \mathbb{1}_{\{X_i = X_{(j)}(x)\}} p_{nj}(x)$.

To check the conditions of Stone's theorem, first note that

$$\begin{aligned} p_{ni}(x) &= \mathbb{P}\{mU_i \le i \le \min_{j<i} mU_j\} + \mathbb{P}\{i < mU_i \le \min_{j\le n} \max(j, mU_j)\} \\ &= \mathbb{1}_{\{i\le m\}} \frac{i}{m}\left(1-\frac{i}{m}\right)^{i-1} + \mathbb{P}\{i < mU_i \le \min_{j\le n} \max(j, mU_j)\}\ . \end{aligned}$$

Now we are prepared to check the conditions of Stone's theorem. To prove that (i) holds, note that by monotonicity of $p_{ni}(x)$ in i, it suffices to show that $p_{n1}(x) \to 0$.

But clearly, for $m \ge 2$,

$$\begin{aligned} p_{n1}(x) &\le \frac{1}{m} + \mathbb{P}\left\{U_1 \le \min_{j\le m} \max\left(\frac{j}{m}, U_j\right)\right\} \\ &= \frac{1}{m} + \mathbb{E}\left[\prod_{j=2}^{m} \mathbb{P}\left\{U_1 \le \max\left(\frac{j}{m}, U_j\right) | U_1\right\}\right] \\ &= \frac{1}{m} + \mathbb{E}\left[\prod_{j=2}^{m} \left[1 - \mathbb{1}_{\{U_1 > j/m\}} U_1\right]\right] \\ &\le \frac{1}{m} + \mathbb{E}\left[(1-U_1)^{mU_1-2} \mathbb{1}_{\{\lfloor mU_1\rfloor \ge 3\}}\right] + \mathbb{P}\left\{\lfloor mU_1\rfloor < 3\right\} \end{aligned}$$

which converges to zero by monotone convergence as $m \to \infty$.

(ii) follows by the condition $m/n \to 0$ since $\sum_{i=1}^n W_{ni}(X)\mathbb{1}_{\{\|X_i - X\| > a\}} = 0$ whenever the distance of m-th nearest neighbor of X to X is at most a. But this happens eventually, almost surely, see (Devroye, Györfi, and Lugosi, 1996, Lemma 5.1).

Finally, to check (iii), we use again the monotonicity of $p_{ni}(x)$ in i. We may write $p_{ni}(x) = a_i + a_{i+1} + \cdots + a_n$ for some non-negative numbers $a_j, 1 \le j \le n$, depending upon m and n but not x. Observe that $\sum_{j=1}^n j a_j = \sum_{i=1}^n p_{ni}(x) = 1$. But then

$$\begin{aligned} &\mathbb{E}\left[\sum_{i=1}^n W_{ni}(X) f(X_i)\right] \\ &= \mathbb{E}\left[\sum_{i=1}^n p_{ni}(X) f(X_{(i)})\right] \\ &= \mathbb{E}\left[\sum_{i=1}^n \sum_{j=i}^n a_j f(X_{(i)})\right] \\ &= \mathbb{E}\left[\sum_{j=1}^n a_j \sum_{i=1}^j f(X_{(i)})\right] \\ &= \sum_{j=1}^n a_j \mathbb{E}\left[\sum_{i=1}^j f(X_{(i)})\right] \end{aligned}$$

$$\leq \quad c\sum_{j=1}^{n} a_j j\mathbb{E}f(X)$$

(by Stone's (1977) lemma, see (Devroye, Györfi, and Lugosi, 1996, Lemma 5.3), where c is a constant)

$$= \quad c\mathbb{E}f(X)\sum_{j=1}^{n} a_j j = c\mathbb{E}f(X)$$

as desired. □

5. Bagging

One of the first and simplest ways of randomizing and averaging classifiers in order to improve their performance is *bagging*, suggested by Breiman (1996). In bagging, randomization is achieved by generating many bootstrap samples from the original data set. Breiman suggests selecting n training pairs (X_i,Y_i) at random, *with replacement* from the *bag* of all training pairs $\{(X_1,Y_1),\ldots,(X_n,Y_n)\}$. Denoting the random selection process by Z, this way one obtains new training data $D_n(Z)$ with possible repetitions and given a classifier $g_n(X,D_n)$, one can calculate the randomized classifier $g_n(X,Z,D_n) = g_n(X,D_n(Z))$. Breiman suggests repeating this procedure for many independent draws of the bootstrap sample, say m of them, and calculating the voting classifier $g_n^{(m)}(X,Z^m,D_n)$ as defined in Section 2.

In this section we consider a generalized version of bagging predictors in which the size of the bootstrap samples is not necessary the same as that the original sample. Also, to avoid complications and ambiguities due to replicated data points, we exclude repetitions in the bootstrapped data. This is assumed for convenience but sampling with replacement can be treated by minor modifications of the arguments below.

To describe the model we consider, introduce a parameter $q_n \in [0,1]$. In the bootstrap sample $D_n(Z)$ each data pair (X_i,Y_i) is present with probability q_n, independently of each other. Thus, the size of the bootstrapped data is a binomial random variable N with parameters n and q_n. Given a sequence of (non-randomized) classifiers $\{g_n\}$, we may thus define the randomized classifier

$$g_n(X,Z,D_n) = g_N(X,D_n(Z)) \ ,$$

that is, the classifier is defined based on the randomly re-sampled data. By drawing m independent bootstrap samples $D_n(Z_1),\ldots,D_n(Z_m)$ (with sizes $N_1,\ldots,N_m$), we may define the *bagging classifier* $g_n^{(m)}(X,Z^m,D_n)$ as the voting classifier based on the randomized classifiers $g_{N_1}(X,D_n(Z_1)),\ldots,$ $g_{N_m}(X,D_n(Z_m))$ as in Section 2. For the theoretical analysis it is more convenient to consider the averaged classifier $\bar{g}_n(x,D_n) = \mathbb{1}_{\{\mathbb{E}_Z g_N(x,D_n(Z))\geq 1/2\}}$ which is the limiting classifier one obtains as the number m of the bootstrap replicates grows to infinity.

The following result establishes consistency of bagging classifiers under the assumption that the original classifier is consistent. It suffices that the expected size of the bootstrap sample goes to infinity. The result is an immediate consequence of Proposition 1. Note that the choice of m does not matter in Theorem 6. It can be one, constant, or a function of n.

Theorem 6 *Let $\{g_n\}$ be a sequence of classifiers that is consistent for the distribution of (X,Y). Consider the bagging classifiers $g_n^{(m)}(x,Z^m,D_n)$ and $\bar{g}_n(x,D_n)$ defined above, using parameter q_n. If $nq_n \to \infty$ as $n \to \infty$ then both classifiers are consistent.*

If a classifier is insensitive to duplicates in the data, Breiman's original suggestion is roughly equivalent to taking $q_n \approx 1-1/e$.

However, it may be advantageous to choose much smaller values of q_n. In fact, small values of q_n may turn inconsistent classifiers into consistent ones via the bagging procedure. We illustrate this phenomenon on the simple example of the 1-nearest neighbor rule.

Recall that the 1-nearest neighbor rule sets $g_n(x,D_n) = Y_{(1)}(x)$ where $Y_{(1)}(x)$ is the label of the feature vector $X_{(1)}(x)$ whose Euclidean distance to x is minimal among all $X_1,\ldots,X_n$. Ties are broken in favor of smallest indices. It is well-known that g_n is consistent only if either $L^* = 0$ or $L^* = 1/2$, otherwise its asymptotic probability of error is strictly greater than L^*. However, by bagging one may turn the 1-nearest neighbor classifier into a consistent one, provided that the size of the bootstrap sample is sufficiently small. The next result characterizes consistency of the bagging version of the 1-nearest neighbor classifier in terms of the parameter q_n.

Theorem 7 *The bagging averaged* 1*-nearest neighbor classifier* $\overline{g}_n(x,D_n)$ *is consistent for all distributions of* (X,Y) *if and only if* $q_n \to 0$ *and* $nq_n \to \infty$.

Proof It is obvious that both $q_n \to 0$ and $nq_n \to \infty$ are necessary for consistency for all distributions.

Assume now that $q_n \to 0$ and $nq_n \to \infty$. The key observation is that $\overline{g}_n(x,D_n)$ is a locally weighted average classifier for which Stone's consistency theorem, recalled in Section 4, applies.

Recall that for a fixed $x \in \mathbb{R}$, $X_{(1)}(x), X_{(2)}(x), \ldots, X_{(n)}(x)$ denotes the ordering of the data points $X_1,\ldots,X_n$ according to increasing distances from x. (Points with equal distances to x are ordered according to their indices.) Observe that $\overline{g}_n$ may be written as

$$\overline{g}_n(x,D_n) = \mathbb{1}_{\{\sum_{i=1}^n Y_i W_{ni}(x) \geq \sum_{i=1}^n (1-Y_i) W_{ni}(x)\}}$$

where $W_{ni}(x) = \sum_{j=1}^n \mathbb{1}_{\{X_i = X_{(j)}(x)\}} p_{nj}(x)$ and $p_{ni}(x) = (1-q_n)^{i-1} q_n$ is defined as the probability (with respect to the random selection Z of the bootstrap sample) that $X_{(i)}(x)$ is the nearest neighbor of x in the sample $D_n(Z)$. It suffices to prove that the weights $W_{ni}(X)$ satisfy the three conditions of Stone's theorem.

Condition (i) obviously holds because $\max_{1\leq i\leq n} W_{ni}(X) = p_{n1}(X) = q_n \to 0$.

To check condition (ii), define $k_n = \left\lceil \sqrt{n/q_n} \right\rceil$. Since $nq_n \to \infty$ implies that $k_n/n \to 0$, it follows from (Devroye, Györfi, and Lugosi, 1996, Lemma 5.1) that eventually, almost surely, $\|X - X_{(k_n)}(X)\| \leq a$ and therefore

$$\begin{aligned}
\sum_{i=1}^n W_{ni}(X) \mathbb{1}_{\{\|X_i - X\| > a\}} &\leq \sum_{i=k_n+1}^n p_{ni}(X) \\
&= \sum_{i=k_n+1}^n q_n (1-q_n)^{i-1} \\
&\leq (1-q_n)^{k_n} \\
&\leq (1-q_n)^{\sqrt{n/q_n}} \\
&\leq e^{-\sqrt{nq_n}}
\end{aligned}$$

where we used $1 - q_n \leq e^{-q_n}$. Therefore, $\sum_{i=1}^n W_{ni}(X) \mathbb{1}_{\{\|X_i - X\| > a\}} \to 0$ almost surely and Stone's second condition is satisfied by dominated convergence.

Finally, condition (iii) follows from the fact that $p_{ni}(x)$ is monotone decreasing in i, after using an argument as in the proof of Theorem 5. $\square$

6. Random Forests Based on Greedily Grown Trees

In this section we study random forest classifiers that are based on randomized tree classifiers that are constructed in a greedy manner, by recursively splitting cells to minimize an empirical error criterion. Such greedy forests were introduced by Breiman (2001, 2004) and have shown excellent performance in many applications. One of his most popular classifiers is an averaging classifier, $\overline{g}_n$, based on a randomized tree classifier $g_n(x,Z)$ defined as follows. The algorithm has a parameter $1 \leq v < d$ which is a positive integer. The feature space $\mathbb{R}^d$ is partitioned recursively to form a tree partition. The root of the random tree is $\mathbb{R}^d$. At each step of the construction of the tree, a leaf is chosen uniformly at random. v variables are selected uniformly at random from the d candidates $x^{(1)},\ldots,x^{(d)}$. A split is selected along one of these v variables to minimize the number of misclassified training points if a majority vote is used in each cell. The procedure is repeated until every cell contains exactly one training point X_i. (This is always possible if the distribution of X has non-atomic marginals.)

In some versions of Breiman's algorithm, a bootstrap subsample of the training data is selected before the construction of each tree to increase the effect of randomization.

As observed by Lin and Jeon (2006), Breiman's classifier is a weighted *layered nearest neighbor* classifier, that is, a classifier that takes a (weighted) majority vote among the layered nearest neighbors of the observation x. X_i is called a layered nearest neighbor of x if the rectangle defined by x and X_i as their opposing vertices does not contain any other data point X_j ($j \neq i$). This property of Breiman's random forest classifier is a simple consequence of the fact that each tree is grown until every cell contains just one data point. Unfortunately, this simple property prevents the random tree classifier from being consistent for all distributions:

Proposition 8 *There exists a distribution of (X,Y) such that X has non-atomic marginals for which Breiman's random forest classifier is not consistent.*

Proof The proof works for any weighted layered nearest neighbor classifier. Let the distribution of X be uniform on the segment $\{x = (x^{(1)},\ldots,x^{(d)}) : x^{(1)} = \cdots = x^{(d)}, x^{(1)} \in [0,1]\}$ and let the distribution of Y be such that $L^* \neq \{0,1/2\}$. Then with probability one, X has only two layered nearest neighbors and the classification rule is not consistent. (Note that Problem 11.6 in Devroye, Györfi, and Lugosi 1996 erroneously asks the reader to prove consistency of the (unweighted) layered nearest neighbor rule for any distribution with non-atomic marginals. As the example in this proof shows, the statement of the exercise is incorrect. Consistency of the layered nearest neighbor rule is true however, if the distribution of X has a density.) $\square$

One may also wonder whether Breiman's random forest classifier is consistent if instead of growing the tree down to cells with a single data point, one uses a different stopping rule, for example if one fixes the total number of cuts at k and let k grow slowly as in the examples of Section 3. The next two-dimensional example provides an indication that this is not necessarily the case. Consider the joint distribution of (X,Y) sketched in Figure 1. X has a uniform distribution on $[0,1]\times[0,1] \cup [1,2]\times[1,2] \cup [2,3]\times[2,3]$. Y is a function of X, that is $\eta(x) \in \{0,1\}$ and $L^* = 0$. The lower left square $[0,1]\times[0,1]$ is divided into countably infinitely many vertical stripes in

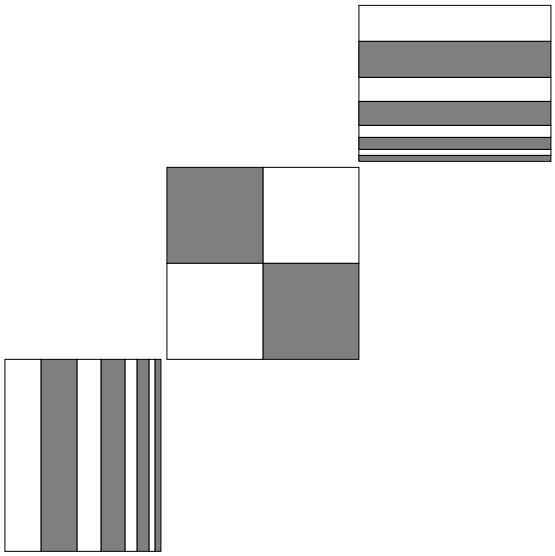

Figure 1: An example of a distribution for which greedy random forests are inconsistent. The distribution of X is uniform on the union of the three large squares. White areas represent the set where $\eta(x) = 0$ and on the grey regions $\eta(x) = 1$.

which the stripes with $\eta(x) = 0$ and $\eta(x) = 1$ alternate. The upper right square $[2,3] \times [2,3]$ is divided similarly into horizontal stripes. The middle rectangle $[1,2] \times [1,2]$ is a 2×2 checkerboard. Consider Breiman's random forest classifier with $v = 1$ (the only possible choice when $d = 2$).

For simplicity, consider the case when, instead of minimizing the empirical error, each tree is grown by minimizing the true probability of error at each split in each random tree. Then it is easy to see that no matter what the sequence of random selection of split directions is and no matter for how long each tree is grown, no tree will ever cut the middle rectangle and therefore the probability of error of the corresponding random forest classifier is at least $1/6$.

It is not so clear what happens in this example if the successive cuts are made by minimizing the empirical error. Whether the middle square is ever cut will depend on the precise form of the stopping rule and the exact parameters of the distribution. The example is here to illustrate that consistency of greedily grown random forests is a delicate issue. Note however that if Breiman's original algorithm is used in this example (i.e., when all cells with more than one data point in it are split) then one obtains a consistent classification rule. If, on the other hand, horizontal or vertical cuts are selected to minimize the probability of error, and $k \to \infty$ in such a way that $k = O(n^{1/2-\varepsilon})$ for some $\varepsilon > 0$, then, as errors on the middle square are never more than about $O(1/\sqrt{n})$ (by the limit law for the Kolmogorov-Smirnov statistic), we see that thin strips of probability mass more than $1/\sqrt{n}$ are preferentially cut. By choosing the probability weights of the strips, one can easily see that we can construct more than $2k$ such strips. Thus, when $k = O(n^{1/2-\varepsilon})$, no consistency is possible on that example.

We note here that many versions of random forest classifiers build on random tree classifiers based on bootstrap subsampling. This is the case of Breiman's principal random forest classifier.

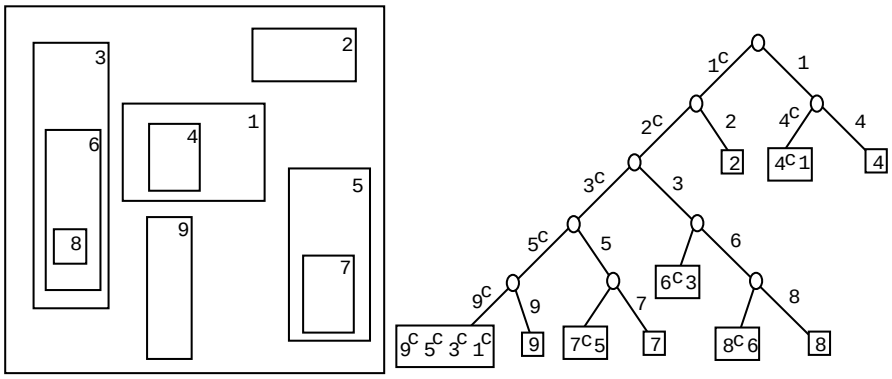

Figure 2: A tree based on partitioning the plane into rectangles. The right subtree of each internal node belongs to the inside of a rectangle, and the left subtree belongs to the complement of the same rectangle (i^c denotes the complement of i). Rectangles are not allowed to overlap.

Breiman suggests to take a random sample of size n drawn with replacement from the original data. While this may result in an improved behavior in some practical instances, it is easy to see that such a subsampling procedure does not vary the consistency property of any of the classifiers studied in this paper. For example, non-consistency of Breiman's random forest classifier with bootstrap resampling for the distribution considered in the proof of Proposition 8 follows from the fact that the two layered nearest neighbors on both sides are included in the bootstrap sample with a probability bounded away from zero and therefore the weight of these two points is too large, making consistency impossible.

In order to remedy the inconsistency of greedily grown tree classifiers, (Devroye, Györfi, and Lugosi, 1996, Section 20.14) introduce a greedy tree classifier which, instead of cutting every cell along just one direction, cuts out a whole hyper-rectangle from a cell in a way to optimize the empirical error. The disadvantage of this method is that in each step, d parameters need to be optimized jointly and this may be computationally prohibitive if d is not very small. (The computational complexity of the method is $O(n^d)$.) However, we may use the methodology of random forests to define a computationally feasible consistent greedily grown random forest classifier.

In order to define the consistent greedy random forest, we first recall the tree classifier of (Devroye, Györfi, and Lugosi, 1996, Section 20.14).

The space is partitioned into rectangles as shown in Figure 2.

A hyper-rectangle defines a split in a natural way. A partition is denoted by $\mathcal{P}$, and a decision on a set $A \in \mathcal{P}$ is by majority vote. We write $g_{\mathcal{P}}$ for such a rule:

$$g_{\mathcal{P}}(x) = \mathbb{1}_{\{\sum_{i:X_i \in A(x)} Y_i > \sum_{i:X_i \in A(x)} (1-Y_i)\}}$$

where $A(x)$ denotes the cell of the partition containing x. Given a partition $\mathcal{P}$, a legal hyper-rectangle T is one for which $T \cap A = \emptyset$ or $T \subseteq A$ for all sets $A \in \mathcal{P}$. If we refine $\mathcal{P}$ by adding a legal rectangle T somewhere, then we obtain the partition $\mathcal{T}$. The decision $g_{\mathcal{T}}$ agrees with $g_{\mathcal{P}}$ except on the set $A \in \mathcal{P}$ that contains T.

Introduce the convenient notation

$$\begin{aligned} \nu_j(A) &= \mathbb{P}\{X \in A, Y = j\},\ j \in \{0,1\}, \\ \nu_{j,n}(A) &= \frac{1}{n}\sum_{i=1}^{n} I_{\{X_i \in A, Y_i = j\}},\ j \in \{0,1\}. \end{aligned}$$

The empirical error of $g_{\mathcal{P}}$ is

$$\widehat{L}_n(\mathcal{P}) \stackrel{\text{def}}{=} \sum_{R \in \mathcal{P}} \widehat{L}_n(R),$$

where

$$\widehat{L}_n(R) = \frac{1}{n}\sum_{i=1}^{n} I_{\{X_i \in R, g_{\mathcal{P}}(X_i) \neq Y_i\}} = \min(\nu_{0,n}(R), \nu_{1,n}(R)).$$

We may similarly define $\widehat{L}_n(\mathcal{T})$. Given a partition $\mathcal{P}$, the greedy classifier selects that legal rectangle T for which $\widehat{L}_n(\mathcal{T})$ is minimal (with any appropriate policy for breaking ties). Let R be the set of $\mathcal{P}$ containing T. Then the greedy classifier picks that T for which

$$\widehat{L}_n(T) + \widehat{L}_n(R - T) - \widehat{L}_n(R)$$

is minimal. Starting with the trivial partition $\mathcal{P}_0 = \{\mathbb{R}^d\}$, we repeat the previous step k times, leading thus to $k+1$ regions. The sequence of partitions is denoted by $\mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_k$.

(Devroye, Györfi, and Lugosi, 1996, Theorem 20.9) establish consistency of this classifier. More precisely, it is shown that if X has non-atomic marginals, then the greedy classifier with $k \to \infty$ and $k = o\left(\sqrt{n/\log n}\right)$ is consistent.

Based on the greedy tree classifier, we may define a random forest classifier by considering its bagging version. More precisely, let $q_n \in [0,1]$ be a parameter and let $Z = Z(D_n)$ denote a random subsample of size binomial (n, q_n) of the training data (i.e., each pair (X_i, Y_i) is selected at random, without replacement, from D_n, with probability q_n) and let $g_n(x, Z)$ be the greedy tree classifier (as defined above) based on the training data $Z(D_n)$. Define the corresponding averaged classifier $\overline{g}_n$. We call $\overline{g}_n$ the *greedy random forest* classifier. Note that $\overline{g}_n$ is just the bagging version of the greedy tree classifier and therefore Theorem 6 applies:

Theorem 9 *The greedy random forest classifier is consistent whenever X has non-atomic marginals in $\mathbb{R}^d$, $nq_n \to \infty$, $k \to \infty$ and $k = o\left(\sqrt{nq_n/\log(nq_n)}\right)$ as $n \to \infty$.*

Proof This follows from Theorem 6 and the fact that the greedy tree classifier is consistent (see Theorem 20.9 of Devroye, Györfi, and Lugosi (1996)). □

Observe that the computational complexity of building the randomized tree classifier $g_n(x, Z)$ is $O((nq_n)^d)$. Thus, the complexity of computing the voting classifier $g_n^{(m)}$ is $m(nq_n)^d$. If $q_n \ll 1$, this may be a significant speed-up compared to the complexity $O(n^d)$ of computing a single tree classifier using the full sample. Repeated subsampling and averaging may make up for the effect of decreased sample size.

Abstract

We provide a comprehensive overview of many recent algorithms for approximate inference in Gaussian process models for probabilistic binary classification. The relationships between several approaches are elucidated theoretically, and the properties of the different algorithms are corroborated by experimental results. We examine both 1) the quality of the predictive distributions and 2) the suitability of the different marginal likelihood approximations for model selection (selecting hyperparameters) and compare to a gold standard based on MCMC. Interestingly, some methods produce good predictive distributions although their marginal likelihood approximations are poor. Strong conclusions are drawn about the methods: The Expectation Propagation algorithm is almost always the method of choice unless the computational budget is very tight. We also extend existing methods in various ways, and provide unifying code implementing all approaches.

Keywords: Gaussian process priors, probabilistic classification, Laplaces's approximation, expectation propagation, variational bounding, mean field methods, marginal likelihood evidence, MCMC

1. Introduction

Gaussian processes (GPs) can conveniently be used to specify prior distributions for Bayesian inference. In the case of regression with Gaussian noise, inference can be done simply in closed form, since the posterior is also a GP. For non-Gaussian likelihoods, such as e.g., in binary classification, exact inference is analytically intractable.

One prolific line of attack is based on approximating the non-Gaussian posterior with a tractable Gaussian distribution. One might think that finding such an approximating GP is a well-defined problem with a largely unique solution. However, we find no less than three different types of solution in the recent literature: Laplace Approximation (LA) (Williams and Barber, 1998), Expectation Propagation (EP) (Minka, 2001a) and Kullback-Leibler divergence (KL) minimization (Opper and Archambeau, 2008) comprising Variational Bounding (VB) (Gibbs and MacKay, 2000) as a special

∗. Also at Max Planck Institute for Biological Cybernetics, Spemannstraße 38, 72076 Tübingen, Germany.

case. Another approach is based on a factorial approximation, rather than a Gaussian (Csató et al., 2000).

Practical applications reflect the richness of approximate inference methods: LA has been used for sequence annotation (Altun et al., 2004) and prostate cancer prediction (Chu et al., 2005), EP for affect recognition (Kapoor and Picard, 2005), VB for weld cracking prognosis (Gibbs and MacKay, 2000), Label Regression (LR) serves for object categorization (Kapoor et al., 2007) and MCMC sampling is applied to rheuma diagnosis (Schwaighofer et al., 2002). Brain computer interfaces (Zhong et al., 2008) even rely on several (LA, EP, VB) methods.

In this paper, we compare these different approximations and provide insights into the strengths and weaknesses of each method, extending the work of Kuss and Rasmussen (2005) in several directions: We cover many more approximation methods (VB,KL,FV,LR), put all of them in common framework and provide generic implementations dealing with both the logistic and the cumulative Gaussian likelihood functions and clarify the aspects of the problem causing difficulties for each method. We derive Newton's method for KL and VB. We show how to accelerate MCMC simulations. We highlight numerical problems, comment on computational complexity and supply runtime measurements based on experiments under a wide range of conditions, including different likelihood and different covariance functions. We provide deeper insights into the methods behavior by systematically linking them to each other. Finally, we review the tight connections to methods from the literature on Statistical Physics, including the TAP approximation and TAPnaive.

The quantities of central importance are the quality of the probabilistic predictions and the suitability of the approximate marginal likelihood for selecting parameters of the covariance function (hyperparameters). The marginal likelihood for any Gaussian approximate posterior can be lower bounded using Jensen's inequality, but the specific approximation schemes also come with their own marginal likelihood approximations.

We are able to draw clear conclusions. Whereas every method has good performance under some circumstances, only a single method gives consistently good results. We are able to theoretically corroborate our experimental findings; together this provides solid evidence and guidelines for choosing an approximation method in practice.

2. Gaussian Processes for Binary Classification

We describe probabilistic binary classification based on Gaussian processes in this section. For a graphical model representation see Figure 1 and for a 1d pictorial description consult Figure 2. Given data points $\mathbf{x}_i$ from a domain $\mathcal{X}$ with corresponding class labels $y_i \in \{-1,+1\}$, one would like to predict the class membership probability for a test point $\mathbf{x}_*$. This is achieved by using a *latent function* f whose value is mapped into the unit interval by means of a sigmoid function $\mathrm{sig}:\mathbb{R}\to[0,1]$ such that the class membership probability $\mathbb{P}(y=+1|\mathbf{x})$ can be written as $\mathrm{sig}(f(\mathbf{x}))$. The class membership probability must normalize $\sum_y \mathbb{P}(y|\mathbf{x})=1$, which leads to $\mathbb{P}(y=+1|\mathbf{x})=1-\mathbb{P}(y=-1|\mathbf{x})$. If the sigmoid function satisfies the point symmetry condition $\mathrm{sig}(t)=1-\mathrm{sig}(-t)$, the *likelihood* can be compactly written as

$$\mathbb{P}(y|\mathbf{x}) \quad = \quad \mathrm{sig}(y\cdot f(\mathbf{x}))\,.$$

In this paper, two point symmetric sigmoids are considered

$$\begin{aligned} \mathrm{sig}_{\mathrm{logit}}(t) &:= \frac{1}{1+e^{-t}} \\ \mathrm{sig}_{\mathrm{probit}}(t) &:= \int_{-\infty}^{t} \mathcal{N}(\tau|0,1)\mathrm{d}\tau. \end{aligned}$$

The two functions are very similar at the origin (showing locally linear behavior around $\mathrm{sig}(0) = 1/2$ with slope $1/4$ for $\mathrm{sig}_{\mathrm{logit}}$ and $1/\sqrt{2\pi}$ for $\mathrm{sig}_{\mathrm{probit}}$) but differ in how fast they approach $0/1$ when t goes to infinity. For large negative values of t, we have the asymptotics

$$\mathrm{sig}_{\mathrm{logit}}(t) \approx \exp(-t) \quad \text{and} \quad \mathrm{sig}_{\mathrm{probit}}(t) \approx \exp(-\frac{1}{2}t^2 + 0.158t - 1.78), \text{ for } t \ll 0.$$

Linear decay of $\ln(\mathrm{sig}_{\mathrm{logit}})$ corresponds to a weaker penalty for wrongly classified examples than the quadratic decay of $\ln(\mathrm{sig}_{\mathrm{probit}})$.

For notational convenience, the following shorthands are used: The matrix $\mathbf{X} = [\mathbf{x}_1, \ldots, \mathbf{x}_n]$ of size $n \times d$ collects the training points, the vector $\mathbf{y} = [y_1, \ldots, y_n]^\top$ of size $n \times 1$ collects the target values and latent function values are summarized by $\mathbf{f} = [f_1, \ldots, f_n]^\top$ with $f_i = f(\mathbf{x}_i)$. Observed data is written as $\mathcal{D} = \{(\mathbf{x}_i, y_i) \,|\, i = 1, \ldots, n\} = (\mathbf{X}, \mathbf{y})$. Quantities carrying an asterisk refer to test points, that is, $\mathbf{f}_*$ contains the latent function values for test points $[\mathbf{x}_{*,1}, \ldots, \mathbf{x}_{*,m}] = \mathbf{X}_* \subset \mathcal{X}$. Covariances between latent values $\mathbf{f}$ and $\mathbf{f}_*$ at data points $\mathbf{x}$ and $\mathbf{x}_*$ follow the same notation, namely $[\mathbf{K}_{**}]_{ij} = k(\mathbf{x}_{*,i}, \mathbf{x}_{*,j})$, $[\mathbf{K}_*]_{ij} = k(\mathbf{x}_i, \mathbf{x}_{*,j})$, $[\mathbf{k}_*]_i = k(\mathbf{x}_i, \mathbf{x}_*)$ and $k_{**} = k(x_*, x_*)$, where $[\mathbf{A}]_{ij}$ denotes the entry A_{ij} of the matrix $\mathbf{A}$.

Given the latent function f, the class labels are assumed to be Bernoulli distributed and independent random variables, which gives rise to a *factorial likelihood*, factorizing over data points (see Figure 1)

$$\mathbb{P}(\mathbf{y}|f) \;=\; \mathbb{P}(\mathbf{y}|\mathbf{f}) \;=\; \prod_{i=1}^{n} \mathbb{P}(y_i|f_i) \;=\; \prod_{i=1}^{n} \mathrm{sig}(y_i f_i). \tag{1}$$

A GP (Rasmussen and Williams, 2006) is a stochastic process fully specified by a *mean function* $m(\mathbf{x}) = \mathbb{E}[f(\mathbf{x})]$ and a positive definite *covariance function* $k(\mathbf{x}, \mathbf{x}') = \mathbb{V}[f(\mathbf{x}), f(\mathbf{x}')]$. This means that a random variable $f(\mathbf{x})$ is associated to every $\mathbf{x} \in \mathcal{X}$, such that for any set of inputs $\mathbf{X} \subset \mathcal{X}$, the joint distribution $\mathbb{P}(\mathbf{f}|\mathbf{X}, \boldsymbol{\theta}) = \mathcal{N}(\mathbf{f}|\mathbf{m}_0, \mathbf{K})$ is Gaussian with mean vector $\mathbf{m}_0$ and covariance matrix $\mathbf{K}$. The mean function and covariance functions may depend on additional *hyperparameters* $\boldsymbol{\theta}$. For notational convenience we will assume $m(x) \equiv 0$ throughout. Thus, the elements of $\mathbf{K}$ are $K_{ij} = k(\mathbf{x}_i, \mathbf{x}_j, \boldsymbol{\theta})$.

By application of Bayes' rule, one gets an expression for the *posterior* distribution over the latent values $\mathbf{f}$

$$\mathbb{P}(\mathbf{f}|\mathbf{y}, \mathbf{X}, \boldsymbol{\theta}) \;=\; \frac{\mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X}, \boldsymbol{\theta})}{\int \mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X}, \boldsymbol{\theta})\,\mathrm{d}\mathbf{f}} \;=\; \frac{\mathcal{N}(\mathbf{f}|\mathbf{0}, \mathbf{K})}{\mathbb{P}(\mathbf{y}|\mathbf{X}, \boldsymbol{\theta})} \prod_{i=1}^{n} \mathrm{sig}(y_i f_i), \tag{2}$$

where $Z = \mathbb{P}(\mathbf{y}|\mathbf{X}, \boldsymbol{\theta}) = \int \mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X}, \boldsymbol{\theta})\,\mathrm{d}\mathbf{f}$ denotes the *marginal likelihood* or *evidence* for the hyperparameter $\boldsymbol{\theta}$. The joint prior over training and test latent values $\mathbf{f}$ and $\mathbf{f}_*$ given the corresponding inputs is

$$\mathbb{P}(\mathbf{f}_*, \mathbf{f} | \mathbf{X}_*, \mathbf{X}, \boldsymbol{\theta}) \quad = \quad \mathcal{N}\left(\begin{bmatrix} \mathbf{f} \\ \mathbf{f}_* \end{bmatrix} \middle| \mathbf{0}, \begin{bmatrix} \mathbf{K} & \mathbf{K}_* \\ \mathbf{K}_*^\top & \mathbf{K}_{**} \end{bmatrix} \right).$$

When making predictions, we marginalize over the training set latent variables

$$\mathbb{P}(\mathbf{f}_* | \mathbf{X}_*, \mathbf{y}, \mathbf{X}, \boldsymbol{\theta}) = \int \mathbb{P}(\mathbf{f}_*, \mathbf{f} | \mathbf{X}_*, \mathbf{y}, \mathbf{X}, \boldsymbol{\theta}) \, \mathrm{d}\mathbf{f} = \int \mathbb{P}(\mathbf{f}_* | \mathbf{f}, \mathbf{X}_*, \mathbf{X}, \boldsymbol{\theta}) \, \mathbb{P}(\mathbf{f} | \mathbf{y}, \mathbf{X}, \boldsymbol{\theta}) \, \mathrm{d}\mathbf{f}, \tag{3}$$

where the joint posterior is factored into the product of the posterior and the conditional prior

$$\mathbb{P}(\mathbf{f}_* | \mathbf{f}, \mathbf{X}_*, \mathbf{X}, \boldsymbol{\theta}) \quad = \quad \mathcal{N}\left(\mathbf{f}_* | \mathbf{K}_*^\top \mathbf{K}^{-1} \mathbf{f}, \mathbf{K}_{**} - \mathbf{K}_*^\top \mathbf{K}^{-1} \mathbf{K}_* \right).$$

Finally, the predictive class membership probability $p_* := \mathbb{P}(y_* = 1 | \mathbf{x}_*, \mathbf{y}, \mathbf{X}, \boldsymbol{\theta})$ is obtained by averaging out the test set latent variables

$$\mathbb{P}(y_* | \mathbf{x}_*, \mathbf{y}, \mathbf{X}, \boldsymbol{\theta}) = \int \mathbb{P}(y_* | f_*) \, \mathbb{P}(f_* | \mathbf{x}_*, \mathbf{y}, \mathbf{X}, \boldsymbol{\theta}) \, d f_* \; = \; \int \mathrm{sig}(y_* f_*) \, \mathbb{P}(f_* | \mathbf{x}_*, \mathbf{y}, \mathbf{X}, \boldsymbol{\theta}) \, \mathrm{d} f_*. \tag{4}$$

The integral is analytically tractable for $\mathrm{sig}_{\mathrm{probit}}$ (Rasmussen and Williams, 2006, Ch. 3.9) and can be efficiently approximated for $\mathrm{sig}_{\mathrm{logit}}$ (Williams and Barber, 1998, App. A).

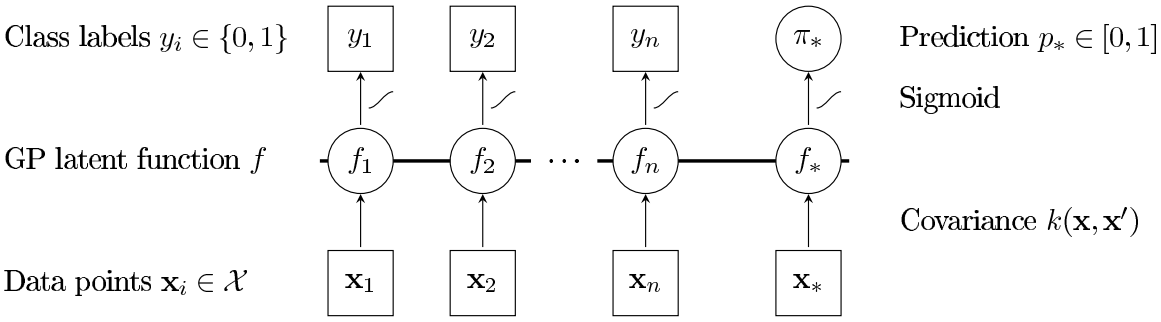

Figure 1: Graphical Model for binary Gaussian process classification: Circles represent unknown quantities, squares refer to observed variables. The horizontal thick line means fully connected latent variables. An observed label y_i is conditionally independent of all other nodes given the corresponding latent variable f_i. Labels y_i and latent function values f_i are connected through the sigmoid likelihood; all latent function values f_i are fully connected, since they are drawn from the same GP. The labels y_i are binary, whereas the prediction p_* is a probability and can thus have values from the whole interval $[0,1]$.

2.1 Stationary Covariance Functions

In preparation for the analysis of the approximation schemes described in this paper, we investigate some simple properties of the posterior for stationary covariance functions in different regimes

encountered in classification. Stationary covariances of the form $k(\mathbf{x},\mathbf{x}',\boldsymbol{\theta}) = \sigma_f^2 g(|\mathbf{x}-\mathbf{x}'|/\ell)$ with $g:\mathbb{R}\to\mathbb{R}$ a monotonously decreasing function[1] and $\boldsymbol{\theta} = \{\sigma_f,\ell\}$ are widely used. The following section supplies a geometric intuition of that specific prior in the classification scenario by analyzing the limiting behavior of the covariance matrix $\mathbf{K}$ as a function of the length scale ℓ and the limiting behavior of the likelihood as a function of the latent function scale σ_f. A pictorial illustration of the setting is given in Figure 3.

2.1.1 LENGTH SCALE

Two limiting cases of "ignorance with respect to the data" with marginal likelihood $Z = 2^{-n}$ can be distinguished, where $\mathbb{1} = [1,\dots 1]^\top$ and $\mathbf{I}$ is the identity matrix (see Appendix B.1)

$$\begin{aligned}\lim_{\ell\to 0}\mathbf{K} &= \sigma_f^2\mathbf{I},\\ \lim_{\ell\to\infty}\mathbf{K} &= \sigma_f^2\mathbb{1}\mathbb{1}^\top.\end{aligned}$$

For very small length scales ($\ell\to 0$), the prior is simply isotropic as all points are deemed to be far away from each other and the whole model factorizes. Thus, the (identical) posterior moments can be calculated dimension-wise. (See Figure 3, regimes 1, 4 and 7.)

For very long length scales ($\ell\to\infty$), the prior becomes degenerate as all datapoints are deemed to be close to each other and takes the form of a cigar along the hyper-diagonal. (See Figure 3, regimes 3, 6 and 9.) A 1d example of functions drawn from GP priors with different lengthscales ℓ is shown in Figure 2 on the left. The lengthscale has to be suited to the data; if chosen too small, we will overfit, if chosen too high underfitting will occur.

2.1.2 LATENT FUNCTION SCALE

The sigmoid likelihood function $\mathrm{sig}(y_i f_i)$ measures the agreement of the signs of the latent function and the label in a smooth way, that is, values close to one if the signs of y_i and f_i are the same and $|f_i|$ is large, and values close to zero if the signs are different and $|f_i|$ is large. The latent function scale σ_f of the data can be moved into the likelihood $\tilde{\mathrm{sig}}_{\sigma_f}(t) = \mathrm{sig}(\sigma_f^2 t)$, thus σ_f models the steepness of the likelihood and finally the smoothness of the agreement by interpolation between the two limiting cases "ignorant" and "hard cut"

$$\begin{aligned}\lim_{\sigma_f\to 0}\mathrm{sig}(t) &\equiv \frac{1}{2} \quad \text{"ignorant",}\\ \lim_{\sigma_f\to\infty}\mathrm{sig}(t) &\equiv \mathrm{step}(t) := \begin{cases} 0, t<0; & \frac{1}{2}, t=0; & 1, 0<t \end{cases} \quad \text{"hard cut".}\end{aligned}$$

In the case of very small latent scales ($\sigma_f\to 0$), the likelihood is flat causing the posterior to equal the prior. The marginal likelihood is again $Z = 2^{-n}$. (See Figure 3, regimes 7, 8 and 9.)

In the case of large latent scales ($\sigma_f \gg 1$), the likelihood approaches the step function. (See Figure 3, regimes 1, 2 and 3.) A further increase of the latent scale does not change the model anymore. The model is effectively the same for all σ_f above a threshold.

1. Furthermore, we require $g(0) = 1$ and $\lim_{t\to\infty} g(t) = 0$.

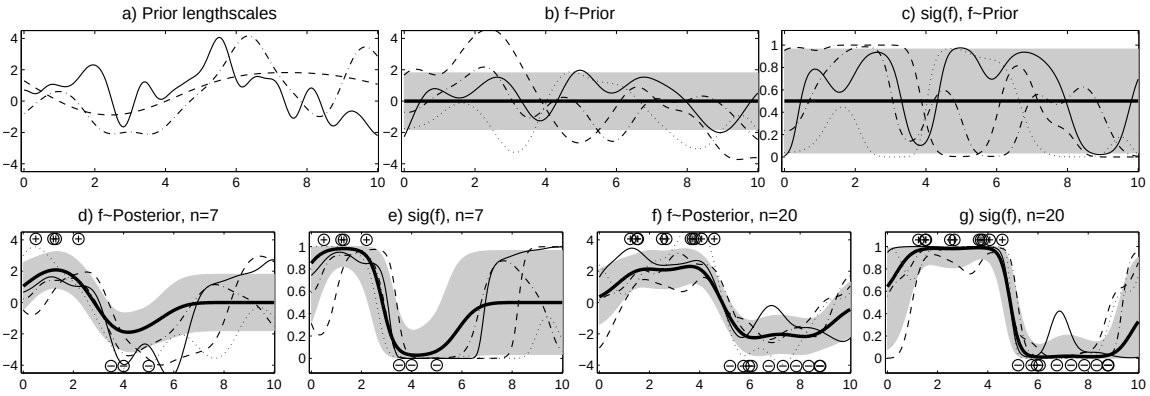

Figure 2: Pictorial illustration of binary Gaussian process classification in 1d: Plot a) shows 3 sample functions drawn from GPs with different lengthscales ℓ. Then, three pairs of plots show distributions over functions $f : \mathbb{R} \to \mathbb{R}$ and $\mathrm{sig}(f) : \mathbb{R} \to [0,1]$ occurring in GP classification. b+c) the prior, d+e) a posterior with $n = 7$ observations and f+g) a posterior with $n = 20$ observations along with the n observations with binary labels. The thick black line is the mean, the gray background is the $\pm$ standard deviation and the thin lines are sample functions. With more and more data points observed, the uncertainty is gradually shrunk. At the decision boundary the uncertainty is smallest.

2.2 Gaussian Approximations

Unfortunately, the posterior over the latent values (Equation 2) is not Gaussian due to the non-Gaussian likelihood (Equation 1). Therefore, the latent distribution (Equation 3), the predictive distribution (Equation 4) and the marginal likelihood Z cannot be written as analytical expressions. To obtain exact answers, one can resort to sampling algorithms (MCMC). However, if sig is concave in the logarithmic domain, the posterior can be shown to be unimodal motivating Gaussian approximations to the posterior. Five different Gaussian approximations corresponding to methods explained later onwards in the paper are depicted in Figure 4.

A quadratic approximation to the log likelihood $\phi(f_i) := \ln \mathbb{P}(y_i|f_i)$ at $\tilde{f}_i$

$$\phi(f_i) \;\approx\; \phi(\tilde{f}_i) + \phi'(\tilde{f}_i)(f_i - \tilde{f}_i) + \frac{1}{2}\phi''(\tilde{f}_i)(f_i - \tilde{f}_i)^2 \;=\; -\frac{1}{2} w_i f_i^2 + b_i f_i + \mathrm{const}_{f_i}$$

motivates the following approximate posterior $\mathbb{Q}(\mathbf{f}|\mathbf{y}, \mathbf{X}, \boldsymbol{\theta})$

$$\begin{aligned}
\ln \mathbb{P}(\mathbf{f}|\mathbf{y}, \mathbf{X}, \boldsymbol{\theta}) &\overset{(2)}{=} -\frac{1}{2}\mathbf{f}^\top \mathbf{K}^{-1}\mathbf{f} + \sum_{i=1}^{n} \ln \mathbb{P}(y_i|f_i) + \mathrm{const}_{\mathbf{f}} \\
&\overset{\text{quad. approx.}}{\approx} -\frac{1}{2}\mathbf{f}^\top \mathbf{K}^{-1}\mathbf{f} - \frac{1}{2}\mathbf{f}^\top \mathbf{W}\mathbf{f} + \mathbf{b}^\top \mathbf{f} + \mathrm{const}_{\mathbf{f}} \\
&\overset{\mathbf{m}:=(\mathbf{K}^{-1}+\mathbf{W})^{-1}\mathbf{b}}{=} -\frac{1}{2}(\mathbf{f}-\mathbf{m})^\top \left(\mathbf{K}^{-1} + \mathbf{W}\right)(\mathbf{f}-\mathbf{m}) + \mathrm{const}_{\mathbf{f}} \\
&= \ln \mathcal{N}(\mathbf{f}|\mathbf{m}, \mathbf{V}) \;=:\; \ln \mathbb{Q}(\mathbf{f}|\mathbf{y}, \mathbf{X}, \boldsymbol{\theta}),
\end{aligned} \tag{5}$$

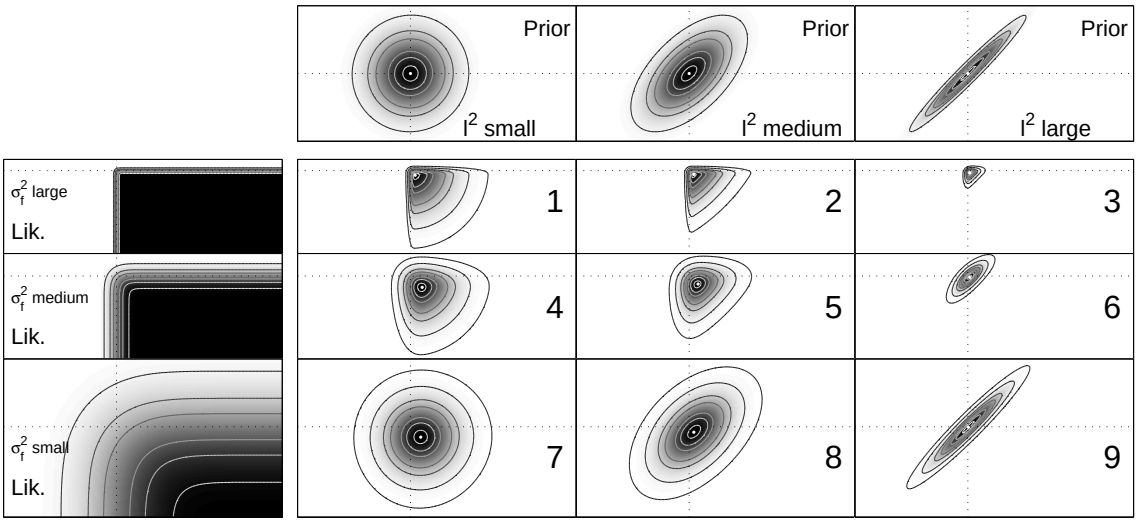

Figure 3: Gaussian Process Classification: Prior, Likelihood and exact Posterior: Nine numbered quadrants show posterior obtained by multiplication of different priors and likelihoods. The leftmost column illustrates the likelihood function for three different steepness parameters σ_f and the upper row depicts the prior for three different length scales ℓ. Here, we use σ_f as a parameter of the likelihood. Alternatively, rows correspond to "degree of Gaussianity" and columns stand for "degree of isotropy". The axes show the latent function values $f_1 = f(\mathbf{x}_1)$ and $f_2 = f(\mathbf{x}_2)$. A simple toy example employing the cumulative Gaussian likelihood and a squared exponential covariance $k(\mathbf{x},\mathbf{x}') = \sigma_f^2 \exp(-\|\mathbf{x}-\mathbf{x}'\|^2/2\ell^2)$ with length scales $\ln \ell = \{0,1,2.5\}$ and latent function scales $\ln \sigma_f = \{-1.5,0,1.5\}$ is used. Two data points $\mathbf{x}_1 = \sqrt{2}$, $\mathbf{x}_2 = -\sqrt{2}$ with corresponding labels $y_1 = 1$, $y_2 = -1$ form the data set.

where $\mathbf{V}^{-1} = \mathbf{K}^{-1} + \mathbf{W}$ and $\mathbf{W}$ denotes the precision of the effective likelihood (see Equation 7). It turns out that the methods discussed in the following sections correspond to particular choices of $\mathbf{m}$ and $\mathbf{V}$.

Let us assume, we have found such a Gaussian approximation to the posterior with mean $\mathbf{m}$ and (co)variance $\mathbf{V}$. Consequently, the latent distribution for a test point becomes a tractable one-dimensional Gaussian $\mathbb{P}(f_*|\mathbf{x}_*,\mathbf{y},\mathbf{X},\boldsymbol{\theta}) = \mathcal{N}(f_*|\mu_*,\sigma_*^2)$ with the following moments (Rasmussen and Williams, 2006, p. 44 and 56):

$$\begin{array}{rclcrcl} \mu_* & = & \mathbf{k}_*^\top \mathbf{K}^{-1}\mathbf{m} = \mathbf{k}_*^\top \boldsymbol{\alpha}, & & \boldsymbol{\alpha} & = & \mathbf{K}^{-1}\mathbf{m}, \\ \sigma_*^2 & = & k_{**} - \mathbf{k}_*^\top \left(\mathbf{K}^{-1} - \mathbf{K}^{-1}\mathbf{V}\mathbf{K}^{-1}\right)\mathbf{k}_* & = & k_{**} - \mathbf{k}_*^\top \left(\mathbf{K}+\mathbf{W}^{-1}\right)^{-1}\mathbf{k}_*. & & \end{array} \tag{6}$$

Since Gaussians are closed under multiplication, one can—given the Gaussian prior $\mathbb{P}(\mathbf{f}|\mathbf{X},\boldsymbol{\theta})$ and the Gaussian approximation to the posterior $\mathbb{Q}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})$—deduce the Gaussian factor $\mathbb{Q}(\mathbf{y}|\mathbf{f})$ such that $\mathbb{Q}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta}) \propto \mathbb{Q}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X},\boldsymbol{\theta})$. Consequently, this Gaussian factor can be thought of as an *effective likelihood*. Five different effective likelihoods, corresponding to methods discussed sub-

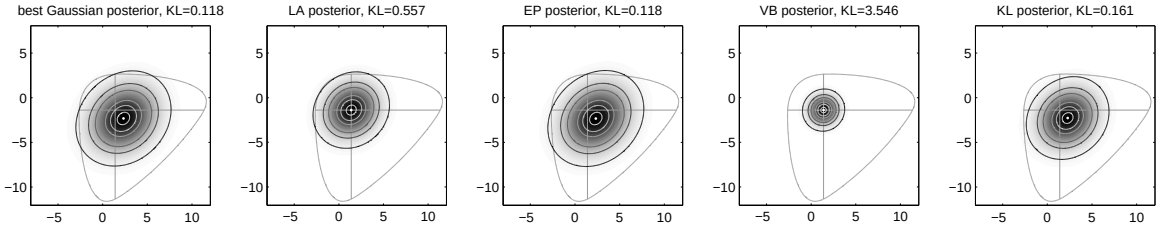

Figure 4: Five Gaussian Approximations to the Posterior (exact Posterior and mode in gray): Different Gaussian approximations to the exact posterior using the regime 2 setting of Figure 3 are shown. The exact posterior is represented in gray by a cross at the mode and a single equiprobability contour line. From left to right: The best Gaussian approximation (intractable) matches the moments of the true posterior, the Laplace approximation does a Taylor expansion around the mode, the EP approximation iteratively matches marginal moments, the variational method maximizes a lower bound on the marginal likelihood and the KL method minimizes the Kullback-Leibler to the exact posterior. The axes show the latent function values $f_1 = f(\mathbf{x}_1)$ and $f_2 = f(\mathbf{x}_2)$.

sequently in the paper, are depicted in Figure 5. By "dividing" the approximate Gaussian posterior (see Appendix B.2) by the true Gaussian prior we find the contribution of the effective likelihood $\mathbb{Q}(\mathbf{y}|\mathbf{f})$:

$$\mathbb{Q}(\mathbf{y}|\mathbf{f}) \propto \frac{\mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})}{\mathcal{N}(\mathbf{f}|\mathbf{0},\mathbf{K})} \propto \mathcal{N}\left(\mathbf{f}|\,(\mathbf{K}\mathbf{W})^{-1}\mathbf{m}+\mathbf{m},\mathbf{W}^{-1}\right). \tag{7}$$

We see (also from Equation 5) that $\mathbf{W}$ models the precision of the effective likelihood. In general, $\mathbf{W}$ is a full matrix containing n^2 parameters.[2] However, all algorithms maintaining a Gaussian posterior approximation work with a diagonal $\mathbf{W}$ to enforce the effective likelihood to factorize over examples (as the true likelihood does, see Figure 1) in order to reduce the number of parameters. We are not aware of work quantifying the error made by this assumption.

2.3 Log Marginal Likelihood

Prior knowledge over the latent function f is encoded in the choice of a covariance function k containing hyperparameters $\boldsymbol{\theta}$. In principle, one can do inference jointly over f and $\boldsymbol{\theta}$ e.g., by sampling techniques. Another approach to model selection is maximum likelihood type II also known as the evidence framework (MacKay, 1992), where the hyperparameters $\boldsymbol{\theta}$ are chosen to maximize the marginal likelihood or evidence $\mathbb{P}(\mathbf{y}|\mathbf{X},\boldsymbol{\theta})$. In other words, one maximizes the agreement between observed data and the model. Therefore, one has a strong motivation to estimate the marginal likelihood.

Geometrically, the marginal likelihood measures the volume of the prior times the likelihood. High volume implies a strong consensus between our initial belief and our observations. In GP classification, each data point $\mathbf{x}_i$ gives rise to a dimension f_i in latent space. The likelihood implements a mechanism, for smoothly restricting the posterior along the axis of f_i to the side corresponding

2. Numerical moment matching with $\mathbf{K} = \begin{bmatrix} 7 & 6 \\ 6 & 7 \end{bmatrix}$, $y_1 = y_2 = 1$ and $\mathrm{sig}_{\mathrm{probit}}$ leads to $\mathbf{W} = \begin{bmatrix} 0.142 & -0.017 \\ -0.017 & 0.142 \end{bmatrix}$.

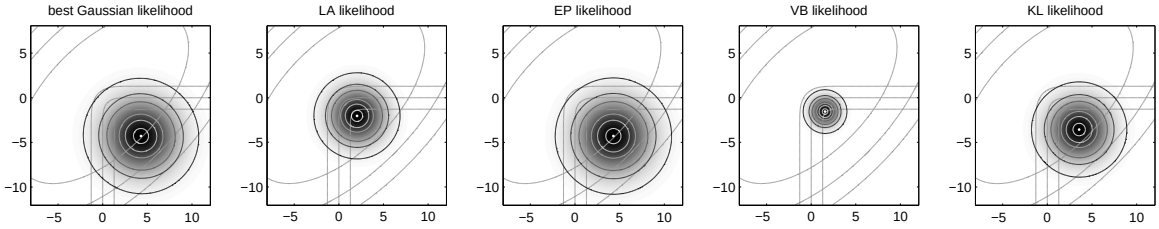

Figure 5: Five Effective Likelihoods (exact Prior/Likelihood in gray): A Gaussian approximation to the posterior induces a Gaussian effective likelihood (Equation 7). Different effective likelihoods are shown; order and setting are the same as described in Figure 4. The axes show the latent function values $f_1 = f(\mathbf{x}_1)$ and $f_2 = f(\mathbf{x}_2)$. The effective likelihood replaces the non-Gaussian likelihood (indicated by three gray lines). A good replacement behaves like the exact likelihood in regions of high prior density (indicated by gray ellipses). EP and KL yield a good coverage of that region. However LA and VB yield too concentrated replacements.

to the sign of y_i . Thus, the latent space $\mathbb{R}^n$ is softly cut down to the orthant given by the values in $\mathbf{y}$. The log marginal likelihood measures, what fraction of the prior lies in that orthant. Finally, the value $Z = 2^{-n}$ corresponds to the case, where half of the prior lies on either side along each axis in latent space. Consequently, successful inference is characterized by $Z > 2^{-n}$.

Some posterior approximations (Sections 3 and 4) provide an approximation to the marginal likelihood, other methods provide a lower bound (Sections 5 and 6). Any Gaussian approximation $\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta}) = \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})$ to the posterior $\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})$ gives rise to a lower bound Z_B to the marginal likelihood Z by application of Jensen's inequality. This bound has been used in the context of sparse approximations (Seeger, 2003).

$$\begin{aligned}\ln Z = \ln \mathbb{P}(\mathbf{y}|\mathbf{X},\boldsymbol{\theta}) \quad &= \quad \ln \int \mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X},\boldsymbol{\theta})\,\mathrm{d}\mathbf{f} = \ln \int \mathbb{Q}(\mathbf{f}|\boldsymbol{\theta})\,\frac{\mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X},\boldsymbol{\theta})}{\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta})}\mathrm{d}\mathbf{f} \\ &\overset{\text{Jensen}}{\geq} \quad \int \mathbb{Q}(\mathbf{f}|\boldsymbol{\theta}) \ln \frac{\mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X},\boldsymbol{\theta})}{\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta})}\mathrm{d}\mathbf{f} =: \ln Z_B. \end{aligned} \tag{8}$$

Some algebra (Appendix B.3) leads to the following expression for $\ln Z_B$:

$$\underbrace{\sum_{i=1}^{n} \int \mathcal{N}(f|,0,1) \ln \mathrm{sig}\left(y_i\left\{\sqrt{V_{ii}}f + m_i\right\}\right)\mathrm{d}f}_{\text{1) data fit}} + \frac{1}{2}[n - \underbrace{\mathbf{m}^\top \mathbf{K}^{-1}\mathbf{m}}_{\text{2) data fit}} + \underbrace{\ln\left|\mathbf{V}\mathbf{K}^{-1}\right| - \mathrm{tr}\left(\mathbf{V}\mathbf{K}^{-1}\right)}_{\text{3) regularizer}}]. \tag{9}$$

Model selection means maximization of $\ln Z_B$. Term 1) is a sum of one-dimensional Gaussian integrals of sigmoid functions in the logarithmic domain with adjustable offset and steepness. The integrals can be numerically computed in an efficient way using Gauss-Hermite quadrature (Press et al., 1993, §4.5). As the sigmoid in the log domain takes only negative values, the first term will be negative. That means, maximization of the first term is done by shifting the log-sigmoid such that the high-density region of the Gaussian is multiplied by small values. Term 2) is the equivalent

of the data-fit term in GP regression (Rasmussen and Williams, 2006, Ch. 5.4.1). Thus, the first and the second term encourage fitting the data by favouring small variances V_{ii} and large means m_i having the same sign as y_i. The third term can be rewritten as $-\ln|\mathbf{I}+\mathbf{KW}| - \mathrm{tr}\left((\mathbf{I}+\mathbf{KW})^{-1}\right)$ and yields $-\sum_{i=1}^{n}\ln(1+\lambda_i)+\frac{1}{1+\lambda_i}$ with $\lambda_i \geq 0$ being the eigenvalues of $\mathbf{KW}$. Thus, term 3) keeps the eigenvalues of $\mathbf{KW}$ small, thereby favouring a smaller class of functions—this can be seen as an instance of Occam's razor.

Furthermore, the bound

$$\ln Z_B \;=\; \int \mathbb{Q}(\mathbf{f}|\boldsymbol{\theta}) \ln \frac{\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})\,\mathbb{P}(\mathbf{y}|\mathbf{X})}{\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta})} \mathrm{d}\mathbf{f} \;=\; \ln Z - \mathrm{KL}\left(\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta}) \parallel \mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})\right) \qquad (10)$$

can be decomposed into the exact marginal likelihood minus the Kullback-Leibler (KL) divergence between the exact posterior and the approximate posterior. Thus by maximizing the lower bound $\ln Z_B$ on $\ln Z$, we effectively minimize the KL-divergence between $\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})$ and $\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta}) = \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})$. The bound is tight if and only if $\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta}) = \mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})$.

3. Laplace Approximation (LA)

A second order Taylor expansion around the posterior mode $\mathbf{m}$ leads to a natural way of constructing a Gaussian approximation to the log-posterior $\boldsymbol{\Psi}(\mathbf{f}) = \ln\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})$ (Williams and Barber, 1998; Rasmussen and Williams, 2006, Ch. 3). The mode $\mathbf{m}$ is taken as the mean of the approximate Gaussian. Linear terms of $\boldsymbol{\Psi}$ vanish because the gradient at the mode is zero. The quadratic term of $\boldsymbol{\Psi}$ is given by the negative Hessian $\mathbf{W}$, which - due to the likelihood's factorial structure - turns out to be diagonal. The mode $\mathbf{m}$ is found by Newton's method.

3.1 Posterior

$$\begin{aligned}
\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta}) &\approx \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V}) = \mathcal{N}\left(\mathbf{f}|\mathbf{m},\left(\mathbf{K}^{-1}+\mathbf{W}\right)^{-1}\right),\\
\mathbf{m} &= \operatorname*{argmax}_{\mathbf{f}\in\mathbb{R}^n} \mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X},\boldsymbol{\theta}),\\
\mathbf{W} &= -\left.\frac{\partial^2 \ln\mathbb{P}(\mathbf{y}|\mathbf{f})}{\partial\mathbf{f}\partial\mathbf{f}^\top}\right|_{\mathbf{f}=\mathbf{m}} = -\left[\left.\frac{\partial^2 \ln\mathbb{P}(y_i|f_i)}{\partial f_i^2}\right|_{f_i=m_i}\right]_{ii}.
\end{aligned}$$

3.2 Log Marginal Likelihood

The unnormalized posterior $\mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X},\boldsymbol{\theta})$ has its maximum $h = \exp(\boldsymbol{\Psi}(\mathbf{m}))$ at its mode $\mathbf{m}$, where the gradient vanishes. A Taylor expansion of $\boldsymbol{\Psi}$ is then given by $\boldsymbol{\Psi}(\mathbf{f}) \approx h - \frac{1}{2}(\mathbf{f}-\mathbf{m})^\top(\mathbf{K}^{-1}+\mathbf{W})(\mathbf{f}-\mathbf{m})$. Consequently, the log marginal likelihood can be approximated by plugging in the approximation of $\boldsymbol{\Psi}(\mathbf{f})$.

$$\begin{aligned}
\ln Z = \ln\mathbb{P}(\mathbf{y}|\mathbf{X},\boldsymbol{\theta}) &= \ln\int \mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X},\boldsymbol{\theta})\,\mathrm{d}\mathbf{f} = \ln\int \exp(\boldsymbol{\Psi}(\mathbf{f}))\,\mathrm{d}\mathbf{f}\\
&\approx \ln h + \ln\int \exp\left(-\frac{1}{2}(\mathbf{f}-\mathbf{m})^\top\left(\mathbf{K}^{-1}+\mathbf{W}\right)(\mathbf{f}-\mathbf{m})\right)\mathrm{d}\mathbf{f}\\
&= \ln\mathbb{P}(\mathbf{y}|\mathbf{m}) - \frac{1}{2}\mathbf{m}^\top\mathbf{K}^{-1}\mathbf{m} + \frac{1}{2}\ln|\mathbf{I}+\mathbf{KW}|.
\end{aligned}$$

4. Expectation Propagation (EP)

EP (Minka, 2001b) is an iterative method to find approximations based on approximate marginal moments, which can be applied to Gaussian processes. See (Rasmussen and Williams, 2006, Ch. 3) for details. The individual likelihood terms are replaced by site functions $t_i(f_i)$ being unnormalized Gaussians

$$\mathbb{P}(y_i|f_i) \approx t_i\left(f_i,\mu_i,\sigma_i^2,Z_i\right) := Z_i\mathcal{N}\left(f_i|\mu_i,\sigma_i^2\right)$$

such that the approximate marginal moments of $\mathbb{Q}(f_i) := \int \mathcal{N}(\mathbf{f}|\mathbf{0},\mathbf{K})\prod_{j=1}^n Z_j\mathcal{N}\left(f_j|\mu_j,\sigma_j^2\right)\mathrm{d}\mathbf{f}_{\neg i}$ agree with the marginals of $\int \mathcal{N}(\mathbf{f}|\mathbf{0},\mathbf{K})\mathbb{P}(y_i|f_i)\prod_{j\neq i} Z_j\mathcal{N}\left(f_j|\mu_j,\sigma_j^2\right)\mathrm{d}\mathbf{f}_{\neg i}$ of the approximation based on the exact likelihood term $\mathbb{P}(y_j|f_j)$. That means, there are $3n$ quantities μ_i, σ_i^2 and Z_i to be iteratively optimized. Convergence of EP is not generally guaranteed, but there always exists a fixed-point for the EP updates in GP classification (Minka, 2001a). If the EP iterations converge, the solution obtained is a saddle point of a special energy function (Minka, 2001a). However, an EP update does not necessarily imply a decrease in energy. For our case of log-concave likelihood functions, we always observed convergence, but we are not aware of a formal proof.

4.1 Posterior

Based on these local approximations, the approximate posterior can be written as:

$$\begin{aligned}
\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta}) &\approx \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V}) = \mathcal{N}\left(\mathbf{f}|\mathbf{m},\left(\mathbf{K}^{-1}+\mathbf{W}\right)^{-1}\right),\\
\mathbf{W} &= \left[\sigma_i^{-2}\right]_{ii},\\
\mathbf{m} &= \mathbf{V}\mathbf{W}\boldsymbol{\mu} = \left[\mathbf{I}-\mathbf{K}\left(\mathbf{K}+\mathbf{W}^{-1}\right)^{-1}\right]\mathbf{K}\mathbf{W}\boldsymbol{\mu},\ \boldsymbol{\mu}=(\mu_1,\ldots,\mu_n)^\top.
\end{aligned}$$

4.2 Log Marginal Likelihood

>From the likelihood approximations, one can directly obtain an expression for the approximate log marginal likelihood

$$\begin{aligned}
\ln Z = \ln\mathbb{P}(\mathbf{y}|\mathbf{X},\boldsymbol{\theta}) &= \ln\int \mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X},\boldsymbol{\theta})\,\mathrm{d}\mathbf{f}\\
&\approx \ln\int\prod_{i=1}^n t\left(f_i,\mu_i,\sigma_i^2,Z_i\right)\mathbb{P}(\mathbf{f}|\mathbf{X},\boldsymbol{\theta})\,\mathrm{d}\mathbf{f}\\
&= \sum_{i=1}^n \ln Z_i - \frac{1}{2}\boldsymbol{\mu}^\top\left(\mathbf{K}+\mathbf{W}^{-1}\right)^{-1}\boldsymbol{\mu} - \frac{1}{2}\ln\left|\mathbf{K}+\mathbf{W}^{-1}\right| - \frac{n}{2}\ln 2\pi\\
&= \sum_{i=1}^n \ln\frac{Z_i}{\sqrt{2\pi}} - \frac{1}{2}\mathbf{m}^\top\left(\mathbf{K}^{-1}+\mathbf{K}^{-1}\mathbf{W}^{-1}\mathbf{K}^{-1}\right)\mathbf{m} - \frac{1}{2}\ln\left|\mathbf{K}+\mathbf{W}^{-1}\right| =: \ln Z_{EP}.
\end{aligned}$$

The lower bound provided by Jensen's inequality Z_B (Equation 9) is known to be below the approximation Z_{EP} obtained by EP (Opper and Winther, 2005, page 2183). From $Z_{EP} \geq Z_B$ and $Z \geq Z_B$ it is not clear, which value one should use. In principle, Z_{EP} could be a bad approximation. However, our experimental findings and extensive Monte Carlo simulations suggest that Z_{EP} is very accurate.

4.3 Thouless, Anderson & Palmer method (TAP)

Based on ideas rooted in Statistical Physics, one can approach the problem from a slightly different angle (Opper and Winther, 2000). Individual Gaussian approximations $\mathcal{N}(f_i|\mu_{\neg i},\sigma^2_{\neg i})$ are only made to predictive distributions $\mathbb{P}\left(f_i|\mathbf{x}_i,\mathbf{y}_{\setminus i},\mathbf{X}_{\setminus i},\boldsymbol{\theta}\right)$ for data points $\mathbf{x}_i$ that have been previously removed from the training set. Based on $\mu_{\neg i}$ and $\sigma^2_{\neg i}$ one can derive explicit expressions for $(\boldsymbol{\alpha},\mathbf{W}^{\frac{1}{2}})$, our parameters of interest.

$$\begin{aligned}\alpha_i &\approx \frac{\int \frac{\partial}{\partial f_i}\mathbb{P}(y_i|f_i)\,\mathcal{N}(f_i|\mu_{\neg i},\sigma^2_{\neg i})\mathrm{d}f_i}{\int \mathbb{P}(y_i|f_i)\,\mathcal{N}(f_i|\mu_{\neg i},\sigma^2_{\neg i})\mathrm{d}f_i},\\ \left[\mathbf{W}^{-1}\right]_{ii} &\approx \sigma^2_{\neg i}\left(\frac{1}{\alpha_i\left[\mathbf{K}\boldsymbol{\alpha}\right]_i}-1\right).\end{aligned} \tag{11}$$

In turn, the $2n$ parameters $(\mu_{\neg i},\sigma^2_{\neg i})$ can be expressed as a function of $\boldsymbol{\alpha}$, $\mathbf{K}$ and $\mathbf{W}^{\frac{1}{2}}$.

$$\begin{aligned}\sigma^2_{\neg i} &= 1/\left[\left(\mathbf{K}+\mathbf{W}^{-1}\right)^{-1}\right]_{ii}-\left[\mathbf{W}^{-1}\right]_{ii},\\ \mu_{\neg i} &= \left[\mathbf{K}\boldsymbol{\alpha}\right]_i-\sigma^2_{\neg i}\alpha_i.\end{aligned} \tag{12}$$

As a result, a system (Equations 11/12) of nonlinear equations in $\mu_{\neg i}$ and $\sigma^2_{\neg i}$ has to be solved by iteration. Each step involves a matrix inversion of cubic complexity. A faster "naïve" variant updating only n parameters has also been proposed (Opper and Winther, 2000) but it does not lead to the same fixed point. As in the FV algorithm (Section 7), a formal complex transformation leads to a simplified version by fixing $\sigma^2_{\neg i}=\mathbf{K}_{ii}$, called (TAPnaive) in the sequel.

Finally, for prediction, the predictive posterior $\mathbb{P}(f_*|\mathbf{x}_*,\mathbf{y},\mathbf{X},\boldsymbol{\theta})$ is approximated by a Gaussian $\mathcal{N}(f_*|\mu_*,\sigma^2_*)$ at a test point $\mathbf{x}_*$ based on the parameters $(\boldsymbol{\alpha},\mathbf{W}^{\frac{1}{2}})$ and according to equation (6).

A fixed-point of the TAP mean-field equations is also a fixed-point of the EP algorithm (Minka, 2001a). This theoretical result was confirmed in our numerical simulations. However, the EP algorithm is more practical and typically much faster. For this reason, we are not going to treat the TAP method as an independent algorithm in this paper.

5. KL-Divergence Minimization (KL)

In principle, we simply want to minimize a dissimilarity measure between the approximate posterior $\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta})=\mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})$ and the exact posterior $\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})$. One quantity to minimize is the KL-divergence

$$\mathrm{KL}\left(\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})\parallel\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta})\right) = \int\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})\ln\frac{\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})}{\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta})}\mathrm{d}\mathbf{f}.$$

Unfortunately, this expression is intractable. If instead, we measure the reverse KL-divergence, we regain tractability

$$\mathrm{KL}\left(\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta})\parallel\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})\right) = \int\mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})\ln\frac{\mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})}{\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})}\mathrm{d}\mathbf{f}=:\mathrm{KL}(\mathbf{m},\mathbf{V}).$$

A similar approach has been followed for regression with Laplace or Cauchy noise (Opper and Archambeau, 2008). Finally, we minimize the following objective (see Appendix B.3) with respect to the variables $\mathbf{m}$ and $\mathbf{V}$. Constant terms have been dropped from the expression:

$$\mathrm{KL}(\mathbf{m},\mathbf{V}) \stackrel{c}{=} -\int \mathcal{N}(f)\left[\sum_{i=1}^{n} \ln \mathrm{sig}\left(\sqrt{v_{ii}}y_i f + m_i y_i\right)\right] \mathrm{d}f - \frac{1}{2}\ln|\mathbf{V}| + \frac{1}{2}\mathbf{m}^\top \mathbf{K}^{-1}\mathbf{m} + \frac{1}{2}\mathrm{tr}\left(\mathbf{K}^{-1}\mathbf{V}\right).$$

We refer to the first term of $\mathrm{KL}(\mathbf{m},\mathbf{V})$ as $a(\mathbf{m},\mathbf{V})$ to keep the expressions short. We calculate first derivatives and equate them with zero to obtain necessary conditions that have to be fulfilled at a local optimum $(\mathbf{m}^*,\mathbf{V}^*)$

$$\begin{aligned}
\frac{\partial \mathrm{KL}}{\partial \mathbf{m}} &= \frac{\partial a}{\partial \mathbf{m}} - \mathbf{K}^{-1}\mathbf{m} = \mathbf{0} \;\Rightarrow\; \mathbf{K}^{-1}\mathbf{m} = \frac{\partial a}{\partial \mathbf{m}} = \boldsymbol{\alpha}, \\
\frac{\partial \mathrm{KL}}{\partial \mathbf{V}} &= \frac{\partial a}{\partial \mathbf{V}} + \frac{1}{2}\mathbf{V}^{-1} - \frac{1}{2}\mathbf{K}^{-1} = \mathbf{0} \;\Rightarrow\; \mathbf{V} = \left(\mathbf{K}^{-1} - 2\frac{\partial a}{\partial \mathbf{V}}\right)^{-1} = \left(\mathbf{K}^{-1} - 2\boldsymbol{\Lambda}\right)^{-1}
\end{aligned}$$

which defines $\boldsymbol{\Lambda}$. If the approximate posterior is parametrized by $(\mathbf{m},\mathbf{V})$, there are in principle in the order of n^2 parameters. But if the necessary conditions for a local minimum are fulfilled (i.e., the derivatives $\partial\mathrm{KL}/\partial\mathbf{m}$ and $\partial\mathrm{KL}/\partial\mathbf{V}$ vanish), the problem can be re-parametrized in terms of $(\boldsymbol{\alpha},\boldsymbol{\Lambda})$. Since $\boldsymbol{\Lambda} = \partial a/\partial\mathbf{V}$ is a diagonal matrix (see Equation 17), the optimum is characterized $2n$ free parameters. This fact was already pointed out by Manfred Opper (personal communication) and Matthias Seeger (Seeger, 1999, Ch. 5.21, Eq. 5.3). Thus, a minimization scheme based on Newton iterations on the joint vector $\boldsymbol{\xi} := [\boldsymbol{\alpha}^\top, \boldsymbol{\Lambda}_{ii}]^\top$ takes $O(8\cdot n^3)$ operations. Details about the derivatives $\partial\mathrm{KL}/\partial\boldsymbol{\xi}$ and $\partial^2\mathrm{KL}/\partial\boldsymbol{\xi}\partial\boldsymbol{\xi}^\top$ are provided in Appendix A.2.

5.1 Posterior

Based on these local approximations, the approximate posterior can be written as:

$$\begin{aligned}
\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta}) &\approx \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V}) = \mathcal{N}\left(\mathbf{f}|\mathbf{m},\left(\mathbf{K}^{-1}+\mathbf{W}\right)^{-1}\right), \\
\mathbf{W} &= -2\boldsymbol{\Lambda}, \\
\mathbf{m} &= \mathbf{K}\boldsymbol{\alpha}.
\end{aligned}$$

5.2 Log Marginal Likelihood

Since the method inherently maximizes a lower bound on the marginal likelihood, this bound (Equation 9) is used as approximation to the marginal likelihood.

6. Variational Bounds (VB)

The following variational bounding method (Gibbs and MacKay, 2000) is a special case of the KL method. Instead of optimizing a bound on the joint (Eq. 8), they impose the bounding condition on each likelihood term individually. Here, we treat parametrization based on quadratic lower bounds on the individual likelihoods in the logarithmic domain. We first derive all calculations based on

general likelihoods. Individual likelihood bounds

$$\begin{aligned}\mathbb{P}(y_i|f_i) &\geq \exp\left(a_i f_i^2 + b_i y_i f_i + c_i\right), \forall f_i \in \mathbb{R} \forall i \\ \Rightarrow \mathbb{P}(\mathbf{y}|\mathbf{f}) &\geq \exp\left(\mathbf{f}^\top \mathbf{A}\mathbf{f} + (\mathbf{b}\odot\mathbf{y})^\top \mathbf{f} + \mathbf{c}^\top \mathbb{1}\right) =: \mathbb{Q}(\mathbf{y}|\mathbf{f},\mathbf{A},\mathbf{b},\mathbf{c}), \forall \mathbf{f} \in \mathbb{R}\end{aligned}$$

are defined in terms of coefficients a_i, b_i and c_i, where $\odot$ denotes the element-wise product of two vectors. This lower bound on the likelihood induces a lower bound on the marginal likelihood.

$$Z = \int \mathbb{P}(\mathbf{f}|\mathbf{X})\,\mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathrm{d}\mathbf{f} \quad \geq \quad \int \mathbb{P}(\mathbf{f}|\mathbf{X})\,\mathbb{Q}(\mathbf{y}|\mathbf{f},\mathbf{A},\mathbf{b},\mathbf{c})\,\mathrm{d}\mathbf{f} = Z_B.$$

Carrying out the Gaussian integral

$$Z_B \quad = \quad \int \mathcal{N}(\mathbf{f}|0,\mathbf{K}) \exp\left(\mathbf{f}^\top \mathbf{A}\mathbf{f} + (\mathbf{b}\odot\mathbf{y})^\top \mathbf{f} + \mathbf{c}^\top \mathbb{1}\right) \mathrm{d}\mathbf{f}$$

leads to (see Appendix B.4)

$$\ln Z_B \quad = \quad \mathbf{c}^\top \mathbb{1} + \frac{1}{2}(\mathbf{b}\odot\mathbf{y})^\top \left(\mathbf{K}^{-1} - 2\mathbf{A}\right)^{-1} (\mathbf{b}\odot\mathbf{y}) - \frac{1}{2}\ln|\mathbf{I} - 2\mathbf{A}\mathbf{K}| \tag{13}$$

which can now be maximized with respect to the coefficients a_i, b_i and c_i. In order to get an efficient algorithm, one has to calculate the first and second derivatives $\partial \ln Z_B/\partial \boldsymbol{\varsigma}$, $\partial^2 \ln Z_B/\partial \boldsymbol{\varsigma}\partial \boldsymbol{\varsigma}^\top$ (as done in Appendix A.1). Hyperparameters can be optimized using the gradient $\partial \ln Z_B/\partial \boldsymbol{\theta}$.

6.1 Logit Bound

Optimizing the logistic likelihood function (Gibbs and MacKay, 2000), we obtain the necessary conditions

$$\begin{aligned}\mathbf{A}_{\boldsymbol{\varsigma}} &:= -\boldsymbol{\Lambda}_{\boldsymbol{\varsigma}}, \\ \mathbf{b}_{\boldsymbol{\varsigma}} &:= \frac{1}{2}\mathbb{1}, \\ \mathbf{c}_{\boldsymbol{\varsigma},i} &:= \varsigma_i^2 \lambda(\varsigma_i) - \frac{1}{2}\varsigma_i + \ln \mathrm{sig}_{\mathrm{logit}}(\varsigma_i)\end{aligned}$$

where we define $\lambda(\varsigma_i) = \left(2\mathrm{sig}_{\mathrm{logit}}(\varsigma_i) - 1\right)/(4\varsigma_i)$ and $\boldsymbol{\Lambda}_{\boldsymbol{\varsigma}} = [\lambda(\varsigma_i)]_{ii}$. This shows, that we only have to optimize with respect to n parameters $\boldsymbol{\varsigma}$. We apply Newton's method for this purpose. The bound is symmetric and tight at $\mathbf{f} = \pm\boldsymbol{\varsigma}$.

6.2 Probit Bound

For reasons of completeness, we derive similar expressions (Appendix B.5) for the cumulative Gaussian likelihood $\mathrm{sig}_{\mathrm{probit}}(f_i)$ with necessary conditions

$$\begin{aligned}\mathbf{a}_{\boldsymbol{\varsigma}} &:= -\frac{1}{2}\mathbb{1}, \\ \mathbf{b}_{\boldsymbol{\varsigma},i} &:= \varsigma_i + \frac{\mathcal{N}(\varsigma_i)}{\mathrm{sig}_{\mathrm{probit}}(\varsigma_i)}, \\ \mathbf{c}_{\boldsymbol{\varsigma},i} &:= \left(\frac{\varsigma_i}{2} - b_i\right)\varsigma_i + \ln\left(\mathrm{sig}_{\mathrm{probit}}(\varsigma_i)\right)\end{aligned} \tag{14}$$

which again depend only on a single vector of parameters we optimize using Newton's method. The bound is tight for $\mathbf{f} = \boldsymbol{\varsigma}$.

6.3 Posterior

Based on these local approximations, the approximate posterior can be written as

$$\begin{aligned}\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta}) &\approx \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V}) = \mathcal{N}\left(\mathbf{f}|\mathbf{m},\left(\mathbf{K}^{-1}+\mathbf{W}\right)^{-1}\right),\\ \mathbf{W} &= -2\mathbf{A}_{\boldsymbol{\varsigma}},\\ \mathbf{m} &= \mathbf{V}(\mathbf{y}\odot\mathbf{b}_{\boldsymbol{\varsigma}}) = \left(\mathbf{K}^{-1}-2\mathbf{A}_{\boldsymbol{\varsigma}}\right)^{-1}(\mathbf{y}\odot\mathbf{b}_{\boldsymbol{\varsigma}}),\end{aligned}$$

where we have expressed the posterior parameters directly as a function of the coefficients. Finally, we deal with an approximate posterior $\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta}) = \mathcal{N}(\mathbf{f}|\mathbf{m}_{\boldsymbol{\varsigma}},\mathbf{V}_{\boldsymbol{\varsigma}})$ only depending on a vector $\boldsymbol{\varsigma}$ of n variational parameters and a mapping $\boldsymbol{\varsigma}\mapsto(\mathbf{m}_{\boldsymbol{\varsigma}},\mathbf{V}_{\boldsymbol{\varsigma}})$. In the KL method, every combination of values $\mathbf{m}$ and $\mathbf{W}$ is allowed, in the VB method, $\mathbf{m}_{\boldsymbol{\varsigma}}$ and $\mathbf{V}_{\boldsymbol{\varsigma}}$ cannot be chosen independently, since the have to be compatible with the bounding requirements. Therefore, the variational posterior is more constrained than the general Gaussian posterior and thus easier to optimize.

6.4 Log Marginal Likelihood

It turns out, that the approximation to the marginal likelihood (Equation 13) is often quite poor and the more general Jensen bound approach (Equation 9) is much tighter. In practice, one would have to evaluate both of them and keep the maximum value.

7. Factorial Variational Method (FV)

Instead of approximating the posterior $\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})$ by the closest Gaussian distribution, one can use the closest factorial distribution $\mathbb{Q}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta}) = \prod_i \mathbb{Q}(f_i)$, also called *ensemble learning* (Csató et al., 2000). Another kind of factorial approximation $\mathbb{Q}(\mathbf{f}) = \mathbb{Q}(\mathbf{f}^+)\mathbb{Q}(\mathbf{f}^-)$—a posterior factorizing over classes—is used in multi-class classification (Girolami and Rogers, 2006).

7.1 Posterior

As a result of free-form minimization of the Kullback-Leibler divergence $\mathrm{KL}(\mathbb{Q}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta}) \parallel \mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta}))$ by equating its functional derivative $\delta\mathrm{KL}/\delta\mathbb{Q}(f_i)$ with the zero function (Appendix B.6), one finds the best approximation to be of the following form:

$$\begin{aligned}\mathbb{Q}(f_i) &\propto \mathcal{N}\left(f_i\,|\mu_i,\sigma_i^2\right)\mathbb{P}(y_i|f_i),\\ \mu_i &= m_i - \sigma_i^2\left[\mathbf{K}^{-1}\mathbf{m}\right]_i = [\mathbf{K}\boldsymbol{\alpha}]_i - \sigma_i^2\alpha_i,\\ \sigma_i^2 &= \left[\mathbf{K}^{-1}\right]_{ii}^{-1},\\ m_i &= \int f_i\mathbb{Q}(f_i)\,\mathrm{d}f_i.\end{aligned} \tag{15}$$

In fact, the best product distribution consists of a factorial Gaussian times the original likelihood. The Gaussian has the same moments as the Leave-One-Out prediction (Sundararajan and Keerthi, 2001). Since the posterior is factorial, the effective likelihood of the factorial approximation has an odd shape. It effectively has to annihilate the correlations in the prior, and these correlations are usually what allows learning to happen in the first place. However, the best fitting factorial is still able to ensure that the latent means have the right signs. Even though all correlations are neglected,

it is still possible that the model picks up the most important structure, since the expectations are coupled. Of course, at test time, it is essential that correlations are taken into account again using Equation 6, as it would otherwise be impossible to inject any knowledge into the predictive distribution. For predictions we use the Gaussian $\mathcal{N}(\mathbf{f}|\mathbf{m},\mathrm{Dg}(\mathbf{v}))$ instead of $\mathbb{Q}(\mathbf{f})$. This is a further approximation, but it allows to stay inside the Gaussian framework.

Parameters μ_i and m_i are found by the following algorithm. Starting from $\mathbf{m}=\mathbf{0}$, iterate the following until convergence; (1) compute μ_i, (2) update m_i by taking a step in the direction towards m_i as given by Equation 15. Stepsizes are adapted.

7.2 Log Marginal Likelihood

Surprisingly, one can obtain a lower bound on the marginal likelihood (Csató et al., 2000):

$$\ln Z \quad \geq \quad \sum_{i=1}^{n} \ln \mathrm{sig}\left(\frac{y_i m_i}{\sigma_i}\right) - \frac{1}{2}\boldsymbol{\alpha}^\top \left(\mathbf{K} - \mathrm{Dg}(\left[\sigma_1^2,\ldots,\sigma_n^2\right]^\top)\right)\boldsymbol{\alpha} - \frac{1}{2}\ln|\mathbf{K}| + \sum_{i=1}^{n}\ln\sigma_i.$$

8. Label Regression Method (LR)

Classification has also been treated using label regression or least squares classification (Rifkin and Klautau, 2004). In its simplest form, this method simply ignores the discreteness of the class labels at the cost of not being able to provide proper probabilistic predictions. However, we treat LR as a heuristic way of choosing $\boldsymbol{\alpha}$ and $\mathbf{W}$, which allows us to think of it as yet another Gaussian approximation to the posterior allowing for valid predictions of class probabilities.

8.1 Posterior

After inference, according to Equation 6, the moments of the (Gaussian approximation to the) posterior GP can be written as $\mu_* = \mathbf{k}_*^\top \boldsymbol{\alpha}$ and $\sigma_*^2 = k_{**} - \mathbf{k}_*^\top \left(\mathbf{K}+\mathbf{W}^{-1}\right)^{-1}\mathbf{k}_*$. Fixing

$$\mathbf{W}^{-1} = \sigma_n^2\mathbf{I} \quad \text{and} \quad \boldsymbol{\alpha} = \left(\mathbf{K}+\mathbf{W}^{-1}\right)^{-1}\left(\mathbf{K}+\mathbf{W}^{-1}\right)\boldsymbol{\alpha} = \left(\mathbf{K}+\mathbf{W}^{-1}\right)^{-1}\mathbf{y},$$

we obtain GP regression from data points $\mathbf{x}_i \in \mathcal{X}$ to real labels $y_i \in \mathbb{R}$ with noise of variance σ_n^2 as a special case. In regression, the posterior moments are given by $\mu_* = \mathbf{k}_*^\top \left(\mathbf{K}+\sigma_n^2\mathbf{I}\right)^{-1}\mathbf{y}$ and $\sigma_*^2 = k_{**} - \mathbf{k}_*^\top \left(\mathbf{K}+\sigma_n^2\mathbf{I}\right)^{-1}\mathbf{k}_*$ (Rasmussen and Williams, 2006). The arbitrary scale of the discrete $\mathbf{y}$ can be absorbed by the hyperparameters. There is an additional parameter σ_n, describing the width of the effective likelihood. In experiments, we selected $\sigma_n \in [0.5, 2]$ to maximise the log marginal likelihood.

8.2 Log Marginal Likelihood

There are two ways of obtaining an estimate of the log marginal likelihood. One can simply ignore the binary nature and use the regression marginal likelihood $\ln Z_{\mathrm{reg}}$ as proxy for $\ln Z$—an approach we only mention but not use in the experiments

$$\ln Z_{\mathrm{reg}} \quad = \quad -\frac{1}{2}\boldsymbol{\alpha}^\top\left(\mathbf{K}+\sigma_n^2\mathbf{I}\right)\boldsymbol{\alpha} - \frac{1}{2}\ln\left|\mathbf{K}+\sigma_n^2\mathbf{I}\right| - \frac{n}{2}\ln 2\pi.$$

Alternatively, the Jensen bound (8) yields a lower bound $\ln Z \geq \ln Z_B$—which seems more in line with the classification scenario than $\ln Z_{\mathrm{reg}}$.

9. Relations Between the Methods

All considered approximations can be separated into *local* and *global methods*. Local methods exploit properties (such as derivatives) of the posterior at a special location only. Global methods minimize the KL-divergence $\mathrm{KL}(\mathbb{Q}||\mathbb{P}) = \int \mathbb{Q}(\mathbf{f}) \ln \mathbb{Q}(\mathbf{f}) / \mathbb{P}(\mathbf{f}) \, \mathrm{d}\mathbf{f}$ between the posterior $\mathbb{P}(\mathbf{f})$ and a tractable family of distributions $\mathbb{Q}(\mathbf{f})$. Often this methodology is also referred to as a variational algorithm.

assumption	relation	conditions	approx. posterior $\mathbb{Q}(\mathbf{f})$	name
$\mathbb{Q}(\mathbf{f}) = \mathcal{N}(\mathbf{f}\|\mathbf{m},\mathbf{V})$	$\rightarrow$	$\mathbf{m} = \operatorname{argmax}_{\mathbf{f}} \mathbb{P}(\mathbf{f})$ $\mathbf{W} = -\frac{\partial^2 \ln \mathbb{P}(\mathbf{y}\|\mathbf{f})}{\partial \mathbf{f} \partial \mathbf{f}^\top}$	$\mathcal{N}(\mathbf{f}\|\mathbf{m},(\mathbf{K}^{-1}+\mathbf{W})^{-1})$	LA
$\mathbb{Q}(\mathbf{f}) = \prod_i q_i(f_i)$	$\rightarrow$	$\frac{\delta \mathrm{KL}}{\delta q_i(f_i)} \equiv \mathbf{0}$	$\prod_i \mathcal{N}(f_i\|\mu_i,\sigma_i^2)\mathbb{P}(y_i\|f_i)$	FV
	$\searrow$			
		$\left\langle f_i^d \right\rangle_{q_i(f_i)} = \left\langle f_i^d \right\rangle_{\mathbb{Q}(f_i)}$	$\mathcal{N}\left(\mathbf{f}\|\mathbf{m},(\mathbf{K}^{-1}+\mathbf{W})^{-1}\right)$	EP
	$\nearrow$			
$\mathbb{Q}(\mathbf{f}) = \mathcal{N}(\mathbf{f}\|\mathbf{m},\mathbf{V})$	$\rightarrow$	$\frac{\partial \mathrm{KL}}{\partial \mathbf{V},\mathbf{m}} = \mathbf{0}$	$\mathcal{N}\left(\mathbf{f}\|\mathbf{m},(\mathbf{K}^{-1}+\mathbf{W})^{-1}\right)$	KL
	$\searrow$			
$\mathbb{P}(y_i\|f_i) \geq \mathcal{N}(f_i\|\mu_{\varsigma i},\sigma_{\varsigma i}^2)$	$\rightarrow$	$\frac{\partial \mathrm{KL}}{\partial \boldsymbol{\varsigma}_*} = \mathbf{0}$	$\mathcal{N}\left(\mathbf{f}\|\mathbf{m}_{\boldsymbol{\varsigma}_*},(\mathbf{K}^{-1}+\mathbf{W}_{\boldsymbol{\varsigma}_*})^{-1}\right)$	VB
$\mathbb{P}(y_i\|f_i) := \mathcal{N}(f_i\|y_i,\sigma_n^2)$	$\rightarrow$	$\mathbf{m} = (\mathbf{I}+\sigma_n^2\mathbf{K}^{-1})^{-1}\mathbf{y}$	$\mathcal{N}(\mathbf{f}\|\mathbf{m},(\mathbf{K}^{-1}+\sigma_n^{-2}\mathbf{I})^{-1})$	LR

The only local method considered is the LA approximation matching curvature at the posterior mode. Common tractable distributions for global methods include factorial and Gaussian distributions. They have their direct correspondent in the FV method and the KL method. Individual likelihood bounds make the VB method a more constrained and easier-to-optimize version of the KL method. Interestingly, EP can be seen in some sense as a hybrid version of FV and KL, combining the advantages of both methods. Within the Expectation Consistence framework (Opper and Winther, 2005), EP can be thought of as an algorithm that implicitly works with two distributions—a factorial and a Gaussian—having the same marginal moments $\left\langle f_i^d \right\rangle$. By means of iterative updates, one keeps these expectations consistent and produces a posterior approximation.

In the divergence measure and message passing framework (Minka, 2005), EP is cast as a message passing algorithm template: Iterative minimization of local divergences to a tractable family of distributions yields a small global divergence. From that viewpoint, FV and KL are considered as special cases with divergence measure $\mathrm{KL}(\mathbb{Q}||\mathbb{P})$ combined with factorial and Gaussian distributions.

There is also a link between local and global methods, namely from the KL to the LA method. The necessary conditions for the LA method do hold *on average* for the KL method (Opper and Archambeau, 2008).

Finally, LR neither qualifies as local nor global—it is just a heuristic way of setting $\mathbf{m}$ and $\mathbf{W}$.

10. Markov Chain Monte Carlo (MCMC)

The only way of getting a handle on the ground truth for the moments Z, $\mathbf{m}$ and $\mathbf{V}$ is by applying sampling techniques. In the limit of long runs, one is guaranteed to get the right answer. But in practice, these methods can be very slow, compared to analytic approximations discussed previously. MCMC runs are rather supposed to provide a gold standard for the comparison of the other methods.

It turns out to be most challenging to obtain reliable marginal likelihood estimates as it is equivalent to solving the free energy problem in physics. We employ Annealed Importance Sampling (AIS) and thermodynamic integration to yield the desired marginal likelihoods. Instead of starting annealing from the prior distribution, we propose to directly start from an approximate posterior in order to speed up the sampling process.

Accurate estimates of the first and second moments can be obtained by sampling directly from the (unnormalized) posterior using Hybrid Monte Carlo methods (Neal, 1993).

10.1 Thermodynamic Integration

The goal is to calculate the marginal likelihood $Z = \int \mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X})\,\mathrm{d}\mathbf{f}$. AIS (Neal, 1993, 2001) works with intermediate quantities $Z_t := \int \mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t)}\,\mathbb{P}(\mathbf{f}|\mathbf{X})\,\mathrm{d}\mathbf{f}$. Here, $\tau : \mathbb{N} \supset [0,T] \to [0,1] \subset \mathbb{R}$ denotes an inverse temperature schedule with the properties $\tau(0) = 0$, $\tau(T) = 1$ and $\tau(t+1) \geq \tau(t)$ leading to $Z_0 = \int \mathbb{P}(\mathbf{f}|\mathbf{X})\,\mathrm{d}\mathbf{f} = 1$ and $Z_T = Z$.

On the other hand, we have $Z = Z_T/Z_0 = \prod_{t=1}^{T} Z_t/Z_{t-1}$—an expanded fraction. Each factor Z_t/Z_{t-1} can be approximated by importance sampling with samples $\mathbf{f}_s$ from the "intermediate posterior" $\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},t-1) := \mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t-1)}\,\mathbb{P}(\mathbf{f}|\mathbf{X})\,/Z_{t-1}$ at time t.

$$\begin{aligned}
\frac{Z_t}{Z_{t-1}} &= \frac{\int \mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t)}\,\mathbb{P}(\mathbf{f}|\mathbf{X})\,\mathrm{d}\mathbf{f}}{Z_{t-1}} = \int \frac{\mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t)}}{\mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t-1)}} \frac{\mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t-1)}\,\mathbb{P}(\mathbf{f}|\mathbf{X})}{Z_{t-1}}\mathrm{d}\mathbf{f} \\
&= \int \mathbb{P}(\mathbf{y}|\mathbf{f})^{\Delta\tau(t)}\,\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},t-1)\,\mathrm{d}\mathbf{f} \\
&\approx \frac{1}{S}\sum_{s=1}^{S} \mathbb{P}(\mathbf{y}|\mathbf{f}_s)^{\Delta\tau(t)}, \qquad \mathbf{f}_s \sim \mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},t-1)\,.
\end{aligned}$$

This works fine for small temperature changes $\Delta\tau(t) := \tau(t) - \tau(t-1)$. In the limit, we smoothly interpolate between $\mathbb{P}(\mathbf{y}|\mathbf{f})^0\,\mathbb{P}(\mathbf{f}|\mathbf{X})$ and $\mathbb{P}(\mathbf{y}|\mathbf{f})^1\,\mathbb{P}(\mathbf{f}|\mathbf{X})$, that is, we start by sampling from the prior and finally approach the posterior. Note that sampling is algorithmically possible even though the distribution is only known up to a constant factor.

10.2 Amelioration Using an Approximation to the Posterior

In practice, the posterior can be quite different from the prior. That means that individual fractions Z_t/Z_{t-1} may be difficult to estimate. One can make these fractions more similar by increasing the number of steps T or by "starting" from a distribution close to the posterior rather than from the prior. Let $\mathbb{Q}(\mathbf{f}) = \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V}) \approx \mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},T) = \mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X})\,/Z_T$ denote an approximation to the posterior. Setting $\mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V}) = \mathbb{Q}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X})$, one can calculate the effective likelihood $\mathbb{Q}(\mathbf{y}|\mathbf{f})$ by division (see Appendix B.2).

For the integration we use $Z_t = \int \mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t)}\,\mathbb{Q}(\mathbf{y}|\mathbf{f})^{1-\tau(t)}\,\mathbb{P}(\mathbf{f}|\mathbf{X})\,\mathrm{d}\mathbf{f}$ where $Z_0 = \int \mathbb{Q}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X})\,\mathrm{d}\mathbf{f}$ can be computed analytically. Again, each factor $\frac{Z_t}{Z_{t-1}}$ of the expanded fraction can be approximated

by importance sampling from the modified intermediate posterior:

$$\begin{aligned}\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},t-1) &= \mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t-1)}\mathbb{Q}(\mathbf{y}|\mathbf{f})^{1-\tau(t-1)}\mathbb{P}(\mathbf{f}|\mathbf{X})/Z_{t-1} \\ &= \left[\frac{\mathbb{P}(\mathbf{y}|\mathbf{f})}{\mathbb{Q}(\mathbf{y}|\mathbf{f})}\right]^{\tau(t-1)}\mathbb{Q}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X})/Z_{t-1},\end{aligned}$$

$$\begin{aligned}\frac{Z_t}{Z_{t-1}} &= \frac{\int \mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t)}\mathbb{Q}(\mathbf{y}|\mathbf{f})^{1-\tau(t)}\mathbb{P}(\mathbf{f}|\mathbf{X})\,\mathrm{d}\mathbf{f}}{Z_{t-1}} \\ &= \int \frac{\mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t)}\mathbb{Q}(\mathbf{y}|\mathbf{f})^{1-\tau(t)}}{\mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t-1)}\mathbb{Q}(\mathbf{y}|\mathbf{f})^{1-\tau(t-1)}}\frac{\mathbb{P}(\mathbf{y}|\mathbf{f})^{\tau(t-1)}\mathbb{Q}(\mathbf{y}|\mathbf{f})^{1-\tau(t-1)}\mathbb{P}(\mathbf{f}|\mathbf{X})}{Z_{t-1}}\mathrm{d}\mathbf{f} \\ &= \int \left[\frac{\mathbb{P}(\mathbf{y}|\mathbf{f})}{\mathbb{Q}(\mathbf{y}|\mathbf{f})}\right]^{\Delta\tau(t)}\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},t-1)\,\mathrm{d}\mathbf{f} \\ &\approx \frac{1}{S}\sum_{s=1}^{S}\left[\frac{\mathbb{P}(\mathbf{y}|\mathbf{f}_s)}{\mathbb{Q}(\mathbf{y}|\mathbf{f}_s)}\right]^{\Delta\tau(t)}, \qquad \mathbf{f}_s \sim \mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},t-1)\,.\end{aligned}$$

The choice of $\mathbb{Q}(\mathbf{f})$ to be a good approximation to the true posterior makes the fraction $\mathbb{P}(\mathbf{y}|\mathbf{f})/\mathbb{Q}(\mathbf{y}|\mathbf{f})$ as constant as possible, which in turn reduces the error due to the finite step size in thermodynamical integration.

10.3 Algorithm

If only one sample $\mathbf{f}_t$ is used per temperature $\tau(t)$, the value of the entire fraction is obtained as

$$\ln\frac{Z_t}{Z_{t-1}} = \Delta\tau(t)\left[\ln\mathbb{P}(\mathbf{y}|\mathbf{f}_t) - \ln\mathbb{Q}(\mathbf{y}|\mathbf{f}_t)\right]$$

which gives rise to the full estimate

$$\ln Z \approx \sum_{t=1}^{T}\ln\frac{Z_t}{Z_{t-1}} = \ln Z_{\mathbb{Q}} + \sum_{t=1}^{T}\Delta\tau(t)\left[\ln\mathbb{P}(\mathbf{y}|\mathbf{f}_t) + \frac{1}{2}(\mathbf{f}_t-\tilde{\mathbf{m}})^{\top}\mathbf{W}(\mathbf{f}_t-\tilde{\mathbf{m}})\right]$$

for a single run r. The finite temperature change bias can be removed by combining results Z_r from R different runs by their arithmetic mean $\frac{1}{R}\sum_r Z_r$ (Neal, 2001)

$$\ln Z = \ln\int \mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X})\,\mathrm{d}\mathbf{f} \approx \ln\left(\frac{1}{R}\sum_{r=1}^{R}Z_r\right).$$

Finally, the only primitive needed to obtain MCMC estimates of Z, $\mathbf{m}$ and $\mathbf{V}$ is an efficient sampler for the "intermediate" posterior $\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},t-1)$. We use Hybrid Monte Carlo sampling (Neal, 1993).

10.4 Results

If the posterior is very close to the prior (as in regimes 7-9 of Figure 3), it does not make a difference, which we start from. However, if the posterior can be well approximated by a Gaussian

(regimes 4-6), but is sufficiently different from the prior, then the method decreases variance and consequently improves runtimes of AIS. Different approximation methods lead also to differences in the improvement. Namely, the Laplace approximation performs worse than the approximation found by Expectation Propagation because Laplace's method approximates around the mode which can be far away from the mean.

For our evaluations of the approximations to the marginal likelihood, however we started the algorithm from the prior. Otherwise, one might be worried of biasing the MCMC simulation towards the initial distribution in cases where the chain fails to mix properly.

11. Implementation

Implementations of all methods discussed are provided at `http://www.kyb.mpg.de/~hn/approxXX.tar.gz`. The code is designed as an extension to the Gaussian Processes for Machine Learning (GPML) (Rasmussen and Williams, 2006) Matlab Code.[3] Approximate inference for Gaussian processes is done by the `binaryGP.m` function, which takes as arguments the covariance function, the likelihood function and the approximation method. The existing GPML package provides `approxLA.m` for Laplace's method and `approxEP.m` for Expectation Propagation. These implementations are generic to the likelihood function. We provide `cumGauss.m` and `logistic.m` that were designed to avoid numerical problems. In the extension, `approxKL.m`, `approxVB.m`, `approxFV.m` and `approxTAP.m` are included, among others not discussed here, for example sparse and online methods outside the scope of the current investigation. The implementations are straight-forward, although special care has been taken to avoid numerical problems e.g., situations where $\mathbf{K}$ is close to singular. More concretely, we use the well-conditioned matrix[4] $\mathbf{B} = \mathbf{W}^{\frac{1}{2}}\mathbf{K}\mathbf{W}^{\frac{1}{2}} + \mathbf{I} = \mathbf{L}\mathbf{L}^{\top}$ and its Cholesky decomposition to calculate $\mathbf{V} = \left(\mathbf{K}^{-1} + \mathbf{W}\right)^{-1}$ or $\mathbf{k}_*^{\top}\left(\mathbf{K} + \mathbf{W}^{-1}\right)^{-1}\mathbf{k}_*$. The posterior mean is represented in terms of $\boldsymbol{\alpha}$ to avoid multiplications with $\mathbf{K}^{-1}$ and facilitate predictions.

Especially LA and EP show a high level of robustness along the full spectrum of possible hyperparameters. KL uses Gauss-Hermite quadrature; we did not notice problems stemming therefrom. The FV and TAP methods work very reliably, although, we had to add a small (10^{-6}) ridge for FV to regularize $\mathbf{K}$. As a general statement, we did not observe any numerical problems for a wide range of hyperparameters reaching from reasonable values to very extreme scales.

In addition to the code for the algorithms, we provide also a tarball containing all necessary scripts to reproduce the figures of the paper. We offer two versions: The first version contains only the code for running the experiments and drawing the figures.[5] The second version additionally includes the results of the experiments.[6]

12. Experiments

The purpose of the experiments is to illustrate the strengths and weaknesses of the different approximation methods. First of all, the quality of the approximation itself in terms of posterior moments Z,

3. The package is available at `http://www.gaussianprocess.org/gpml/code`.
4. All eigenvalues λ of $\mathbf{B}$ satisfy $1 \leq \lambda \leq 1 + \frac{n}{4}\max_{ij}\mathbf{K}_{ij}$, thus $\mathbf{B}^{-1}$ and $|\mathbf{B}|$ can be safely computed.
5. The code base ($\sim$ 9Mb) can be obtained from `http://www.kyb.mpg.de/~hn/supplement_code.tar.gz`.
6. The complete code base ($\sim$ 400Mb) including all simulation results and scripts to generate figures is stored at `http://www.kyb.mpg.de/~hn/supplement_all.tar.gz`.

m and **V** is studied. At a second level, building on the "low-level" features, we compare predictive performance in terms of the predictive probability p_* given by (Equations 4 and 6):

$$p_* := \mathbb{P}(y_* = 1 | \mathbf{x}_*, \mathbf{y}, \mathbf{X}, \boldsymbol{\theta}) \quad \approx \quad \int \mathrm{sig}(f_*)\, \mathcal{N}\left(f_* | \mu_*, \sigma_*^2\right) \mathrm{d}f_*. \tag{16}$$

On a third level, we assess higher order properties such as the information score, describing how much information the model managed to extract about the target labels, and the error rate—a binary measure of whether a test input is assigned the right class. Uncertainty predictions provided by the model are not captured by the error rate.

Accurate marginal likelihood estimates Z are a key to hyperparameter learning. In that respect, Z can be seen as a high-level feature and as the "zeroth" posterior moment at the same time.

A summary of the whole section is provided in Table 1.

12.1 Data Sets

One main idea of the paper is to study the general behavior of approximate GP classification. Our results for the different approximation methods are not specific to a particular data set but apply to a wide range of application domains. This is reflected by the choice of our reference data sets, widely used in the machine learning literature. Due to limited space, we don't include the full experiments on all data sets in this paper. However, we have verified that the same qualitative conclusions hold for all the data sets considered. The full results are available via the web.[7]

Data set	n_{train}	n_{test}	d	Brief description of problem domain
Breast	300	383	9	Breast cancer[8]
Crabs	100	100	6	Sex of Leptograpsus crabs[9]
Ionosphere	200	151	34	Classification of radar returns from the ionosphere[10]
Pima	350	418	8	Diabetes in Pima Indians[11]
Sonar	108	100	60	Sonar signals bounced by a metal or rock cylinder[12]
USPS 3 vs. 5	767	773	256	Binary sub-problem of the USPS handwritten digit data set[13]

12.2 Results

In the following, we report our experimental results covering posterior moments and predictive performance. Findings for all 5 methods are provided to make the methods as comparable as possible.

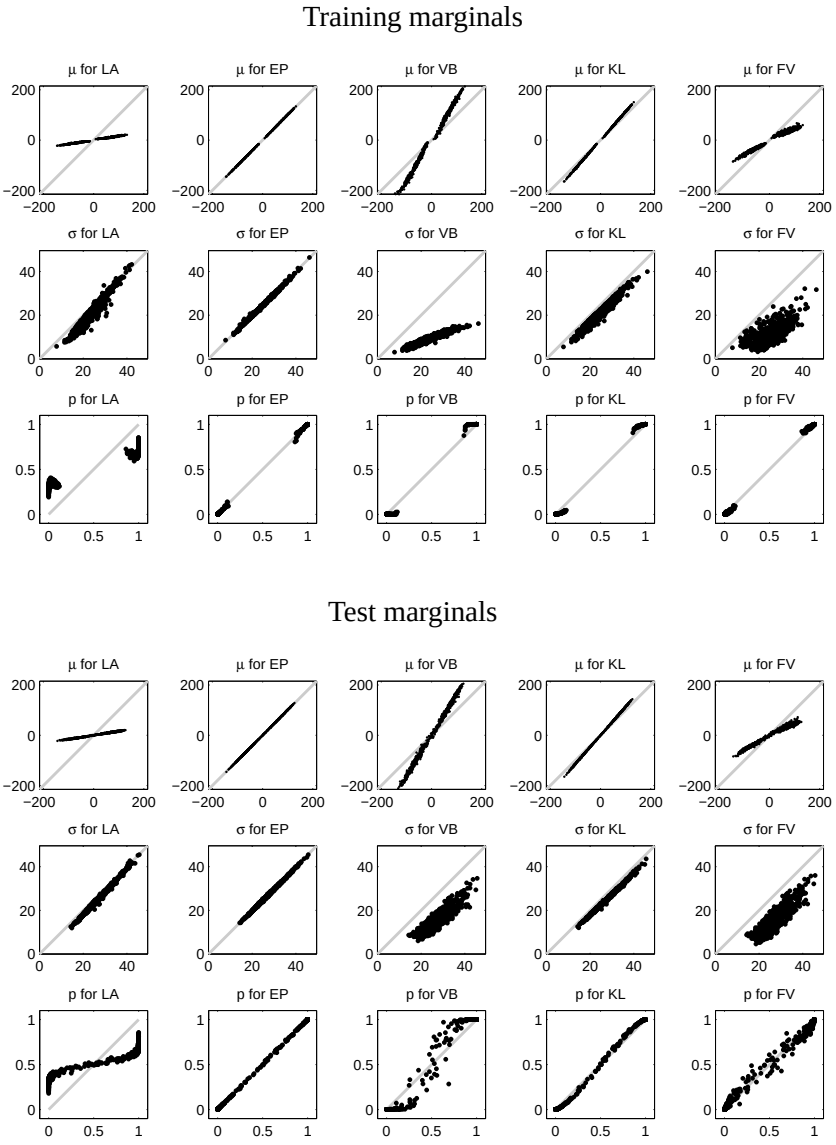

Figure 6: Marginals of USPS 3 vs. 5 for a highly non-Gaussian posterior: Each row consists of five plots showing MCMC ground truth on the x-axis and LA, EP, VB, KL and FV on the y-axis. Based on the logistic likelihood function and the squared exponential covariance function with parameters $\ln \ell = 2.25$ and $\ln \sigma_f = 4.25$ we plot the marginal means, standard deviations and resulting predictive probabilities in rows 1-3. We are working in regime 2 of Figure 3 that means the posterior is highly non-Gaussian. The upper part shows marginals of training points and the lower part shows test point marginals.

Table 1: Feature summary of the considered algorithms: For each of the six algorithms under consideration, the major properties are listed in the above table. The basic idea of the method along with its computational algorithm and complexity is summarized, the requirements to the likelihood functions are given, the accuracy of evidence and moment estimates as well as information is outlined and some striking advantages and drawbacks are compared. Six relations characterize accuracy: – – – extreme underestimation, – – heavy underestimation, – underestimation, = ground truth, $\approx$ good approximation, + overestimation and ++ heavy overestimation. Running times were calculated by running each algorithm for 9 different hyperparameter regimes and both likelihoods on all data sets. An average running time per data set was calculated for each method and scaled to yield 1 for LA. In the table, the average of these numbers are shown. We are well aware of the fact, that these numbers also depend on our Matlab implementations and choices of convergence thresholds.

12.2.1 MEAN $\mathbf{m}$ AND (CO)VARIANCE $\mathbf{V}$

The posterior process, or equivalently the posterior distribution over the latent values $\mathbf{f}$, is determined by its location parameter $\mathbf{m}$ and its width parameter $\mathbf{V}$. In that respect, these two low-level quantities are the basis for all further calculations. In general, one can say that the methods show

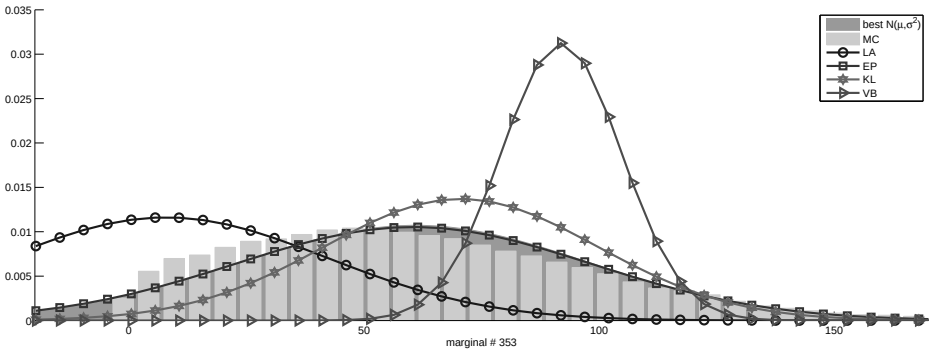

Figure 7: Marginals USPS 3 vs. 5 for digit #353 ≡  : Posterior marginals for one special training point from Figure 6 is shown. Ground truth in terms of true marginal and best Gaussian marginal (matching the moments of the true marginal) are plotted in gray, Gaussian approximations are visualized as lines. For multivariate Gaussians $\mathcal{N}(\mathbf{m},\mathbf{V})$, the *i*-th marginal is given by $\mathcal{N}([\mathbf{m}]_i,[\mathbf{V}]_{ii})$. Thus, the mode m_i of marginal *i* coincides with the *i*-th coordinate of the mode of the joint $[\mathbf{m}]_i$. This relation does not hold for general skewed distribution. Therefore, the marginal given by the Laplace approximation is not centered at the mode of the true marginal.

significant differences in the case of highly non-Gaussian posteriors (regimes 1-5 of Figure 3). Even in the two-dimensional toy example of Figures 4 and 5, significant differences are apparent. The means are inaccurate for LA and VB; whereas the variances are somewhat underestimated by LA and KL and severely so by VB. Marginal means $\mathbf{m}$ and variances $\mathrm{dg}(\mathbf{V})$ for USPS 3 vs. 5 are shown in Figure 6; an exemplary marginal is pictured in Figure 7 for all approximate methods and the MCMC estimate. Along the same lines, a close-to-Gaussian posterior is illustrated in Figure 8. We chose the hyperparameters for the non Gaussian case of Figure 6 to maximize the EP marginal likelihood (see Figure 9), whereas the hyperparameters of Figure 8 were selected to yield a posterior that is almost Gaussian but still has reasonable predictive performance.

The LA method has the principled weakness of expanding around the mode. In high-dimensional spaces, the mode can be very far away from the mean (Kuss and Rasmussen, 2005). The absolute value of the mean is strongly underestimated. Furthermore, the posterior is highly curved at its mode which leads to an underestimated variance, too. These effects can be seen in the first column of Figures 6 and 7, although in the close-to-Gaussian regime LA works well, Figure 8. For large latent function scales σ_f^2, in the limit $\sigma_f^2 \to \infty$, the likelihood becomes a step function, the mode approaches the origin and the curvature at the mode becomes larger. Thus the approximate posterior as found by LA becomes a zero-mean Gaussian which is much too narrow.

The EP method almost perfectly agrees with the MCMC estimates, second column of Figure 6. That means, iterative matching of approximate marginal moments leads to accurate marginal moments of the posterior.

The KL method minimizes the KL-divergence $\mathrm{KL}\left(\mathbb{Q}\left(\mathbf{f}\right) \parallel \mathbb{P}\left(\mathbf{f}\right)\right) = \int \mathbb{Q}\left(\mathbf{f}\right) \ln \frac{\mathbb{Q}(\mathbf{f})}{\mathbb{P}(\mathbf{f})} \mathrm{d}\mathbf{f}$ with the average taken to the approximate distribution $\mathbb{Q}\left(\mathbf{f}\right)$. The method is *zero-forcing* i.e., in regions where $\mathbb{P}\left(\mathbf{f}\right)$ is very small, $\mathbb{Q}\left(\mathbf{f}\right)$ has to be very small as well. In the limit that means $\mathbb{P}\left(\mathbf{f}\right) = 0 \Rightarrow \mathbb{Q}\left(\mathbf{f}\right) = 0$.

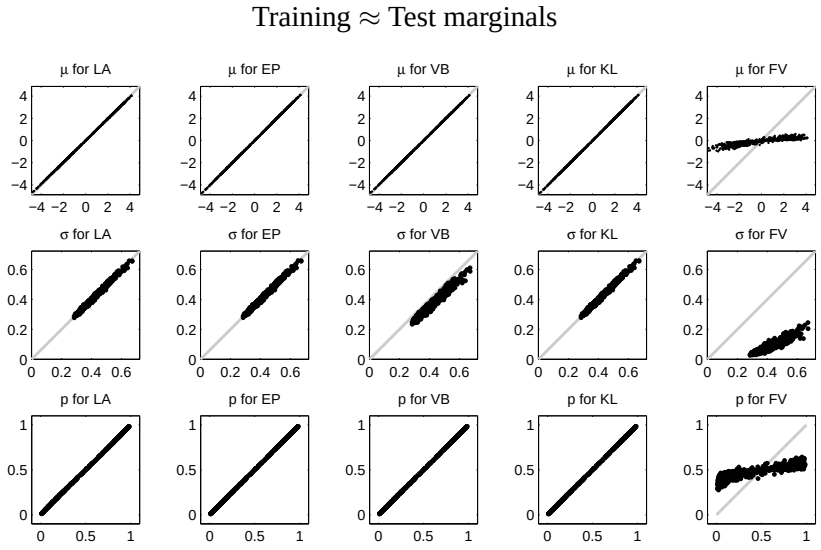

Figure 8: Marginals of USPS 3 vs. 5 for a close-to-Gaussian posterior: Using the squared exponential covariance and the logistic likelihood function with parameters $\ln \ell = 3$ and $\ln \sigma_f = 0.5$, we plot the marginal means, standard deviations and resulting predictive probabilities in rows 1-3. Only the quantities for the trainings set are shown, because the test set results are very similar. We are working in regime 8 of Figure 3 that means the posterior is of rather Gaussian shape. Each row consists of five plots showing MCMC ground truth on the x-axis and LA, EP, VB, KL and FV on the y-axis.

Thus, the support of $\mathbb{Q}(\mathbf{f})$ is smaller than the support of $\mathbb{P}(\mathbf{f})$ and hence the variance is underestimated. Typically, the posterior has a long tail away from zero as seen in Figure 3 regimes 1-5. The zero forcing property shifts the mean of the approximation away from the origin, which results in a slightly overestimated mean, fourth column of Figure 6.

Finally, the VB method can be seen as a more constrained version of the KL method with deteriorated approximation properties. The variance underestimation and mean overestimation is magnified, third column of Figure 6. Due to the required lower bounding property of each individual likelihood term, the approximate posterior has to obey severe restrictions. Especially, the lower bound to the cumulative Gaussian cannot adjust its width since the asymptotic behavior does not depend on the variational parameter (Equation 14).

The FV method has a special rôle because it does not lead to a Gaussian approximation to the posterior but to the closest (in terms of KL-divergence) factorial distribution. If the prior is quite isotropic (regimes 1,4 and 7 of Figure 3), the factorial approximation provides a reasonable approximation. If the latent function values are correlated, the approximation fails. Because of the zero forcing property, mentioned in the discussion of the KL method, both the means and the variances are underestimated. Since a factorial distribution cannot capture correlations, the effect can be severe. It is worth mentioning that there is no difference whether the posterior is close to a

Gaussian or not. In that respect, the FV method complements the LA method, which has difficulties in regimes 1, 2 and 4 of Figure 3.

12.2.2 PREDICTIVE PROBABILITY p_* AND INFORMATION SCORE I

Low-level features like posterior moments are not a goal per se, they are only needed for the purpose of calculating predictive probabilities. Figures 4 and 6 show predictive probabilities in the last row.

In principle, a bad approximation in terms of posterior moments can still provide reasonable predictions. Consider the predictive probability from Equation 16 using a cumulative Gaussian likelihood

$$p_* \quad = \quad \int \mathrm{sig}_{\mathrm{probit}}(f_*)\mathcal{N}(f_*|\mu_*,\sigma_*^2)\mathrm{d}f_* = \mathrm{sig}_{\mathrm{probit}}(\mu_*/\sqrt{1+\sigma_*^2}).$$

It is easy to see that the predictive probability p_* is constant if $\mu_*/\sqrt{1+\sigma_*^2}$ is constant. That means, moving mean μ_* and standard deviation σ_* along the hyperbolic curve $\mu_*^2/C^2-\sigma_*^2=1$, while keeping the sign of μ_* fixed, does not affect the probabilistic prediction. In the limit of large μ_* and large σ_*, rescaling does not change the prediction.

Summarizing all predictive probabilities p_i we consider the scaled information score I. As a baseline model we use the best model ignoring the inputs $\mathbf{x}_i$. This model simply returns predictions matching the class frequencies of the training set

$$B \quad = \quad -\sum_{y=\{+1,-1\}} \frac{n_{\mathrm{test}}^y}{n_{\mathrm{test}}^{+1}+n_{\mathrm{test}}^{-1}} \log_2 \frac{n_{\mathrm{train}}^y}{n_{\mathrm{train}}^{+1}+n_{\mathrm{train}}^{-1}} \leq 1[\mathrm{bit}].$$

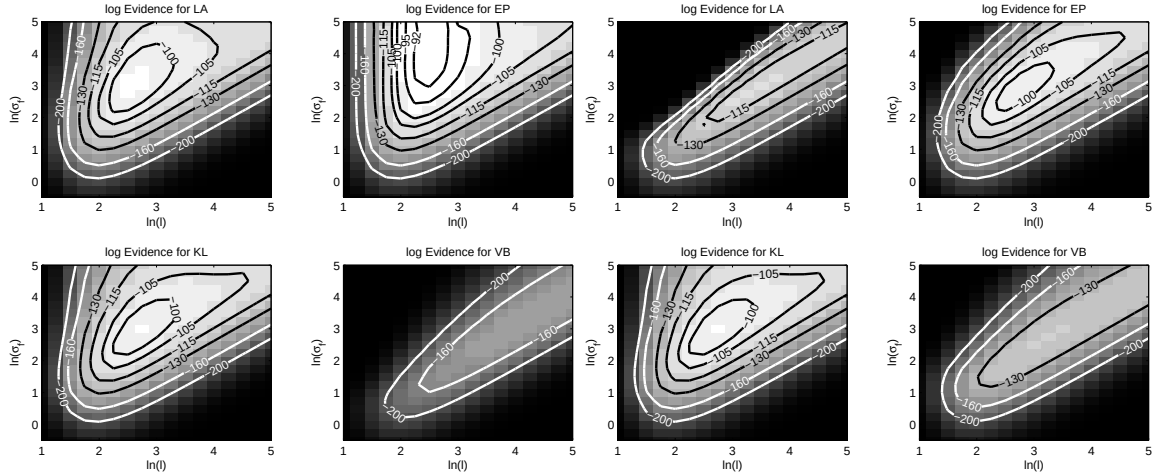
We take the difference between the baseline B (entropy) and the average negative log predictive probabilities $\log_2 \mathbb{P}(y_*|\mathbf{x}_*,\mathbf{y},\mathbf{X})$ to obtain the information score

$$I \quad = \quad B+\frac{1}{2n_{\mathrm{test}}}\sum_{i=1}^{n_{\mathrm{test}}}(1+y_i)\log_2(p_i)+(1-y_i)\log_2(1-p_i),$$

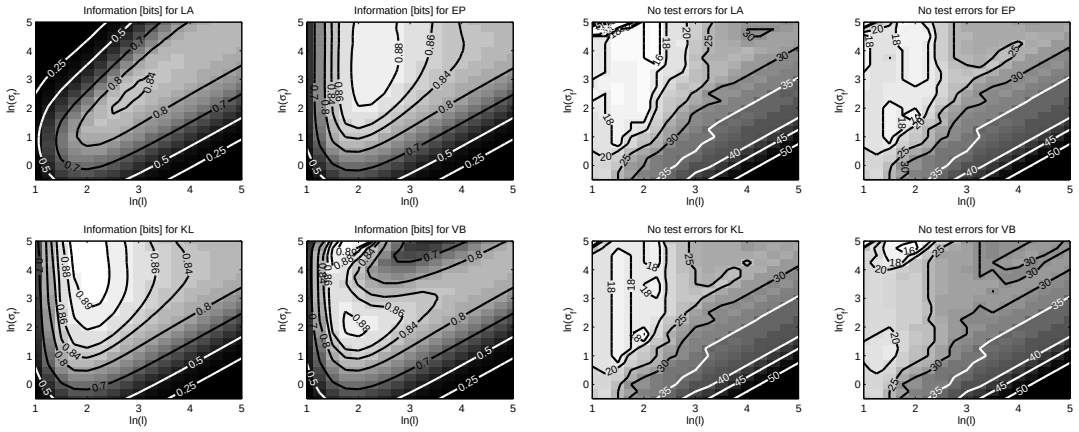
which is $1[\mathrm{bit}]$ for perfect (and confident) prediction and $0[\mathrm{bits}]$ for random guessing (for equiprobable classes). Figures 9(c), 10(middle) and 11(c) contain information scores for 5 different approximation methods on two different data sets as a function of the hyperparameters of the covariance function. According to the EP and KL plots (most prominently in Figure 11(c)), there are two strategies for a model to achieve good predictive performance:

- Find a good length scale ℓ (e.g., $\ln\ell\approx 2$) and choose a latent function scale σ_f above some threshold (e.g., $\ln\sigma_f > 3$).
- Start from a good set of hyperparameters (e.g., $\ln\ell\approx 2$, $\ln\sigma_f\approx 2$) and compensate a harder cutting likelihood ($\sigma_f^2\uparrow$) by making the data points more similar to each other ($\ell^2\uparrow$).

The LA method heavily underestimates the marginal means in the non-Gaussian regime (regimes 1-5 of Figure 3). As a consequence, the predictive probabilities are strongly under-confident in the non-Gaussian regime, first column of Figure 6. The information score's value is too small in the non-Gaussian regime, Figures 9(c) and 11(c).



(a) Evidence (b) Lower bound on evidence



(c) Information in bits (d) Number of errors

Figure 9: Evidence and classification performance for LA, EP, KL & VB on USPS 3 vs. 5: The length scale ℓ and the latent scale σ_f determine the working regime (1-9) of the Gaussian Process as drafted in Figure 3. We use the logistic likelihood and the squared exponential covariance function to classify handwritten digits. The four panels illustrate the model performance in terms of evidence, information and classification errors over the space of hyperparameters (ℓ, σ_f). For better visibility we choose a logarithmic scale of the axes. Panel (a) shows the inherent evidence approximation of the four methods and panel (b) contains the Jensen lower bound (Equation 9) on the evidence used in KL method. Both panels share the same contour levels for all four methods. Note that for the VB method, the general lower bound is a better evidence estimate than the bound provided by the method itself. Panel (c) and (d) show the information score and the number of misclassifications. One can read-off the divergence between posterior and approximation by recalling $\mathrm{KL}(\mathbb{Q}||\mathbb{P}) = \ln Z - \ln Z_B$ from Equation 10 and assuming $\ln Z_{\mathrm{EP}} \approx \ln Z$. In the figure this corresponds to subtracting Subplots (b, LA-VB) from Subplots (a, EP). Obviously, the divergence vanishes for close-to-Gaussian posteriors (regimes 3,5-6,7-9).

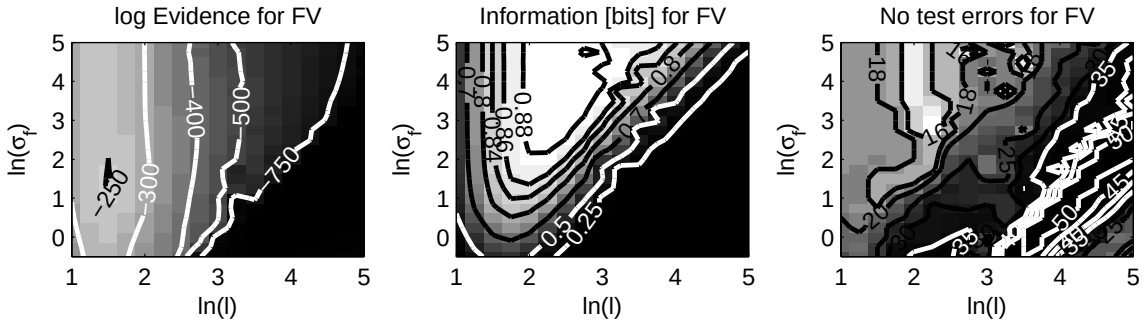


Figure 10: Evidence and classification performance for FV on USPS 3 vs. 5: The plots are a supplement to Figure 9 in that they make the factorial variational method comparable, even though we use the cumulative Gaussian likelihood. The levels of the contour lines for the information score and the number of misclassifications are the same as in Figure 9. For the marginal likelihood other contours are shown, since it has significantly different values.

Since the EP algorithm yields marginal moments very close to the MCMC estimates (second column of Figure 6), its predictive probabilities and information score is consequently also very accurate, Figures 9(c) and 11(c). The plots corresponding to EP can be seen as the quasi gold standard (Kuss and Rasmussen, 2005, Figures 4 and 5).

The KL method slightly underestimates the variance and slightly overestimates the mean which leads to slightly overconfident predictions, fourth column of Figure 6. Overconfidence, in general, leads to a degradation of the information score, however in this example, the information score is very close to the EP values and at the peak it is even slightly (0.01[bits]) higher, Figures 9(c) and 11(c).

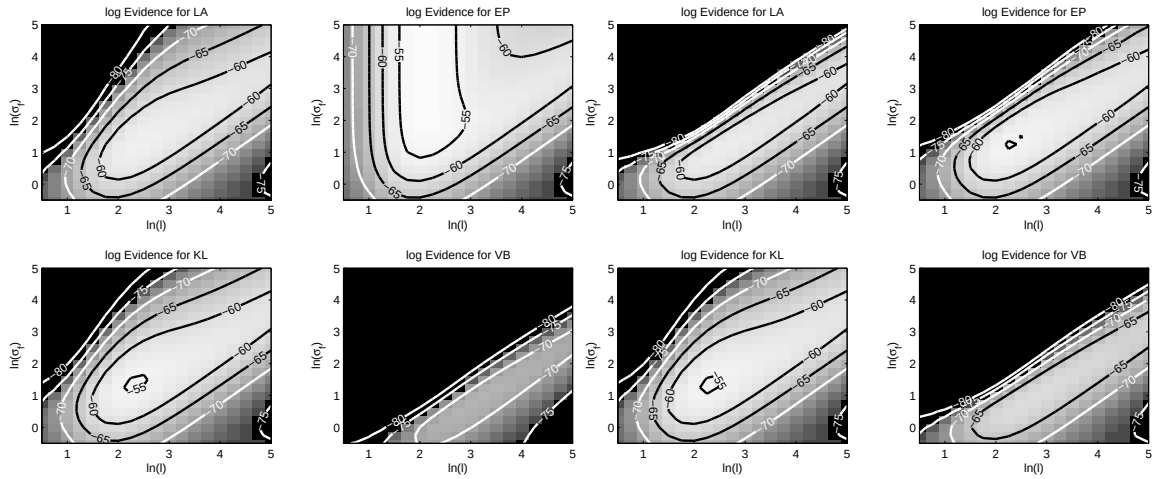
The VB method, again, has the same problems as the KL method only amplified. The predictions are overconfident, third column of Figure 6. Consequently, the information measured score in the non-Gaussian regime is too small. The logistic likelihood function (Figure 9(c)) yields much better results than the cumulative Gaussian likelihood function (Figure 11(c)).

Finally, as the FV method is accurate if the prior is isotropic, predictive probabilities and information scores are very high in regimes 1, 4 and 7 of Figure 3. For correlated priors, the FV method achieves only low information scores, Figure 10(middle). The method seems to benefit from the "hyperbolic scaling invariance" of the predictive probabilities mentioned earlier in that section because both the mean and the variance are strongly underestimated.

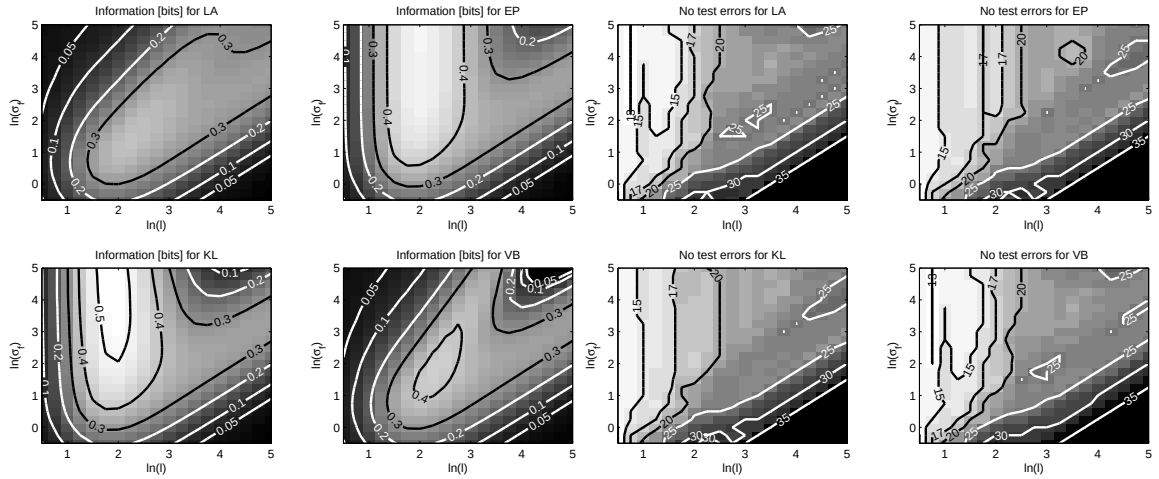
12.2.3 NUMBER OF ERRORS *E*

If one is only interested in the actual class and not in the associated confidence level, one can simply measure the number of misclassifications. Results for 5 approximation methods and 2 data sets are shown in Figures 9(d), 10(right) and 11(d).

Interestingly, all four Gaussian approximation have very similar error rates. The reason is mainly due to the fact that all methods manage to compute the right sign of the marginal mean. Only the FV method with cumulative Gaussian likelihood seems a bit problematic, even though the



(a) Evidence (b) Lower bound on evidence



(c) Information in bits (d) Number of errors

Figure 11: Evidence and classification performance for LA, EP, KL & VB on Sonar: We show the same quantities as in Figure 9, only for the Sonar Mines versus Rocks data set and using the cumulative Gaussian likelihood function.

difference is only very small. Small error rates do not imply high information scores, it is rather the other way round. In Figure 9(d) at $\ln \ell = 2$ and $\ln \sigma_f = 4$ only 16 errors are made by the LA method while the information score (Figure 9(c)) is only of 0.25[bits].

Even the FV method yields very accurate classes, having only small error rates.

12.2.4 MARGINAL LIKELIHOOD Z

Agreement of model and data is typically measured by the marginal likelihood Z. Hyperparameters can conveniently be optimized using Z not least because the gradient $\frac{\partial \ln Z}{\partial \boldsymbol{\theta}}$ can be analytically and efficiently computed for all methods. Formally, the marginal likelihood is the volume of the product of prior and likelihood. In classification, the likelihood is a product of sigmoid functions (Figure 3), so that only the orthant $\{\mathbf{f}|\mathbf{f}\odot\mathbf{y}\geq\mathbf{0}\in\mathbb{R}^n\}$ contains values $\mathbb{P}(\mathbf{f}|\mathbf{y})\geq\frac{1}{2}$. In principle, evidences are bounded by $\ln Z\leq 0$ where $\ln Z=0$ corresponds to a perfect model. As pointed out in Section 2.1.1, the marginal likelihood for a model ignoring the data and having equiprobable targets has the value $\ln Z=-n\ln 2$, which serves as a baseline.

Evidences provided by LA, EP and VB for two data sets are shown in Figures 9(a), 10(left) and 11(a). As the Jensen bound can be applied to any Gaussian approximation of the posterior, we also report it in Figures 9(b) and 11(b).

The LA method strongly underestimates the evidence in the non-Gaussian regime, because it is forced to center its approximation at the mode, Figures 9(a) and 11(a). Nevertheless, there is a good agreement between the value of the marginal likelihood and the corresponding information score. The Jensen lower bound is not tight for the LA approximation, Figures 9(b) and 11(b).

The EP method yields the highest values among all other methods. As described in Section 2.1.2, for high latent function scales σ_f^2, the model becomes effectively independent of σ_f^2. This behavior is only to be seen for the EP method, Figures 9(a) and 11(a). Again, the Jensen bound is not tight for the EP method, Figures 9(b) and 11(b). The difference between EP and MCMC marginal likelihood estimate is vanishingly small (Kuss and Rasmussen, 2005, Figures 4 and 5).

The KL method directly uses the Jensen bound (Equation 8) which can only be tight for Gaussian posterior distributions. If the posterior is very skew, the bound inherently underestimates the marginal likelihood. Therefore, Figures 9(a) and 9(b) and Figures 11(a) and 11(b) show the same values. The disagreement between information score and marginal likelihood makes hyperparameter selection based on the KL method problematic.

The VB method's lower bound on the evidence turns out to be very loose, Figures 9(a) and 11(a). Theoretically, it cannot be better than the more general Jensen bound due to the additional constraints imposed by the individual bound on each likelihood factor, Figures 9(b) and 11(b). In practice, one uses the Jensen bound for hyperparameter selection. Again, the maximum of the bound to the evidence is not very helpful for finding regions of high information score.

Finally, the FV method only yields a poor approximation to the marginal likelihood due to the factorial approximation, Figure 10. The more isotropic the model becomes (small ℓ), the tighter is the bound. For strongly correlated priors (large ℓ) the evidence drops even below the baseline $\ln Z=-n\ln 2$. Thus, the bound is not adequate to do hyperparameter selection as its maximum does not lie in regions with high information score.

12.2.5 CHOICE OF LIKELIHOOD

In the experiments, we worked with two different likelihood functions, namely the logistic and the cumulative Gaussian likelihood. The two functions differ in their slope at the origin and their asymptotic behavior. We did not find empirical evidence supporting the use of either likelihood. Theoretically, the cumulative Gaussian likelihood should be less robust against outliers due to the quadratic asymptotics. Practically, the different slopes result in a shift of the latent function length scale in the order of $\ln\frac{1}{4}-\ln\frac{1}{\sqrt{2\pi}}\approx 0.46$ on a log scale in that the logistic likelihood prefers a

bigger latent scale. Only for the VB method, differences were significant because the logistic bound is more concise. Numerically, however the cumulative Gaussian is preferable.

12.3 Results Across Data Sets

We conclude with a quantitative summary of experiments conducted on 6 data sets (breast, crabs, ionosphere, diabetes, sonar, USPS 3 vs. 5), two different likelihoods (cumulative Gaussian, logistic) and 8 covariance functions (linear, polynomial of degree 1-3, Matérn $\nu \in \{\frac{3}{2}, \frac{5}{2}\}$, squared exponential and neural network) resulting in 96 trials. All 7 approximate classification methods were trained on a 16×16 grid of hyperparameters to compare their behavior under a wide range of conditions. We calculated the maximum (over the hyperparameter grid) amount of information, every algorithm managed to extract from the data in each of the 96 trials. The table shows the number of trials, where the respective algorithm had a maximum information score that was above the mean/median (over the 7 methods).

Test \ Method	**LA**	**EP**	**KL**	**VB**	**FV**	**LR**	**TAPnaive**
# trials, information below **mean**	31	0	0	6	34	92	31
# trials, information below **median**	54	0	0	15	48	96	51

13. Conclusions

In the present paper we provide a comprehensive overview of methods for approximate Gaussian process classification. We present an exhaustive analysis of the considered algorithms using theoretical arguments. We deliver thorough empirical evidence supporting our insights revealing the strengths and weaknesses of the algorithms. Finally, we make a unified and modular implementation of all methods available to the research community.

We are able to conclude that the Expectation Propagation algorithm is, in terms of accuracy, always the method of choice, except when you cannot afford the slightly longer running time compared to the Laplace approximation.

Our comparisons include the Laplace approximation and the Expectation Propagation algorithm (Kuss and Rasmussen, 2005). We extend the latter to the logistic likelihood. We apply Kullback-Leibler divergence minimization to Gaussian process classification and derive an efficient Newton algorithm. Although the principles behind this method have been known for some time, we are unaware that this method has been previously implemented for GPs in practise. The existing variational method (Gibbs and MacKay, 2000) is extended by a lower bound on the cumulative Gaussian likelihood and we provide an implementation based on Newton's method. Furthermore, we give a detailed analysis of the Factorial Variational method (Csató et al., 2000).

All methods are considered in a common framework, approximation quality is assessed, predictive performance is measured and model selection is benchmarked.

In practice, an approximation method has to satisfy a wide range of requirements. If **runtime** is the major concern or one is interested in **error rate** only, the Laplace approximation or label regression should be considered. Only Expectation Propagation and—although a lot slower—the KL-method deliver accurate **marginals** as well as reliable **class probabilities** and allow for faithful **model selection**.

If an application demands a **non-standard likelihood** function, this also affects the choice of the algorithm: The Laplace approximation requires derivatives, Expectation Propagation and the

Factorial Variational method need integrability with respect to Gaussian measures. However, the KL-method simply needs to evaluate the likelihood and known lower bounds naturally lead to the VB algorithm.

Finally, if the classification problem contains a lot of **label noise** (σ_f is small), the exact posterior distribution is effectively close to Gaussian. In that case, the choice of the approximation method is not crucial since in the Gaussian regime, they will give the same answer. For weakly coupled training data, the Factorial Variational method can lead to quite reasonable approximations.

As a future goal remains an in-depth understanding of the properties of sparse and online approximations to the posterior and a coverage of a broader range of covariance functions. Also, the approximation techniques discussed can be applied to other non-Gaussian inference problems besides the narrow applications to binary GP classification discussed here, and there is hope that some of the insights presented may be useful more generally.

Acknowledgments

Thanks to Manfred Opper for pointing us initially to the practical possibility of the KL method and the three anonymous reviewers.

Appendix A. Derivatives

In the following, we provide the expressions for the derivatives needed to implement the VB and the KL method.

A.1 Derivatives for VB

Some notational remarks. Partial derivatives w.r.t. one single parameter such as $\frac{\partial \mathbf{A}_\varsigma}{\partial \varsigma_i}$ or $\frac{\partial \mathbf{b}_\varsigma}{\partial \varsigma_i}$ stay matrices or vectors, respectively. Lowercase letters $\{\mathbf{a},\mathbf{b},\mathbf{c}\}_\varsigma$ indicate vectors, upper case letters $\{\mathbf{A},\mathbf{B},\mathbf{C}\}_\varsigma$ stand for the corresponding diagonal matrices with the vector as diagonal. The dot notation applies to both lower and uppercase letters and denote derivatives w.r.t. the variational parameter vector ς

$$\begin{aligned}
\dot{\mathbf{a}}_\varsigma &:= \left[\frac{\partial a_{\varsigma_i}}{\partial \varsigma_i}\right]_i = \frac{\partial \mathbf{a}_\varsigma}{\partial \varsigma}, \text{ vector,} \\
\ddot{\mathbf{a}}_\varsigma &:= \left[\frac{\partial^2 a_{\varsigma_i}}{\partial \varsigma_i^2}\right]_i = \frac{\partial^2 \mathbf{a}_\varsigma}{\partial \varsigma^2}, \text{ vector,} \\
\dot{\mathbf{A}}_\varsigma &:= \mathrm{Dg}\left(\dot{\mathbf{a}}_\varsigma\right).
\end{aligned}$$

The operators $\mathrm{Dg} : \mathbb{R}^n \to \mathbb{R}^{n\times n}$ and $\mathrm{dg} : \mathbb{R}^{n\times n} \to \mathbb{R}^n$ manipulate matrix diagonals. The result of $\mathrm{Dg}(\mathbf{x})$ is a diagonal matrix $\mathbf{X}$ containing $\mathbf{x}$ as diagonal, whereas $\mathrm{dg}(\mathbf{X})$ returns the diagonal of $\mathbf{X}$ as a vector. Hence, we have $\mathrm{Dg}\left(\mathrm{dg}(\mathbf{x})\right) = \mathbf{x}$, but in general $\mathrm{dg}\left(\mathrm{Dg}(\mathbf{X})\right) = \mathbf{X}$ does only hold true for diagonal matrices.

A.1.1 SOME SHORTCUTS USED LATER ONWARDS

$$
\begin{aligned}
\tilde{\mathbf{K}}_{\boldsymbol{\varsigma}} &:= \left(\mathbf{K}^{-1} - 2\mathbf{A}_{\boldsymbol{\varsigma}}\right)^{-1} \overset{\mathbf{K} \text{ small}}{=} \mathbf{K} - \mathbf{K}\left(\mathbf{K} - \frac{1}{2}\mathbf{A}_{\boldsymbol{\varsigma}}^{-1}\right)^{-1}\mathbf{K}, \\

A.1.5 FIRST DERIVATIVES W.R.T. HYPERPARAMETERS θ_i:

For a gradient optimization with respect to $\boldsymbol{\theta}$, we need the gradient of the objective $\partial \ln Z_B / \partial \boldsymbol{\theta}$. Naïvely, the gradient is given by:

$$\begin{aligned}
\frac{\partial \ln Z_B}{\partial \theta_i} &= \frac{1}{2} \tilde{\mathbf{b}}_{\boldsymbol{\varsigma}}^\top \tilde{\mathbf{K}}_{\boldsymbol{\varsigma}} \mathbf{K}^{-1} \frac{\partial \mathbf{K}}{\partial \theta_i} \mathbf{K}^{-1} \tilde{\mathbf{K}}_{\boldsymbol{\varsigma}} \tilde{\mathbf{b}}_{\boldsymbol{\varsigma}} + \operatorname{tr}\left(\left(\mathbf{I} - 2\mathbf{A}_{\boldsymbol{\varsigma}} \mathbf{K}\right)^{-\top} \mathbf{A}_{\boldsymbol{\varsigma}} \frac{\partial \mathbf{K}}{\partial \theta_i}\right) \\
&\overset{\mathbf{l}_{\boldsymbol{\varsigma}}}{=} \frac{1}{2} \mathbf{l}_{\boldsymbol{\varsigma}}^\top \mathbf{K}^{-1} \frac{\partial \mathbf{K}}{\partial \theta_i} \mathbf{K}^{-1} \mathbf{l}_{\boldsymbol{\varsigma}} + \operatorname{tr}\left(\left(\mathbf{I} - 2\mathbf{A}_{\boldsymbol{\varsigma}} \mathbf{K}\right)^{-\top} \mathbf{A}_{\boldsymbol{\varsigma}} \frac{\partial \mathbf{K}}{\partial \theta_i}\right).
\end{aligned}$$

However, the optimal variational parameter $\boldsymbol{\varsigma}^*$ depends implicitly on the actual choice of $\boldsymbol{\theta}$ and one has to account for that in the derivative by adding an extra "implicit" term

$$\left.\frac{\partial \ln Z_B(\boldsymbol{\theta}, \boldsymbol{\varsigma})}{\partial \theta_i}\right|_{\boldsymbol{\varsigma}=\boldsymbol{\varsigma}^*} = \frac{\partial \ln Z_B(\boldsymbol{\theta}, \boldsymbol{\varsigma}^*)}{\partial \theta_i} + \sum_{j=1}^{n} \frac{\partial \ln Z_B(\boldsymbol{\theta}, \boldsymbol{\varsigma}^*)}{\partial \varsigma_j^*} \frac{\partial \varsigma_j^*}{\partial \theta_i}.$$

The question of how to find an expression for $\frac{\partial \boldsymbol{\varsigma}^*}{\partial \boldsymbol{\theta}}$ can be solved by means of the implicit function theorem for continuous and differentiable functions $\mathbf{F}$:

$$\mathbf{F} : \mathbb{R}^p \times \mathbb{R}^n \to \mathbb{R}^n, \quad \mathbf{F}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \quad \Rightarrow \quad \frac{\partial \mathbf{y}}{\partial \mathbf{x}}(\mathbf{x}) = -\left(\frac{\partial \mathbf{F}}{\partial \mathbf{y}}(\mathbf{x}, \mathbf{y}(\mathbf{x}))\right)^{-1} \frac{\partial \mathbf{F}}{\partial \mathbf{x}}(\mathbf{x}, \mathbf{y}(\mathbf{x})) \text{ if } \mathbf{F}(\mathbf{x}, \mathbf{y}(\mathbf{x})) = \mathbf{0}.$$

Setting $\mathbf{F}(\mathbf{x}, \mathbf{y}) \equiv \frac{\partial \ln Z_B}{\partial \boldsymbol{\varsigma}}(\boldsymbol{\theta}, \boldsymbol{\varsigma})$ leads to

$$\frac{\partial \boldsymbol{\varsigma}_\theta^*}{\partial \boldsymbol{\theta}^\top} = -\left(\frac{\partial^2 \ln Z_B(\boldsymbol{\theta}, \boldsymbol{\varsigma}_\theta^*)}{\partial \boldsymbol{\varsigma} \partial \boldsymbol{\varsigma}^\top}\right)^{-1} \frac{\partial^2 \ln Z_B(\boldsymbol{\theta}, \boldsymbol{\varsigma}_\theta^*)}{\partial \boldsymbol{\theta}^\top \partial \boldsymbol{\varsigma}}$$

and in turn combines to

$$\left.\frac{\partial \ln Z_B}{\partial \theta_i}\right|_{\boldsymbol{\varsigma}=\boldsymbol{\varsigma}^*} = \frac{\partial \ln Z_B}{\partial \theta_i} - \left(\frac{\partial \ln Z_B}{\partial \boldsymbol{\varsigma}}\right)^\top \left(\frac{\partial^2 \ln Z_B}{\partial \boldsymbol{\varsigma} \partial \boldsymbol{\varsigma}^\top}\right)^{-1} \frac{\partial^2 \ln Z_B}{\partial \theta_i \partial \boldsymbol{\varsigma}}$$

where all terms are known.

A.2 Derivatives for KL

The lower bound $\ln Z_B$ to the log marginal likelihood $\ln Z$ is given by Equation 9 as

$$\ln Z \quad \geq \quad = \ln Z_B(\mathbf{m},\mathbf{V}) = a(\mathbf{y},\mathbf{m},\mathbf{V}) + \frac{1}{2}\ln\left|\mathbf{V}\mathbf{K}^{-1}\right| + \frac{n}{2} - \frac{1}{2}\mathbf{m}^\top\mathbf{K}^{-1}\mathbf{m} - \frac{1}{2}\mathrm{tr}\left(\mathbf{V}\mathbf{K}^{-1}\right)$$

where we used the shortcut $a(\mathbf{y},\mathbf{m},\mathbf{V}) = \sum_{i=1}^n \int \mathcal{N}(f_i|m_i,v_{ii}) \ln \mathrm{sig}(y_i f_i) \mathrm{d}f_i$. As a first step, we calculate the first derivatives of $\ln Z_B$ with respect to the posterior moments $\mathbf{m}$ and $\mathbf{V}$ to derive necessary conditions for the optimum by equating them with zero:

$$\begin{aligned}
\frac{\partial \ln Z_B}{\partial \mathbf{V}} = \frac{\partial a(\mathbf{y},\mathbf{m},\mathbf{V})}{\partial \mathbf{V}} + \frac{1}{2}\mathbf{V}^{-1} - \frac{1}{2}\mathbf{K}^{-1} \stackrel{!}{=} \mathbf{0} \quad &\Rightarrow \quad \mathbf{V} = \left(\mathbf{K}^{-1} - 2\mathrm{Dgdg}\frac{\partial a}{\partial \mathbf{V}}\right)^{-1}, \\
\frac{\partial \ln Z_B}{\partial \mathbf{m}} = \frac{\partial a(\mathbf{y},\mathbf{m},\mathbf{V})}{\partial \mathbf{m}} - \mathbf{K}^{-1}\mathbf{m} \stackrel{!}{=} \mathbf{0} \quad &\Rightarrow \quad \mathbf{m} = \mathbf{K}\frac{\partial a}{\partial \mathbf{m}}.
\end{aligned}$$

These two expressions are plugged in the original expression for $\ln Z_B$ using $\mathbf{A} = (\mathbf{I} - 2\mathbf{K}\boldsymbol{\Lambda})^{-1}$ and $\boldsymbol{\Lambda} = \mathrm{Dgdg}\frac{\partial a}{\partial \mathbf{V}}$ to yield:

$$\ln Z_B(\boldsymbol{\alpha},\boldsymbol{\Lambda}) \quad = \quad a\left(\mathbf{y},\mathbf{K}\boldsymbol{\alpha},(\mathbf{K}^{-1}-2\boldsymbol{\Lambda})^{-1}\right) + \frac{1}{2}\ln|\mathbf{A}| - \frac{1}{2}\mathrm{tr}\mathbf{A} + \frac{n}{2} - \frac{1}{2}\boldsymbol{\alpha}^\top\mathbf{K}\boldsymbol{\alpha}.$$

Our algorithm uses the parameters $\boldsymbol{\alpha}$, $\boldsymbol{\Lambda}$, so we calculate first and second derivatives to implement Newton's method.

A.2.1 FIRST DERIVATIVES W.R.T. PARAMETERS $\boldsymbol{\alpha}$, $\boldsymbol{\Lambda}$ YIELDING THE GRADIENT

$$\frac{\partial \ln Z_B}{\partial \boldsymbol{\lambda}} = \frac{\partial a}{\partial \boldsymbol{\lambda}} + \mathrm{dg}(\mathbf{V}) - \mathrm{dg}(\mathbf{V}\mathbf{A}^\top) \quad \text{and} \quad \frac{\partial \ln Z_B}{\partial \boldsymbol{\alpha}} = \frac{\partial a}{\partial \boldsymbol{\alpha}} - \mathbf{K}\boldsymbol{\alpha}.$$

Only the terms containing derivatives of a need further attention, namely

$$\frac{\partial a}{\partial \boldsymbol{\alpha}} = \mathbf{K}\frac{\partial a}{\partial \mathbf{m}} \qquad \text{and}$$

$$\begin{aligned}
\mathrm{d}(\mathrm{dg}\mathbf{V}) \quad &= \quad \mathrm{dg}\left[\mathrm{d}\left(\mathbf{K}^{-1}-2\boldsymbol{\Lambda}\right)^{-1}\right] = 2\mathrm{dg}\left[\mathbf{V}\,\mathrm{d}\boldsymbol{\Lambda}\,\mathbf{V}\right] = 2\mathrm{dg}\left[\sum_k \mathbf{v}_k\mathbf{v}_k^\top \mathrm{d}\lambda_k\right] = 2\sum_k (\mathbf{v}_k \odot \mathbf{v}_k)\,\mathrm{d}\lambda_k \\
&= \quad 2\,(\mathbf{V}\odot\mathbf{V})\,\mathrm{d}\boldsymbol{\lambda} \Rightarrow \frac{\partial \mathrm{dg}\mathbf{V}}{\partial \boldsymbol{\lambda}^\top} = 2\mathbf{V}\odot\mathbf{V}, \\
\frac{\partial a}{\partial \boldsymbol{\lambda}} \quad &= \quad 2(\mathbf{V}\odot\mathbf{V})\frac{\partial a(\mathbf{y},\mathbf{m},\mathbf{V})}{\partial \mathrm{dg}\mathbf{V}}.
\end{aligned}$$

As a last step, the derivatives w.r.t. $\mathbf{m}$ and the diagonal part of $\mathbf{V}$ yield

$$\begin{aligned}
\frac{\partial a}{\partial m_i} &= \int \frac{\partial \mathcal{N}(f|m_i,v_{ii})}{\partial m_i} \ln \mathrm{sig}(y_i f)\mathrm{d}f = \int \frac{f-m_i}{v_{ii}} \mathcal{N}(f|m_i,v_{ii}) \ln \mathrm{sig}(y_i f)\mathrm{d}f \\
&= \frac{1}{\sqrt{v_{ii}}} \int f \cdot \mathcal{N}(f) \ln \mathrm{sig}\left(\sqrt{v_{ii}} y_i f + m_i y_i\right) \mathrm{d}f, \\
\frac{\partial a}{\partial v_{ii}} &= \int \frac{\partial \mathcal{N}(f|m_i,v_{ii})}{\partial v_{ii}} \ln \mathrm{sig}(y_i f)\mathrm{d}f = \int \left(\frac{(f-m_i)^2}{v_{ii}^{\frac{3}{2}}} - \frac{1}{\sqrt{v_{ii}}} \right) \mathcal{N}(f|m_i,v_{ii}) \ln \mathrm{sig}(y_i f)\mathrm{d}f \\
&= \frac{1}{2v_{ii}} \int \left(f^2-1\right) \cdot \mathcal{N}(f) \ln \mathrm{sig}\left(\sqrt{v_{ii}} y_i f + m_i y_i\right) \mathrm{d}f.
\end{aligned}$$

A.2.2 SECOND DERIVATIVES W.R.T. PARAMETERS $\boldsymbol{\alpha}$, $\boldsymbol{\Lambda}$ YIELDING THE HESSIAN

Again, we proceed in two steps, calculating derivatives w.r.t. $\boldsymbol{\alpha}$ and $\boldsymbol{\Lambda}$ and by the chain rule compute those w.r.t. $\mathbf{m}$ and $\mathbf{V}$.

$$\begin{aligned}
\frac{\partial^2 \ln Z_B}{\partial \boldsymbol{\alpha} \partial \boldsymbol{\alpha}^\top} &= \frac{\partial^2 a}{\partial \boldsymbol{\alpha} \partial \boldsymbol{\alpha}^\top} + \mathbf{K} = \frac{\partial}{\partial \boldsymbol{\alpha}} \left[\frac{\partial a}{\partial \mathbf{m}^\top} \frac{\partial \mathbf{m}}{\partial \boldsymbol{\alpha}^\top} \right] + \mathbf{K} = \frac{\partial}{\partial \boldsymbol{\alpha}} \left[\frac{\partial a}{\partial \mathbf{m}^\top} \mathbf{K} \right] + \mathbf{K} \\
&= \frac{\partial}{\partial \boldsymbol{\alpha}} \left[\frac{\partial a}{\partial \mathbf{m}^\top} \right] \mathbf{K} + \mathbf{K} = \frac{\partial \mathbf{m}^\top}{\partial \boldsymbol{\alpha}} \frac{\partial}{\partial \mathbf{m}} \left[\frac{\partial a}{\partial \mathbf{m}^\top} \right] \mathbf{K} + \mathbf{K} \\
&= \mathbf{K} \frac{\partial^2 a}{\partial \mathbf{m} \partial \mathbf{m}^\top} \mathbf{K} + \mathbf{K}, \\
\frac{\partial^2 \ln Z_B}{\partial \boldsymbol{\lambda} \partial \boldsymbol{\alpha}^\top} &= \frac{\partial^2 a}{\partial \boldsymbol{\lambda} \partial \boldsymbol{\alpha}^\top} = \frac{\partial}{\partial \boldsymbol{\lambda}} \left[\frac{\partial a}{\partial \mathbf{m}^\top} \right] \mathbf{K} = \frac{\partial \left(\mathrm{dg}\mathbf{V}\right)^\top}{\partial \boldsymbol{\lambda}} \frac{\partial}{\partial \mathrm{dg}\mathbf{V}} \left[\frac{\partial a}{\partial \mathbf{m}^\top} \right] \mathbf{K} \\
&= 2\mathbf{V} \odot \mathbf{V} \frac{\partial^2 a}{\partial \mathrm{dg}\mathbf{V} \partial \mathbf{m}^\top} \mathbf{K}, \\
\frac{\partial^2 \ln Z_B}{\partial \boldsymbol{\lambda} \partial \boldsymbol{\lambda}^\top} &= \frac{\partial^2 a}{\partial \boldsymbol{\lambda} \partial \boldsymbol{\lambda}^\top} + \mathbf{R}, \quad \mathbf{R} := 2\mathbf{V} \odot \left(\mathbf{V} - \mathbf{A}\mathbf{V}^\top - \mathbf{V}\mathbf{A}^\top\right) \\
&= 2 \frac{\partial}{\partial \boldsymbol{\lambda}} \left[\frac{\partial a}{\partial \left(\mathrm{dg}\mathbf{V}\right)^\top} \mathbf{V} \odot \mathbf{V} \right] + \mathbf{R} \\
&= 2 \frac{\partial^2 a}{\partial \boldsymbol{\lambda} \partial \left(\mathrm{dg}\mathbf{V}\right)^\top} \mathbf{V} \odot \mathbf{V} + 2 \left[\frac{\partial a}{\partial \left(\mathrm{dg}\mathbf{V}\right)^\top} \frac{\partial \mathbf{V} \odot \mathbf{V}}{\partial \lambda_i} \right]_i + \mathbf{R} \\
&= 2 \frac{\partial \left(\mathrm{dg}\mathbf{V}\right)^\top}{\partial \boldsymbol{\lambda}} \frac{\partial^2 a}{\partial \mathrm{dg}\mathbf{V} \partial \left(\mathrm{dg}\mathbf{V}\right)^\top} \mathbf{V} \odot \mathbf{V} + 4 \left[\frac{\partial a}{\partial \left(\mathrm{dg}\mathbf{V}\right)^\top} \left(\mathbf{V} \odot \frac{\partial \mathbf{V}}{\partial \lambda_i} \right) \right]_i + \mathbf{R} \\
&= 4\mathbf{V} \odot \mathbf{V} \frac{\partial^2 a}{\partial \mathrm{dg}\mathbf{V} \partial \left(\mathrm{dg}\mathbf{V}\right)^\top} \mathbf{V} \odot \mathbf{V} + 8 \left[\frac{\partial a}{\partial \left(\mathrm{dg}\mathbf{V}\right)^\top} \left(\mathbf{V} \odot \left(\mathbf{v}_i \mathbf{v}_i^\top \right) \right) \right]_i + \mathbf{R}.
\end{aligned}$$

In the following, we abbreviate $\mathcal{N}(f|m_i,v_{ii})$ by $\mathcal{N}_i$.

$$\begin{aligned}
\frac{\partial^2 a}{\partial m_i^2} &= \int \frac{\partial^2 \mathcal{N}_i}{\partial m_i^2} \ln \mathrm{sig}(y_i f) \mathrm{d}f = \int \frac{(f-m_i)^2 - c_{ii}}{v_{ii}^2} \mathcal{N}_i \ln \mathrm{sig}(y_i f) \mathrm{d}f \\
&= \frac{1}{v_{ii}} \int \left(f^2 - 1\right) \cdot \mathcal{N}(f) \ln \mathrm{sig}(\sqrt{v_{ii}} y_i f + m_i y_i) \mathrm{d}f, \\
\frac{\partial^2 a}{\partial c_{ii} \partial m_i} &= \int \frac{\partial^2 \mathcal{N}_i}{\partial v_{ii} \partial m_i} \ln \mathrm{sig}(y_i f) \mathrm{d}f = \int \frac{(f-m_i)^3 - 3(f-m_i) v_{ii}}{2 v_{ii}^3} \mathcal{N}_i \ln \mathrm{sig}(y_i f) \mathrm{d}f \\
&= \frac{1}{2 v_{ii}^{\frac{3}{2}}} \int \left(f^3 - 3f\right) \cdot \mathcal{N}(f) \ln \mathrm{sig}\left(\sqrt{v_{ii}} y_i f + m_i y_i\right) \mathrm{d}f, \\
\frac{\partial^2 a}{\partial v_{ii}^2} &= \int \frac{\partial^2 \mathcal{N}_i}{\partial v_{ii}^2} \ln \mathrm{sig}(y_i f) \mathrm{d}f = \int \frac{(f-m_i)^4 - 6 v_{ii} (f-m_i)^2 + 3 v_{ii}^2}{4 v_{ii}^4} \mathcal{N}_i \ln \mathrm{sig}(y_i f) \mathrm{d}f \\
&= \frac{1}{4 v_{ii}^2} \int \left(f^4 - 6 f^2 + 3\right) \cdot \mathcal{N}(f) \ln \mathrm{sig}(\sqrt{v_{ii}} y_i f + m_i y_i) \mathrm{d}f.
\end{aligned}$$

A.2.3 FIRST DERIVATIVES W.R.T. HYPERPARAMETERS θ_i:

The direct gradient is given by the following equation where we have marked the dependency of the covariance $\mathbf{K}$ on θ_i by subscripts

$$\begin{aligned}
\frac{\partial \ln Z_B(\boldsymbol{\alpha}, \boldsymbol{\Lambda})}{\partial \theta_i} &= \boldsymbol{\alpha}^\top \frac{\partial \mathbf{K}_\theta}{\partial \theta_i} \frac{\partial a(\mathbf{y}, \mathbf{m}, \mathbf{V})}{\partial \mathbf{m}} + \mathrm{dg}\left(\mathbf{A} \frac{\partial \mathbf{K}_\theta}{\partial \theta_i} \mathbf{A}^\top\right)^\top \frac{\partial a(\mathbf{y}, \mathbf{m}, \mathbf{V})}{\partial \mathrm{dg}\mathbf{V}} \\
&\quad + \mathrm{tr}\left(\mathbf{A}^\top \boldsymbol{\Lambda} \frac{\partial \mathbf{K}_\theta}{\partial \theta_i}\right) - \mathrm{tr}\left(\mathbf{A} \frac{\partial \mathbf{K}_\theta}{\partial \theta_i} \boldsymbol{\Lambda} \mathbf{A}\right) - \frac{1}{2} \boldsymbol{\alpha}^\top \frac{\partial \mathbf{K}_\theta}{\partial \theta_i} \boldsymbol{\alpha}.
\end{aligned}$$

Again we have would have to add an implicit term to the gradient, but in our implementation, we forbore from doing so.

Appendix B. Auxiliary Calculations

In the following, we enumerate some calculations we removed from the main text in order to improve on readability.

B.1 Limits of the Covariance Matrix and Corresponding Marginal Likelihood

We investigate the behavior of the covariance matrix $\mathbf{K}$ for extreme lengthscales ℓ. The matrix is given by $[\mathbf{K}]_{ij} = \sigma_f^2 g(|\mathbf{x}_i - \mathbf{x}_j|/\ell)$ where $g : \mathbb{R} \to \mathbb{R}$ is monotonously decreasing and continuous with $g(0) = 1$ and $\lim_{t\to\infty} g(t) = 0$. >From this definition we have $[\mathbf{K}]_{ii} = \sigma_f^2$. We define $\Delta_{ij} := |\mathbf{x}_i - \mathbf{x}_j|/\ell > 0$ for $i \neq j$. From

$$\begin{aligned}
\lim_{\ell\to 0} [\mathbf{K}]_{ij} &\overset{i\neq j}{=} \lim_{\ell\to 0} \sigma_f^2 g(|\mathbf{x}_i - \mathbf{x}_j|/\ell) = \sigma_f^2 \lim_{\Delta_{ij}\to\infty} g(\Delta_{ij}) = 0, \\
\lim_{\ell\to\infty} [\mathbf{K}]_{ij} &\overset{i\neq j}{=} \lim_{\ell\to\infty} \sigma_f^2 g(|\mathbf{x}_i - \mathbf{x}_j|/\ell) = \sigma_f^2 \lim_{\Delta_{ij}\to 0} g(\Delta_{ij}) = 1
\end{aligned}$$

we conclude

$$\begin{aligned}\lim_{\ell\to 0}\mathbf{K} &= \sigma_f^2\mathbf{I},\\ \lim_{\ell\to\infty}\mathbf{K} &= \sigma_f^2\mathbb{1}\mathbb{1}^\top.\end{aligned}$$

The sigmoids are normalized $\mathrm{sig}(-f_i)+\mathrm{sig}(f_i)=1$ and the Gaussian is symmetric $\mathcal{N}(f_i)=\mathcal{N}(-f_i)$. Consequently, we have

$$\begin{aligned}\int \mathrm{sig}(y_i f_i)\,\mathcal{N}(f_i|0,\sigma_f^2)\mathrm{d}f_i &= \int \mathrm{sig}(f_i)\,\mathcal{N}(f_i|0,\sigma_f^2)\mathrm{d}f_i\\ &= \int_{-\infty}^{0}\mathrm{sig}(f_i)\,\mathcal{N}(f_i|0,\sigma_f^2)\mathrm{d}f_i+\int_0^{\infty}\mathrm{sig}(f_i)\,\mathcal{N}(f_i|0,\sigma_f^2)\mathrm{d}f_i\\ &= \int_0^{\infty}\mathrm{sig}(-f_i)\,\mathcal{N}(-f_i|0,\sigma_f^2)\mathrm{d}f_i+\int_0^{\infty}\mathrm{sig}(f_i)\,\mathcal{N}(f_i|0,\sigma_f^2)\mathrm{d}f_i\\ &= \int_0^{\infty}[\mathrm{sig}(-f_i)+\mathrm{sig}(f_i)]\,\mathcal{N}(f_i|0,\sigma_f^2)\mathrm{d}f_i\\ &= \int_0^{\infty}1\cdot\mathcal{N}(f_i|0,\sigma_f^2)\mathrm{d}f_i=\frac{1}{2}.\end{aligned}$$

The marginal likelihood is given by

$$\begin{aligned}Z &= \int \mathbb{P}(\mathbf{y}|\mathbf{f})\,\mathbb{P}(\mathbf{f}|\mathbf{X},\boldsymbol{\theta})\,\mathrm{d}\mathbf{f}\\ &= \int\prod_{i=1}^{n}\mathrm{sig}(y_i f_i)\,|2\pi\mathbf{K}|^{-\frac{1}{2}}\exp(-\frac{1}{2}\mathbf{f}^\top\mathbf{K}^{-1}\mathbf{f})\mathrm{d}\mathbf{f}.\end{aligned}$$

B.1.1 LENGTHSCALE TO ZERO

For $\mathbf{K}=\sigma_f^2\mathbf{I}$ the prior factorizes and we get

$$\begin{aligned}Z_{\ell\to 0} &= \prod_{i=1}^{n}\int \mathrm{sig}(y_i f_i)\,\frac{1}{\sqrt{2\pi\sigma_f^2}}\exp(-\frac{f_i^2}{2\sigma_f^2})\mathrm{d}f_i\\ &\overset{(17)}{=} \prod_{i=1}^{n}\frac{1}{2}=2^{-n}.\end{aligned}$$

B.1.2 LENGTHSCALE TO INFINITY

To get $\mathbf{K} \to \sigma_f^2 \mathbb{1}\mathbb{1}^\top$ we write $\mathbf{K} = \sigma_f^2 \mathbf{1} + \varepsilon^2 \mathbf{I}$ with $\mathbf{1} = \mathbb{1}\mathbb{1}^\top$ and let $\varepsilon \to 0$. The eigenvalue decomposition of $\mathbf{K}$ is written as $\mathbf{K} = \sum_{i=1}^n \mathbf{u}_i \mathbf{u}_i^\top \lambda_i$ with $\mathbf{u}_1 = \frac{1}{\sqrt{n}}\mathbb{1}$, $\lambda_1 = \sigma_f^2 + \varepsilon^2$ and all other $\lambda_i = \varepsilon^2$

$$
\begin{aligned}
Z_{\frac{1}{\varepsilon}} &\overset{\mathbf{K}=\mathbf{U}\mathbf{\Lambda}\mathbf{U}^\top}{=} \int \prod_{i=1}^n \operatorname{sig}(y_i f_i) \, |2\pi\mathbf{\Lambda}|^{-\frac{1}{2}} \exp(-\frac{1}{2}\mathbf{f}^\top \mathbf{U}\mathbf{\Lambda}^{-1}\mathbf{U}^\top \mathbf{f}) \mathrm{d}\mathbf{f} \\
&\overset{\mathbf{t}=\mathbf{\Lambda}^{-\frac{1}{2}}\mathbf{U}^\top\mathbf{f}}{=} \int \prod_{i=1}^n \operatorname{sig}\left(y_i \sqrt{\lambda_i} \cdot \mathbf{t}^\top \mathbf{u}_i\right) |2\pi\mathbf{\Lambda}|^{-\frac{1}{2}} \exp(-\frac{1}{2}\mathbf{t}^\top\mathbf{t}) \left|\mathbf{\Lambda}^{\frac{1}{2}}\right| \mathrm{d}\mathbf{t} \\
&= \int \prod_{i=1}^n \operatorname{sig}\left(y_i \sqrt{\lambda_i} \cdot \mathbf{t}^\top \mathbf{u}_i\right) \mathcal{N}(t_i) \mathrm{d}\mathbf{t} \\
&= \int \operatorname{sig}\left(\sqrt{\frac{\sigma_f^2 + \varepsilon^2}{n}} \cdot \mathbf{t}^\top \mathbb{1}\right) \mathcal{N}(t_1) \prod_{i=2}^n \left[\operatorname{sig}\left(\varepsilon \cdot \mathbf{t}^\top \mathbf{u}_i\right)\right] \mathcal{N}(t_i) \mathrm{d}\mathbf{t}, \\
Z_{\ell\to\infty} = \lim_{\varepsilon\to 0} Z &= \int \operatorname{sig}\left(\frac{\sigma_f}{\sqrt{n}} \cdot \mathbf{t}^\top \mathbb{1}\right) \mathcal{N}(t_1) \prod_{i=2}^n \left[\frac{1}{2}\right] \mathcal{N}(t_i) \mathrm{d}\mathbf{t} \\
&\overset{(17)}{=} 2^{-n+1} \int \operatorname{sig}\left(\frac{\sigma_f}{\sqrt{n}} \cdot \mathbf{t}^\top \mathbb{1}\right) \mathcal{N}(\mathbf{t}) \mathrm{d}\mathbf{t} \\
&\overset{r=\mathbf{t}^\top\mathbb{1}}{=} 2^{-n+1} \int \operatorname{sig}\left(\frac{\sigma_f}{\sqrt{n}} \cdot r\right) \mathcal{N}(r) \mathrm{d}r \\
&\overset{(17)}{=} 2^{-n}.
\end{aligned}
$$

B.1.3 LATENT SCALE TO ZERO

We define $\sigma_f^2 \tilde{\mathbf{K}} = \mathbf{K}$ and $\sigma_f \tilde{\mathbf{f}} = \mathbf{f}$ and derive

$$
\begin{aligned}
Z_{\sigma_f} &= \int \prod_{i=1}^n \operatorname{sig}(y_i f_i) \, |2\pi\mathbf{K}|^{-\frac{1}{2}} \exp(-\frac{1}{2}\mathbf{f}^\top \mathbf{K}^{-1}\mathbf{f}) \mathrm{d}\mathbf{f} \\
&= \int \prod_{i=1}^n \operatorname{sig}\left(y_i \sigma_f \tilde{f}_i\right) |2\pi\mathbf{K}|^{-\frac{1}{2}} \exp(-\frac{\sigma_f^2}{2}\tilde{\mathbf{f}}^\top \mathbf{K}^{-1}\tilde{\mathbf{f}}) \sigma_f^n \mathrm{d}\tilde{\mathbf{f}} \\
&= \int \prod_{i=1}^n \operatorname{sig}\left(y_i \sigma_f \tilde{f}_i\right) \left|2\pi\sigma_f^2\tilde{\mathbf{K}}\right|^{-\frac{1}{2}} \exp(-\frac{\sigma_f^2}{2}\tilde{\mathbf{f}}^\top \sigma_f^{-2}\tilde{\mathbf{K}}^{-1}\tilde{\mathbf{f}}) \sigma_f^n \mathrm{d}\tilde{\mathbf{f}} \\
&= \int \prod_{i=1}^n \left[\operatorname{sig}\left(y_i \sigma_f \tilde{f}_i\right)\right] \mathcal{N}\left(\tilde{\mathbf{f}} | \mathbf{0}, \tilde{\mathbf{K}}\right) \mathrm{d}\tilde{\mathbf{f}}, \\
Z_{\sigma_f\to 0} = \lim_{\sigma_f\to 0} Z &= \int \prod_{i=1}^n \left[\frac{1}{2}\right] \mathcal{N}\left(\tilde{\mathbf{f}} | \mathbf{0}, \tilde{\mathbf{K}}\right) \mathrm{d}\tilde{\mathbf{f}} = 2^{-n}.
\end{aligned}
$$

Note that the functions, we are using are all well-behaved, such that the limits do exist.

B.2 Posterior Divided by Prior = Effective Likelihood

$$\begin{aligned}
\mathbb{Q}(\mathbf{y}|\mathbf{f}) &= \frac{\mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})}{\mathbb{P}(\mathbf{f}|\mathbf{X})} = \frac{\mathcal{N}\left(\mathbf{f}|\mathbf{m},\left(\mathbf{K}^{-1}+\mathbf{W}\right)^{-1}\right)}{\mathcal{N}(\mathbf{f}|\mathbf{0},\mathbf{K})} \\
&= \frac{\mathcal{N}\left(\mathbf{f}|\tilde{\mathbf{m}},\mathbf{W}^{-1}\right)}{\mathcal{N}(\tilde{\mathbf{m}}|\mathbf{0},\mathbf{K}+\mathbf{W}^{-1})}, \quad \tilde{\mathbf{m}} = (\mathbf{K}\mathbf{W})^{-1}\mathbf{m}+\mathbf{m} \\
&= \frac{(2\pi)^{-\frac{n}{2}}\left|\mathbf{W}^{-1}\right|^{-\frac{1}{2}}\exp\left(-\frac{1}{2}(\mathbf{f}-\tilde{\mathbf{m}})^{\top}\mathbf{W}(\mathbf{f}-\tilde{\mathbf{m}})\right)}{(2\pi)^{-\frac{n}{2}}\left|\mathbf{K}+\mathbf{W}^{-1}\right|^{-\frac{1}{2}}\exp\left(-\frac{1}{2}\tilde{\mathbf{m}}^{\top}(\mathbf{K}+\mathbf{W}^{-1})^{-1}\tilde{\mathbf{m}}\right)} \\
&= \sqrt{|\mathbf{K}\mathbf{W}+\mathbf{I}|}\frac{\exp\left(-\frac{1}{2}(\mathbf{f}-\tilde{\mathbf{m}})^{\top}\mathbf{W}(\mathbf{f}-\tilde{\mathbf{m}})\right)}{\exp\left(-\frac{1}{2}\tilde{\mathbf{m}}^{\top}(\mathbf{K}+\mathbf{W}^{-1})^{-1}\tilde{\mathbf{m}}\right)} \\
&=: \frac{1}{Z_{\mathbb{Q}}}\exp\left(-\frac{1}{2}(\mathbf{f}-\tilde{\mathbf{m}})^{\top}\mathbf{W}(\mathbf{f}-\tilde{\mathbf{m}})\right), \\
\ln Z_{\mathbb{Q}} &= -\frac{1}{2}\tilde{\mathbf{m}}^{\top}\left(\mathbf{K}+\mathbf{W}^{-1}\right)^{-1}\tilde{\mathbf{m}}-\frac{1}{2}\ln|\mathbf{K}\mathbf{W}+\mathbf{I}|
\end{aligned}$$

B.3 Kullback-Leibler Divergence for KL method

We wish to calculate the divergence between the approximate posterior, a Gaussian, and the true posterior

$$\begin{aligned}
\mathrm{KL}\left(\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta}) \parallel \mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})\right) &= \int \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})\ln\frac{\mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})}{\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})}\mathrm{d}\mathbf{f} \\
&\overset{(2)}{=} \int \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})\ln\frac{Z\cdot\mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})}{\mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})\prod_{i=1}^{n}\mathbb{P}(y_i|f_i)}\mathrm{d}\mathbf{f} \\
&= \ln Z + \int \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})\ln\mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})\,\mathrm{d}\mathbf{f} \\
&\quad - \int \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})\ln\prod_{i=1}^{n}\mathbb{P}(y_i|f_i)\mathrm{d}\mathbf{f} \\
&\quad - \int \mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V})\ln\mathcal{N}(\mathbf{f}|\mathbf{0},\mathbf{K})\mathrm{d}\mathbf{f}.
\end{aligned}$$

There are three Gaussian integrals to evaluate; the entropy of the approximate posterior and two other expectations

$$\begin{aligned}
\mathrm{KL}\left(\mathbb{Q}(\mathbf{f}|\boldsymbol{\theta}) \parallel \mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X},\boldsymbol{\theta})\right) &= \ln Z - \frac{1}{2}\ln|\mathbf{V}| - \frac{n}{2} - \frac{n}{2}\ln 2\pi \\
&\quad - \int \mathcal{N}(f)\left[\sum_{i=1}^{n}\ln\mathrm{sig}\left(\sqrt{v_{ii}}y_i f + m_i y_i\right)\right]\mathrm{d}f \qquad (17) \\
&\quad + \frac{n}{2}\ln 2\pi + \frac{1}{2}\ln|\mathbf{K}| + \frac{1}{2}\mathbf{m}^{\top}\mathbf{K}^{-1}\mathbf{m} + \frac{1}{2}\mathrm{tr}\left(\mathbf{K}^{-1}\mathbf{V}\right).
\end{aligned}$$

Summing up and dropping the constant (w.r.t. $\mathbf{m}$ and $\mathbf{V}$) terms, we arrive at

$$\mathrm{KL}(\mathbf{m},\mathbf{V}) \stackrel{c}{=} -\int \mathcal{N}(f)\left[\sum_{i=1}^{n} \ln \mathrm{sig}\left(\sqrt{v_{ii}}y_i f + m_i y_i\right)\right] \mathrm{d}f - \frac{1}{2}\ln|\mathbf{V}| + \frac{1}{2}\mathbf{m}^\top \mathbf{K}^{-1}\mathbf{m} + \frac{1}{2}\mathrm{tr}\left(\mathbf{K}^{-1}\mathbf{V}\right).$$

B.4 Gaussian Integral for VB Lower Bound

$$\begin{aligned}
Z_B &= \int \mathbb{P}(\mathbf{f}|\mathbf{X})\,\mathbb{Q}(\mathbf{y}|\mathbf{f},\mathbf{A},\mathbf{b},\mathbf{c})\,\mathrm{d}\mathbf{f} = \int \mathcal{N}(\mathbf{f}|0,\mathbf{K}) \exp\left(\mathbf{f}^\top \mathbf{A}\mathbf{f} + (\mathbf{b}\odot\mathbf{y})^\top \mathbf{f} + \mathbf{c}^\top \mathbb{1}\right) \mathrm{d}\mathbf{f} \\
&= \frac{\exp\left(\mathbf{c}^\top \mathbb{1}\right)}{\sqrt{(2\pi)^n |\mathbf{K}|}} \int \exp\left(-\frac{1}{2}\mathbf{f}^\top \left(\mathbf{K}^{-1} - 2\mathbf{A}\right)\mathbf{f} + (\mathbf{b}\odot\mathbf{y})^\top \mathbf{f}\right) \mathrm{d}\mathbf{f} \\
&= \frac{\exp\left(\mathbf{c}^\top \mathbb{1}\right)}{\sqrt{(2\pi)^n |\mathbf{K}|}} \sqrt{\frac{(2\pi)^n}{|\mathbf{K}^{-1} - 2\mathbf{A}|}} \exp\left(\frac{1}{2}(\mathbf{b}\odot\mathbf{y})^\top \left(\mathbf{K}^{-1} - 2\mathbf{A}\right)^{-1} (\mathbf{b}\odot\mathbf{y})\right) \\
&= \frac{\exp\left(\mathbf{c}^\top \mathbb{1}\right)}{\sqrt{|\mathbf{I} - 2\mathbf{A}\mathbf{K}|}} \exp\left(\frac{1}{2}(\mathbf{b}\odot\mathbf{y})^\top \left(\mathbf{K}^{-1} - 2\mathbf{A}\right)^{-1} (\mathbf{b}\odot\mathbf{y})\right), \\
\ln Z_B &= \mathbf{c}^\top \mathbb{1} + \frac{1}{2}(\mathbf{b}\odot\mathbf{y})^\top \left(\mathbf{K}^{-1} - 2\mathbf{A}\right)^{-1} (\mathbf{b}\odot\mathbf{y}) - \frac{1}{2}\ln|\mathbf{I} - 2\mathbf{A}\mathbf{K}|.
\end{aligned}$$

B.5 Lower Bound for the Cumulative Gaussian Likelihood

A lower bound

$$\mathrm{sig}_{\mathrm{probit}}(y_i f_i) \;\geq\; \mathbb{Q}(y_i|f_i,\varsigma_i) = a_i f_i^2 + b_i f_i + c_i$$

for the cumulative Gaussian likelihood function is derived by matching the function at one point ς

$$\mathbb{Q}(y_i = +1|f_i,\varsigma_i) \;=\; \mathrm{sig}_{\mathrm{probit}}(\varsigma_i), \forall i$$

and by matching the first derivative

$$\left.\frac{\partial}{\partial f_i}\ln \mathbb{Q}(y_i = +1|f_i,\varsigma_i)\right|_{\varsigma_i} \;=\; \frac{\partial \ln \mathrm{sig}_{\mathrm{probit}}(y_i f_i)}{\partial f_i} = \frac{\mathcal{N}(\varsigma_i)}{\mathrm{sig}_{\mathrm{probit}}(\varsigma_i)}, \forall i$$

at this point for a tight approximation. Solving for these constraints leads to the coefficients

$$\begin{aligned}
\text{asymptotic behavior} \Rightarrow a_i &= -\frac{1}{2}, \\
\text{first derivative} \Rightarrow b_i &= \varsigma_i + \frac{\mathcal{N}(\varsigma_i)}{\mathrm{sig}_{\mathrm{probit}}(\varsigma_i)}, \\
\text{point matching} \Rightarrow c_i &= \left(\frac{\varsigma_i}{2} - b_i\right)\varsigma_i + \log \mathrm{sig}_{\mathrm{probit}}(\varsigma_i).
\end{aligned}$$

B.6 Free Form Optimization for FV

We make a factorial approximation $\mathbb{P}(\mathbf{f}|\mathbf{y},\mathbf{X}) \approx \mathbb{Q}(\mathbf{f}) := \prod_i \mathbb{Q}(f_i)$ to the posterior by minimizing

$$\begin{aligned}\mathrm{KL}[\mathbb{Q}(\mathbf{f})||\mathbb{P}(\mathbf{f})] &= \int \prod_{i=1}^n \mathbb{Q}(f_i) \ln \frac{Z \cdot \prod_{i=1}^n \mathbb{Q}(f_i)}{\mathcal{N}(\mathbf{f}|\mathbf{m},\mathbf{V}) \prod_{i=1}^n \mathbb{P}(y_i|f_i)} \mathrm{d}\mathbf{f} \\ &= \sum_i \int \mathbb{Q}(f_i) \ln \frac{\mathbb{Q}(f_i)}{\mathbb{P}(y_i|f_i)} \mathrm{d}f_i + \frac{1}{2} \int \prod_{i=1}^n \mathbb{Q}(f_i) \mathbf{f}^\top \mathbf{K}^{-1} \mathbf{f} \mathrm{d}\mathbf{f} + \mathrm{const}_{\mathbf{f}}.\end{aligned}$$

Free-form optimization proceeds by equating the functional derivative with zero

$$\frac{\delta \mathrm{KL}}{\delta \mathbb{Q}(f_i)} = \ln \mathbb{Q}(f_i) + 1 - \ln \mathbb{P}(y_i|f_i) + \frac{1}{2} \frac{\delta}{\delta \mathbb{Q}(f_i)} \int \prod_{i=1}^n \mathbb{Q}(f_i) \mathbf{f}^\top \mathbf{K}^{-1} \mathbf{f} \mathrm{d}\mathbf{f}. \tag{18}$$

We abbreviate the integral in the last term with ξ and rewrite it in terms of simple one-dimensional integrals $m_l = \int f_l \mathbb{Q}(f_l) \mathrm{d}f_l$ and $v_l = \int f_l^2 \mathbb{Q}(f_l) \mathrm{d}f_l - m_l^2$

$$\begin{aligned}\xi &= \int \prod_i \mathbb{Q}_i \sum_{j,k} f_j \left[\mathbf{K}^{-1}\right]_{jk} f_k \mathrm{d}\mathbf{f} \\ &= \int \prod_{i \neq l} \mathbb{Q}_i \left[\int \mathbb{Q}_l \left(f_l^2 \left[\mathbf{K}^{-1}\right]_{ll} + 2 f_l \sum_{j \neq l} f_j \left[\mathbf{K}^{-1}\right]_{jl} + \sum_{j \neq l, k \neq l} f_j \left[\mathbf{K}^{-1}\right]_{jk} f_k \right) \mathrm{d}f_l \right] \mathrm{d}\mathbf{f}_{\neg l} \\ &= \int \prod_{i \neq l} \mathbb{Q}_i \left[\left[\mathbf{K}^{-1}\right]_{ll} \underbrace{\int f_l^2 \mathbb{Q}_l \mathrm{d}f_l}_{v_l + m_l^2} + 2 \left(\sum_{j \neq l} f_j \left[\mathbf{K}^{-1}\right]_{jl}\right) \underbrace{\int f_l \mathbb{Q}_l \mathrm{d}f_l}_{m_l} + \sum_{j \neq l, k \neq l} f_j \left[\mathbf{K}^{-1}\right]_{jk} f_k \right] \mathrm{d}\mathbf{f}_{\neg l} \\ &= \left[\mathbf{K}^{-1}\right]_{ll} (v_l + m_l^2) + 2 \sum_{j \neq l} m_j \left[\mathbf{K}^{-1}\right]_{jl} m_l + \int \prod_{i \neq l} \mathbb{Q}_i \sum_{j \neq l, k \neq l} f_j \left[\mathbf{K}^{-1}\right]_{jk} f_k \mathrm{d}\mathbf{f}_{\neg l} \\ &= \text{induction over } l \\ &= \sum_l \left[\mathbf{K}^{-1}\right]_{ll} (v_l + m_l^2) + 2 \sum_{j<l} m_j \left[\mathbf{K}^{-1}\right]_{jl} m_l.\end{aligned}$$

Plugging this into Equation 18 and using $\frac{\delta \int f_l^p \mathbb{Q}(f_l) \mathrm{d}f_l}{\delta \mathbb{Q}(f_l)} = f_l^p$, we find

$$\begin{aligned}\frac{\delta \mathrm{KL}}{\delta \mathbb{Q}(f_i)} &= \ln \mathbb{Q}(f_i) + 1 - \ln \mathbb{P}(y_i|f_i) + \frac{1}{2} f_i \left[\mathbf{K}^{-1}\right]_{ii} f_i + f_i \sum_l \left[\mathbf{K}^{-1}\right]_{il} m_l \stackrel{!}{\equiv} 0 \\ \Rightarrow \mathbb{Q}(f_i) &\propto \exp\left(-\frac{1}{2} f_i \left[\mathbf{K}^{-1}\right]_{ii} f_i - f_i \sum_{l \neq i} \left[\mathbf{K}^{-1}\right]_{il} m_l \right) \mathbb{P}(y_i|f_i) \\ \Rightarrow \mathbb{Q}(f_i) &\propto \mathcal{N}\left(f_i \middle| m_i - \frac{\left[\mathbf{K}^{-1}\mathbf{m}\right]_i}{\left[\mathbf{K}^{-1}\right]_{ii}}, \left[\mathbf{K}^{-1}\right]_{ii}^{-1} \right) \mathbb{P}(y_i|f_i)\end{aligned}$$

as the functional form of the best possible factorial approximation, namely a product of the true likelihood times a Gaussian with the same precision as the prior marginal.

Abstract

We consider the problem of estimating the value of a multiattribute resource, where the attributes are categorical or discrete in nature and the number of potential attribute vectors is very large. The problem arises in approximate dynamic programming when we need to estimate the value of a multiattribute resource from estimates based on Monte-Carlo simulation. These problems have been traditionally solved using aggregation, but choosing the right level of aggregation requires resolving the classic tradeoff between aggregation error and sampling error. We propose a method that estimates the value of a resource at different levels of aggregation simultaneously, and then uses a weighted combination of the estimates. Using the optimal weights, which minimizes the variance of the estimate while accounting for correlations between the estimates, is computationally too expensive for practical applications. We have found that a simple inverse variance formula (adjusted for bias), which effectively assumes the estimates are independent, produces near-optimal estimates. We use the setting of two levels of aggregation to explain why this approximation works so well.

Keywords: hierarchical statistics, approximate dynamic programming, mixture models, adaptive learning, multiattribute resources

1. Introduction

We consider the problem of managing resources (people, equipment) that can be described using a vector of attributes $a = (a_1, a_2, \ldots, a_M)$. Our work has grown out of a series of projects with industry and the military that involve managing resources over time under uncertainty. In all of these projects, we use algorithms that require estimating the marginal value of a resource with attribute vector a. As these projects have made the transition from laboratory experiments to industrial implementations, we have found that one and two dimensional attributes (for example, location and possibly equipment type) quickly grow to five or ten dimensions, with an exponential growth in the number of potential attributes. Examples of actual projects we have worked on which exhibit this behavior include:

- Managing pilots for business jets - The attributes of a pilot include elements such as home city, number of days away from home and the equipment that he is trained to fly. Decisions about pilots can include assigning a pilot to a particular flight, or a decision to send a pilot for training on a new type of aircraft.

- Managing locomotives - The decision to assign a particular locomotive to a particular train has to consider attributes such as the type of locomotive, the number of days until it has to be maintained, its current location and its home maintenance shop.

- Managing a fleet of freight cars - Freight cars have attributes such as location, time until arrival to a destination, loaded or empty status, ownership, and maintenance status.

- Managing a fleet of trucks to move loads - The truck can be described using attributes such as its current location, the home domicile of the driver, the maintenance level and whether it is being driven by a solo driver or a team of two drivers. Decisions include where to move to and whether to move loaded or empty.

- Managing cargo aircraft for the military - We have to decide which aircraft should be assigned to satisfy a particular requirement (a movement of freight or passengers). Choosing the best aircraft requires knowing the value of an aircraft at the destination which depends on the type of aircraft, cargo configuration, whether it is loaded or empty (and if loaded, the load characteristics), and its maintenance status.

- Managing blood inventories - Blood is characterized by blood type, age, location, and whether it has been frozen. New supplies of, and the demand for, blood is random.

All of these are examples of resource allocation problems where a decision has to be made now to act on resources (trucks, jets, locomotives) which will bring about a change in their attributes. Let $a \in \mathcal{A}$ be the attribute vector describing a resource now. If we act on the resource, we may produce a resource with attribute a' with value $v_{a'}$. In a dynamic programming setting, the value $v_{a'}$ refers to the solution of a finite horizon discounted reward dynamic program. In practical applications, we cannot compute $v_{a'}$ exactly, so we resort to Monte Carlo methods where we might observe random observations $\hat{v}_{a'}$ and use these to produce a statistical estimate $\bar{v}_{a'}$ (see Bertsekas and Tsitsiklis 1996 and Sutton and Barto 1998 for an introduction to the techniques of approximate dynamic programming). The problem is that in realistic problems, the attribute space $\mathcal{A}$ can be extremely large, and we may obtain only a few observations of $\hat{v}_{a'}$ for a particular a'. As a result, the statistical error in $\bar{v}_{a'}$ can be quite large.

One of the standard strategies in approximate dynamic programming is to aggregate the state (attribute) space. Instead of estimating $\bar{v}_a$, we might define an aggregation function $G(a)$ which produces an aggregated attribute $\bar{a}$ which has fewer outcomes. For example, a five-digit zip code can be aggregated up to a three-digit zip; a numerical attribute can be divided into fewer ranges; or an attribute can be completely ignored. The resulting smaller attribute space produces more observations of each attribute, but at a cost of aggregation error.

There are a variety of statistical strategies for estimating value functions which take advantage of the structure of a specific attribute vector a. In a trucking problem, we might design a statistical function that depends on the location of a driver, his days away from home, the fuel level of his tank and his home domicile. However, after designing a statistical model that works for this application,

we would have to start from scratch if we wished to switch to another application. In fact, simply adding an attribute would require redesigning and refitting the statistical equation. This can be particularly hard when several of the attributes are categorical, and which interact to determine the effect of the attributes on the system. A truck driver might be characterized by his location and his home domicile; the value of a driver at a location depends very much on where he lives.

We are interested in developing a method for estimating the value $\bar{v}_a$ of a resource with attribute a, making minimal assumptions about the structure of the attribute space. We take advantage of the fact that for every application with which we are familiar, it is quite easy to design a family of aggregation functions $\mathcal{G}$ where $G^{(g)} : \mathcal{A} \rightarrow \mathcal{A}^{(g)}$ is an aggregation of the attribute space $\mathcal{A}$. For example, we can create an aggregation function simply by ignoring an attribute. Aside from assuming the existence of this family of functions, we make no further assumptions about the nature of the attribute space. For example, we do not even require the existence of a metric that would provide a measure of the distance between two attribute vectors, which prevents the use of standard methods such as non-parametric statistics or regression trees.

Aggregation has traditionally been a powerful technique in dynamic programming. A good general review of aggregation techniques is given by Rogers et al. (1991). Aggregation strategies in a dynamic programming setting may be governed by the desire to solve exactly a smaller dynamic program, or by the iterative nature of the algorithms. Techniques range from picking a fixed level of aggregation (Whitt, 1978; Bean et al., 1987; Athans et al., 1995; Zhang and Sethi, 1998; Wang and Dietterich, 2000), or using adaptive techniques that change the level of aggregation as the sampling process progresses (Mendelssohn, 1982; Bertsekas and Tsitsiklis, 1996; Luus, 2000; Kim and Dean, 2003), but which still use a single level of aggregation at any given time (many authors used a fixed level of aggregation to produce a smaller Markov Decision Process (MDP) that can be solved optimally). Tsitsiklis and Van Roy (1996) (see also Bertsekas and Tsitsiklis, 1996) show how value functions can be approximated using a fixed set of *features*; this strategy encompasses both static and hierarchical aggregation as special cases, but the use of these techniques in our setting is prohibitive because of the extremely large number of values that need to be estimated. Feng et al. (2003) presents a work that identifies state aggregations based on "structural similarity" where states are considered similar if they have similar value estimates or similar sets of successor states, rather than "input similarity" which is typically measured by some distance metric defined over the state space. Bertsekas and Castanon (1989) introduces a creative approach which adaptively clusters states with similar values of residual errors at each iteration, requiring no structure among the states of the system. While we also do not have any structure, we do take advantage of the presence of a family of aggregation functions, and our technique does not require the overhead of solving clustering problems. A nice discussion of aggregation and abstraction techniques in an approximate dynamic programming setting is given in Boutilier et al. (1999).

Instead of using a single level of aggregation, researchers have considered combining estimates from all the levels of aggregation at once. In the literature, there exist several techniques for combining estimates to improve accuracy (see Wolpert, 1992; LeBlanc and Tibshirani, 1996; Yang, 2001). It is well-known that if the estimates being combined are independent and unbiased, then it is optimal to combine them in inverse proportion to their variances (Guttman et al., 1965). When different estimates are based on different levels of aggregation, they are neither independent nor unbiased. It is also possible to use a weighted combination of estimates where the weights are estimated using regression techniques. For our application, there can be hundreds of thousands of such models, making the updating of regression models computationally expensive.

In this paper, we solve the problem of optimally combining (correlated) value estimates at different levels of aggregation in an approximate dynamic programming setting and derive expressions for optimal weights. The result generalizes a well-known result for optimally combining independent estimates. We point out that the independence assumptions used for deriving the results are true only in idealized regression settings, and not in an approximate dynamic programming setting.

The major contribution of this paper lies in finding that an inverse-variance weighting formula (adjusted for bias), which is optimal only when the estimates are independent, proves to be near-optimal even though estimates at different levels of aggregation are not independent. We explain this behavior analytically for the case with two levels of aggregation. We show that if we compute optimal weights (without assuming independence) and compare the results if we do assume independence, the results are the same for two extremes: when the difference between the aggregate and disaggregate value estimates is very large or very small. We show experimentally that the error for intermediate values is extremely small.

We also show, in the context of a single vehicle routing problem, that our weighting method produces value function estimates that are within five to ten percent of the optimal value functions, outperforming other estimates. The method of weighting a family of aggregate estimates is shown to naturally shift the weight from aggregate to disaggregate estimates as the algorithm progresses. We also demonstrate that this method is easy to implement in large-scale, on-line learning applications that arise in approximate dynamic programming, where it produces much faster convergence (which implies approaching a consistently better solution quality in a fewer number of iterations) than would be produced using a single, static level of aggregation. Further work on this application is explained in detail in Simao et al. (2008).

The paper is organized as follows. In Section 2, we describe a generic approximate dynamic programming technique, which estimates the value functions associated with various states. This section provides an introduction to the context in which our statistical estimation problem arises. The next three sections, however, focus purely on the statistics of aggregation outside of a dynamic programming setting. Section 3 provides a theoretical model of the sampling process and defines bias and variance for aggregated statistics. Then, Section 4 poses the problem of computing optimal weights for combining estimates of values at different levels of aggregation. The problem with this formula is that it is too expensive to use for our problem class. For this reason, we propose a simpler formula that assumes that statistics from different levels of aggregation are independent. In Section 5, we compare the two weighting formulas (with and without the independence assumption) for the special case where there are only two levels of aggregation which allows the optimal weights to be computed analytically. We show theoretically that assuming independent estimates introduces zero expected error at two extremes of the problem. We then show experimentally that ignoring the dependence between the estimates gives results that are very similar. In Section 6, we demonstrate our approximation method in the context of an approximate dynamic programming algorithm for solving a multiattribute resource allocation problem. We use both a single truck problem, which can be solved exactly, as well as a problem of managing a large fleet of trucks. We provide our concluding remarks in Section 7.

2. Approximate Dynamic Programming

This section is designed as a brief introduction to approximate dynamic programming, and introduces the context in which our problem arises. Our interest lies in the context of dynamic resource

allocation problems. Dynamic programming techniques can be applied to solve these problems which are typically modeled as MDPs. Using the notation of Powell (2007), we let S_t be the state of our system. We also let $d \in \mathcal{D}$ be a type of a decision, and we let $x_d = 1$ if we choose decision d, and $x_d = 0$ otherwise. $x_t = (x_d)_{d \in \mathcal{D}}$ is the vector of decisions that we make at time t. Bellman's equation allows us to express the value of being in state S_t as

$$V(S_t) \quad = \quad \max_{x_t} \left[C(S_t, x_t) + \mathbb{E} \left\{ V \left(S_{t+1}(S_t, x_t, W_{t+1}) \right) | S_t \right\} \right],$$

where W_{t+1} is a random variable representing new information that arrives between t and $t+1$. The exact values can be determined using traditional backward dynamic programming techniques such as value iteration and policy iteration. In these methods, the values are computed recursively starting from the final state, making use of the state transition probabilities.

When the state and action spaces become large, as in most real-life stochastic planning problems, it is not practical to enumerate the states to determine their values. In such problems, compact feature-based representations of the MDP, also called factored MDPs (see Boutilier et al., 2000) can be used to make the problem computationally tractable. Factored MDPs can be represented using a factored state transition model and a reward function that is additive. In these representations, a smaller set of variables (also called features or attributes) are used to describe the state of the system.

Dynamic resource allocation problems span dynamic vehicle routing (Gendreau and Potvin, 1998; Ichoua et al., 2005), where there has been recent interest in the application of approximate dynamic programming for the single vehicle routing problem (Secomandi, 2000, 2001). Powell and Carvalho (1998) uses an approximate dynamic programming algorithm for a fleet management problem, but the attributes of the vehicles were very simple. Powell et al. (2002) uses an approximate dynamic programming algorithm for multiattribute resources, but does not address statistical sampling issues. Spivey and Powell (2004) applies approximate dynamic programming for optimizing a fleet of vehicles, using a linear value function approximation that also requires estimating the value of a resource characterized by a vector of attributes. This research estimated the value of a resource at different levels of aggregation, but kept track of the variance of these estimates at each level of aggregation and always used the estimate that provided the smallest variance.

Resource allocation problems can be modeled by letting $a \in \mathcal{A}$ be an attribute vector (a may consist of categorical and numerical attributes), and by letting R_{ta} be the number of resources with attribute a. We then let $R_t = R_{ta})_{a \in \mathcal{A}}$ be the resource state vector. This research addresses problems where the vector a is large enough that the attribute space $\mathcal{A}$ becomes too large to enumerate. We develop these ideas in the context of a single entity. If a_t is the attribute of the entity at time t, then a_t is effectively our state variable.

In this section, we describe the basic approximate dynamic programming (ADP) strategy to solve the problem of managing a single resource with multiple attributes, the *nomadic trucker*. This is a single resource version of the dynamic fleet management problem, where there is a single trucker who needs to move between various locations to cover loads that arise and gains rewards in the process.

The state of the resource is defined by an attribute vector, a, composed of multiple attributes, which may be numerical or categorical. For the nomadic trucker problem, examples of attributes include the location of the truck, the home domicile of the driver and the number of hours driven. We could represent the attribute vector as $a = (a_{location}, a_{time}, a_{domicile}, \ldots)$. The state space, $\mathcal{A}$, for

this problem would consist of all possible combinations of the attributes of the trucker. We can let the decision be represented by the vector $(x_d)_{d\in\mathcal{D}}$, but for a single entity problem, $\sum_{d\in\mathcal{D}} x_d = 1$, which means we can also write the problem as choosing a decision $d \in \mathcal{D}$. Typically, the set of potential decisions depends on the current state (attributes) of our resource, so we let $\mathcal{D}_a$ be the decisions available to a resource with attribute a. We assume that the impact of a decision d on a resource with attribute a is deterministic, and is given by the function $a' = a^M(a,d)$.

In approximate dynamic programming, we sample the various states by choosing decisions that are locally optimal based on current estimates of the value functions. For example, we could follow a procedure where we choose a decision that maximizes the sum of the one-period rewards and the future value (discounted by factor γ) as follows:

$$d(a,\omega) \quad = \quad \arg\max_{d\in\mathcal{D}_a(\omega)} \left\{ c(a,d,\omega) + \gamma v_{a^M(a,d)} \right\}.$$

Here, ω represents a sample realization of random information (for example, $\mathcal{D}_a(\omega)$ is a sample realization of the decision set), $a^M(a,d)$ is the state at the destination and $v_{a^M(a,d)}$ the value associated with $a^M(a,d)$. This model is easily generalized to handle stochastic transitions, but this is not relevant to the focus of this paper.

We outline the steps of a typical approximate dynamic programming algorithm for the nomadic trucker problem in Figure 1. This algorithm has two stages. In the forward pass, we use the current estimates of the optimal value functions to simulate a sample trajectory of the truck. The next state that is visited is determined using a transition function $a^M(a_m,d_m)$, as depicted in Equation 2, where the resource in state a_m undergoes a transformation to state $a_{m+1} = a^M(a_m,d_m)$ when acted upon by decision d_m. Once the end of the time horizon is reached, we perform a backward pass, where we first compute the observations of values of the various states in the current sample path using Equation 3. We point out that the estimates of the future values are discounted by a factor γ. We then use these to update the value estimates, as in Equation 4, and the associated statistics (number of observations and sample variance) of the states that are visited.

There are a number of variations of approximate dynamic programming. One family is known as $TD(\lambda)$-learning (see Sutton, 1988; Sutton and Barto, 1998), typically parameterized by an artificial discount factor λ. Using a pure forward pass algorithm is equivalent to $TD(0)$, while another variation follows a policy (determined by the current set of approximations), and then does a backward traversal to obtain updates of the estimate of the value of being in each state (this is equivalent to $TD(1)$). Another popular strategy is Q-learning (see Watkins, 1989), where we estimate the quantities $Q(a,d)$ which is the value of being in a state a and making decision d. Since the statistical problem of estimating the value of a state-action pair is, of course, even harder than the problem of estimating the value of being in a state, we have not used this approach. Since Q-learning allows you to determine a decision directly from the Q-factors (rather than solving an optimization problem), it is typically presented as a "model-free" algorithm (that is, one that does not require an explicit model of the transition function), although estimating the Q-factors does require some source that determines the next state given a state and action. All of these methods can be used without an explicit model of the exogenous information process (for example, we do not use a one-step transition function) as long as we have some mechanism for creating the sample realizations.

As with most ADP algorithms, the only way to obtain an estimate of the value of being in a state is to actually visit the state. In real applications, there may be millions of states but we may be limited to only thousands of observations. In practice, most states are never visited, and many are

Step 0. Initialize an approximation for the value function $\bar{v}_a^0$ for all attribute vector states $a \in \mathcal{A}$ and set $n = 1$.

Step 1. Iteration n:

Step 2. *Forward pass*: Set $m = 0$ and randomly sample attribute vector a_m, but fixing the start time at the beginning of the time horizon.

Step 3. Obtain the set of possible decisions, $\mathcal{D}_{a_m}(\omega)$.

Step 4. Solve for the optimal decision, given the current value function estimates.

$$d_m(\omega) = \arg\max_{d \in \mathcal{D}_{a_m}(\omega)} \left[c(a_m, d) + \gamma \bar{v}^{n-1}_{a^M(a_m,d)} \right] \quad (1)$$

Step 5. Evaluate the next state to visit:

$$a_{m+1} = a^M(a_m, d_m) \quad (2)$$

Step 6. If the end of the time horizon (T) is reached, then set $m = m+1$ and go to **step 3**, else go to **step 7**.

Step 7. *Backward pass*: For $j = m-1, m-2, \cdots, 0$, update the value function estimates as follows:

$$\hat{v}^n_{a_j} = c(a_j, d_j) + \gamma \hat{v}^n_{a_{j+1}} \quad (3)$$

$$\bar{v}^n_{a_j} = (1-\alpha)\bar{v}^{n-1}_{a_j} + \alpha \hat{v}^n_{a_j} \quad (4)$$

Step 8. Let $n = n+1$. If $n < N$ go to **step 1**, else for each state a, return the value function $\bar{v}^n_a$.

Figure 1: An approximate dynamic programming algorithm using a backward pass for the nomadic trucker problem

visited only a few times. As a result, there can be a high level of statistical noise in our estimates of the value of being in a state.

This section provides the context in which our adaptive learning problem arises. The next three sections consider the general problem of estimating a quantity (the value of a resource with attribute a) outside of the context of approximate dynamic programming. We assume we have a source of (unbiased) observations of the value associated with attribute a, from which we have to develop statistically robust (i.e., low-variance) estimates of the value associated with attribute a. We then use the method in the context of approximate dynamic programming to demonstrate that it produces better results than other methods, even though we no longer have unbiased observations.

3. The Statistics of Aggregation

In this section, we investigate the statistics of aggregation by studying a sampling process where at iteration n we first sample the attribute vector $a = \hat{a}^n$. We then use a sample realization of the random information which provides us with an unbiased observation of the value of the resource $\hat{v}^n$, producing a sequence of observations of (attribute vector, value) pairs. We wish to use this information to produce a statistically reliable estimate of the true value associated with a. The analysis in this section is not done in the context of dynamic programming (which allows us to assume that our observations of values are unbiased). Rather, it is intended as a pure study of the statistics of aggregation.

Our assumption that the observations of values, $\hat{v}^n$, are unbiased will not be true in a dynamic programming setting, but allows us to focus on the tradeoff between bias and variance.

We begin by defining the following:

$\mathcal{N} =$ The set of indices corresponding to the observations of the attribute vectors and values.

$\mathcal{S} =$ A sample of observations $(\hat{a}^n, \hat{v}^n)_{n \in \mathcal{N}}$.

$\nu_a =$ The true value associated with attribute vector a.

$N_a =$ The number of observations of attribute vector a given our sample $\mathcal{S}$.

$\hat{a}^n =$ The attribute vector at observation n.

$\hat{v}^n =$ The observation of the value corresponding to index n.

$1_{\{\hat{a}^n = a\}} =$ 1, if the nth observation is of attribute vector a.

An estimate of ν_a can be obtained as an average across all the observations of values corresponding to a:

$$\bar{v}_a = \frac{1}{N_a} \sum_{n \in \mathcal{N}} \hat{v}^n 1_{\{\hat{a}^n = a\}}.$$

Throughout our presentation, we use the hat notation (as in $\hat{v}$) to represent exogenous information, and bars (as in $\bar{v}$) to represent statistics derived from exogenous information.

Consider a case where the attribute vector has more than one dimension, with A_i denoting the number of distinct states that attribute a_i can assume. The number of values that need to be estimated is $\prod_i A_i$. Needless to say, as the attribute vector grows, the state space grows exponentially, making it impossible to obtain statistically reliable estimates. One strategy is to resort to aggregation (such as dropping one or more dimensions of a) which can quickly reduce the number of values but introduces structural error. An alternative is to assume a structural property such as separability, which reduces the number of values to be estimated to $\sum_i A_i$. This has fewer values, but requires that we introduce separability as an approximation. In one of our trucking applications, one attribute is the location of the truck, while a second attribute is the driver's home domicile. The value of a driver in a location depends very much on his home domicile. Assuming these are independent would introduce significant errors.

In general, aggregation of attribute vectors is performed using a collection of aggregation functions, $G^g : \mathcal{A} \rightarrow \mathcal{A}^{(g)}$, where $\mathcal{A}^{(g)}$ represents the g^{th} level of aggregation of the attribute space $\mathcal{A}$. We define the following:

$a^{(g)} =$ $G^g(a)$, the g^{th} level aggregation of the attribute vector a.

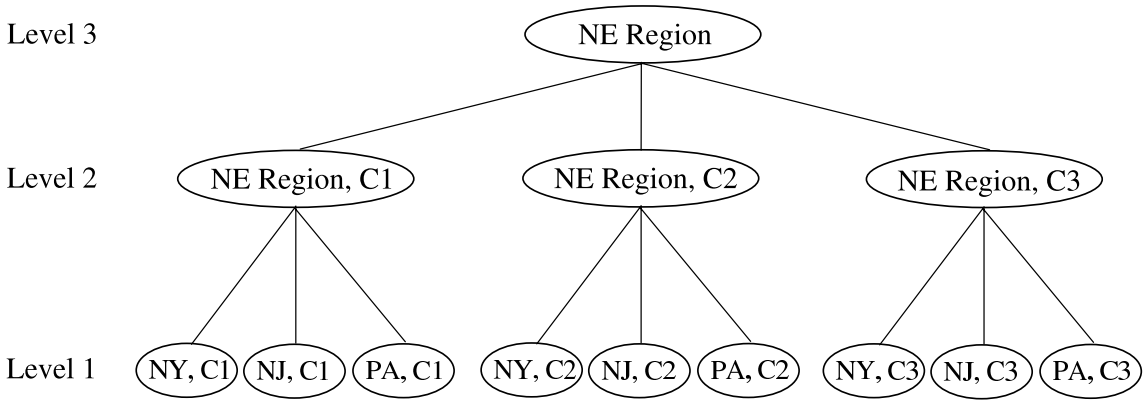

Figure 2: Aggregation of the state space for a multiattribute problem.

$\mathcal{G} =$ The set of indices corresponding to the levels of aggregation.

Aggregation can thus be used to create a sequence of state spaces, $\left\{\mathcal{A}^{(g)}, g = 1,2,\ldots,|\mathcal{G}|\right\}$, with fewer elements than the original state space. This can be better illustrated using the example in Figure 2, where we consider the nomadic trucker problem with the state of the truck defined by two attributes - current location and capacity type. The number of possible states with three locations (NY, NJ and PA), and three capacity types (C1, C2 and C3), is nine at the most disaggregate level. The first-level aggregation function, $G^{(1)}$, involves aggregating the location to the regional level which reduces the number of states to three. The second-level aggregation function, $G^{(2)}$, would be defined as aggregating out the capacity type attribute completely, which leaves us with a single state. As in this example and in the experimental work to follow, it is usually the case that the gth level of aggregation acts on the $(g-1)$st level.

We let ε^n denote the error in the nth observation with respect to the true value associated with $\hat{a}^n$ (which, using the notation defined earlier in this section, would be represented using $\nu_{\hat{a}^n}$). For analysis purposes, we assume that the elements of the sequence $\{\varepsilon^n\}_{n\in\mathcal{N}}$ are independent and identically distributed, with a mean value of zero. This is, of course, an idealization, but it will help us understand the tradeoffs between structural errors (due to aggregation) and statistical errors. We can express the observed value as follows:

$$\hat{v}^n = \nu_{\hat{a}^n} + \varepsilon^n.$$

We define the following probability spaces,

$\Omega^a =$ The set of outcomes of observations of attribute vectors.

$\Omega^\varepsilon =$ The set of outcomes of observations of the errors in the values.

$\Omega =$ The overall set of outcomes

$= \Omega^a \times \Omega^\varepsilon.$

$\omega =$ $(\omega^a, \omega^\varepsilon)$

$=$ An element of the outcome space.

We now define the following terms which will be useful in obtaining an estimate of the value associated with the attribute vector a at any level of aggregation:

$\mathcal{N}_a^{(g)} =$ The set of indices that correspond to observations of the attribute vector a at the gth level of aggregation

$= \{n \mid G^g(\hat{a}^n) = G^g(a)\}.$

$N_a^{(g)} = \left|\mathcal{N}_a^{(g)}\right|.$

$\bar{v}_a^{(g)} =$ The estimate of the value associated with the attribute vector a at the gth level of aggregation, given the sample, $\mathcal{N}$.

We can compute the estimate, $\bar{v}_a^{(g)}$, as

$$\bar{v}_a^{(g)} = \frac{1}{N_a^{(g)}} \sum_{n \in \mathcal{N}_a^{(g)}} \hat{v}^n.$$

We provide a numerical example to illustrate the idea of forming estimates at different levels of aggregation. Consider the state of a resource to be composed of two attributes, namely, location of the resource and resource type. There are four locations, namely, New York, Philadelphia, Boston and Washington. The type can be Single or Team. Thus, there are eight possible states. We use aggregation functions that aggregate out the type attribute and then the location attribute to obtain three different levels of aggregation. Suppose we have the following observations of state-value

a	Location	Type	N_a	$\bar{v}_a$	$N_a^{(1)}$	$\bar{v}_a^{(1)}$	$N_a^{(2)}$	$\bar{v}_a^{(2)}$
a_1	New York	Single	2	4.5				
a_2	New York	Team	1	7.0	3	5.3		
a_3	Philadelphia	Single	3	3.7				
a_4	Philadelphia	Team	1	2.0	4	3.3	12	4.8
a_5	Boston	Single	2	8.5				
a_6	Boston	Team	0	-	2	8.5		
a_7	Washington	Single	1	1.0				
a_8	Washington	Team	2	5.5	3	4.0		

Table 1: Numerical example illustrating the computation of value estimates using aggregation. For example, $\bar{v}_{a_1}^{(0)} = (7+2)/2 = 4.5$, and $\bar{v}_{a_7}^{(1)} = (5+1+6)/3 = 4.0$.

pairs - $\{(a_3,4),(a_4,2),(a_1,7),(a_5,8),(a_3,2),(a_8,5),(a_7,1),(a_5,9),(a_8,6),(a_2,7),(a_3,5),(a_1,2)\}$. We can form estimates of the values of the various states at the different levels of aggregation as illustrated in Table 1.

Now that we have an estimate of the value, v_a, for each level of aggregation, the question arises as to what is the best level of aggregation. A traditional strategy is to choose the right level of aggregation by trading off statistical and structural errors to find a model with the least overall error.

In order to better understand these two kinds of errors in an aggregation setting, we first let $\overline{\delta}_a^{(g)}$ denote the total error in the estimate, $\overline{v}_a^{(g)}$, from the true value associated with attribute vector a:

$$\overline{\delta}_a^{(g)} = \overline{v}_a^{(g)} - \nu_a.$$

An important component of our prediction error will be aggregation bias. Consider our most recently observed attribute vector $\hat{a}^n$ and some other attribute a, where $\hat{a}^n$ and a may aggregate up to the same aggregated attribute at some level $g \in \mathcal{G}$, that is, $G^g(a) = G^g(\hat{a}^n)$ (for the moment, these are simply two attribute vectors). In our derivations below, it is useful to define a bias term,

$$\mu_a^n = \nu_{\hat{a}^n} - \nu_a.$$

We can use this notation to rewrite $\hat{v}^n$ as follows:

$$\begin{aligned} \hat{v}^n &= \nu_a + (\nu_{\hat{a}^n} - \nu_a) + \varepsilon^n \\ &= \nu_a + \mu_a^n + \varepsilon^n \quad \forall\, a, n. \end{aligned}$$

We can express $\overline{v}_a^{(g)}$ in terms of its bias and noise components as follows:

$$\begin{aligned} \overline{v}_a^{(g)} &= \frac{1}{N_a^{(g)}} \sum_{n \in \mathcal{N}_a^{(g)}} (\nu_a + \mu_a^n + \varepsilon^n) \\ &= \nu_a + \left(\frac{1}{N_a^{(g)}} \sum_{n \in \mathcal{N}_a^{(g)}} \mu_a^n \right) + \left(\frac{1}{N_a^{(g)}} \sum_{n \in \mathcal{N}_a^{(g)}} \varepsilon^n \right). \end{aligned}$$

We let,

$$\begin{aligned} \overline{\mu}_a^{(g)} &= \frac{1}{N_a^{(g)}} \sum_{n \in \mathcal{N}_a^{(g)}} \mu_a^n, \\ \overline{\varepsilon}_a^{(g)} &= \frac{1}{N_a^{(g)}} \sum_{n \in \mathcal{N}_a^{(g)}} .\varepsilon^n. \end{aligned}$$

This enables us to express the total error as follows:

$$\overline{\delta}_a^{(g)} = \overline{\mu}_a^{(g)} + \overline{\varepsilon}_a^{(g)} \tag{5}$$

where $\overline{\mu}_a^{(g)}$ gives an estimate of the bias between the values of a at the gth level of aggregation and at the disaggregate level. $\overline{\mu}_a^{(g)}$ is a random variable that is a function of the set of points sampled. $\overline{\varepsilon}_a^{(g)}$ is an estimate of the random error that has zero expected value. By assumption, the variability in $\overline{\varepsilon}_a^{(g)}$ occurs because of the statistical noise in the observation of the values. We point out that the terms, $\overline{\delta}_a^{(g)}$, $\overline{\mu}_a^{(g)}$ and $\overline{\varepsilon}_a^{(g)}$, are not statistical estimators, because a knowledge of the true values is required for computing these. $\overline{\mu}_a^{(g)}$ is representative of the structural error that is introduced due to aggregation, while $\overline{\varepsilon}_a^{(g)}$ represents the statistical error due to noise in the observations. Moreover, these two error terms need not be uncorrelated in a general setting.

In an approximate dynamic programming setting, the right tradeoff between statistical and structural errors will change as we collect more observations. Furthermore, we generally do not control the sampling process of the attributes, and we will encounter instances where some regions of the attribute space $\mathcal{A}$ will be sampled more than others. Although it is common in practice to choose a single level of aggregation that produces the lower overall error, it can be useful to combine estimates from several levels of aggregation.

4. Combining Estimates

In this section, we propose methods to compute weights to combine value estimates that have been formed from a given set of observations. In the context of ADP, the weights are computed at a given iteration of the algorithm in Figure 1.

We consider a set of estimates, $\left\{\bar{v}_a^{(g)}, g \in \mathcal{G}\right\}$, of a value, ν_a, at different levels of aggregation. We let $\sigma_a^{(g)}$ denote the population standard deviation associated with the observations used to compute $\bar{v}_a^{(g)}$. Breiman (1996) proposes a method called stacked regression which in our setting would be equivalent to combining estimates at different levels of aggregation using

$$\bar{v}_a = \sum_{g \in \mathcal{G}} w^{(g)} \cdot \bar{v}_a^{(g)},$$

where $w^{(g)}$ is a set of weights for each level of aggregation. This method ignores the important feature that the best weighting depends on how many times we have observed a particular attribute. We prefer to use the strategy suggested by LeBlanc and Tibshirani (1996) (Section 8), where the weights depend on the attribute:

$$\bar{v}_a = \sum_{g \in \mathcal{G}} w_a^{(g)} \cdot \bar{v}_a^{(g)}.$$

The practical challenge here is that we have to estimate a set of weights $(w_a^{(g)})$ for *each* attribute a (that we observe). If we use classical regression methods for our applications, this can mean maintaining hundreds of thousands of regression models. Storing and updating these models is computationally demanding for large industrial applications. In this section, we develop both exact and approximate methods for estimating weights, where our approximation makes the assumption that the estimates $\bar{v}_a^{(g)}$ are independent. Section 5 presents theoretical and experimental arguments supporting the accuracy of the weights when we assume independence (even when the assumption is not even approximately true), which dramatically simplifies the procedure.

In Section 4.1, we formulate the problem of finding the optimal weights for the general case where the estimates may be biased and dependent on each other, and later derive these weights. However, the computation of these weights can prove cumbersome for large-scale problems. We provide, in Section 4.2, a simpler formula for the weights which assumes that the estimates are independent, but accounts for the possibility of biases in the estimates. In Section 4.3, we propose an approximation of the weights derived in Section 4.2, for the case where the bias and variance of the estimators are unknown.

4.1 Optimal Weights

We begin by finding the weighting scheme that will optimally combine the estimates at the different levels of aggregation, that is, the weights which give a combined estimate with the least squared deviation from the true value associated with attribute vector a. We can formulate the problem as follows:

$$\min_{w_a^{(g)}, g \in \mathcal{G}} \mathbb{E}\left[\frac{1}{2}\left(\sum_{g \in \mathcal{G}} w_a^{(g)} \cdot \bar{v}_a^{(g)} - \nu_a\right)^2\right], \tag{6}$$

subject to:

$$\sum_{g \in \mathcal{G}} w_a^{(g)} = 1. \tag{7}$$

In a setting where the estimates are unbiased, it is useful to have an affine combination of the estimates (LeBlanc and Tibshirani, 1996, Section 2) since the individual estimates and hence the affine combination are equal to the true value in expectation. Even though this is not necessarily true in a general setting, we choose to retain this constraint.

We state the following proposition for computing the optimal weights that solves the problem formulated in Equations 6-7:

Proposition 1 *For a given attribute vector, a, the optimal weights, $w_a^{(g)}$, $g \in \mathcal{G}$, to combine individual estimates that are correlated in a hierarchical fashion, are obtained by solving the following system of linear equations in (w, λ):*

$$\sum_{g \in \mathcal{G}} w_a^{(g)} \mathbb{E}\left[\bar{\delta}_a^{(g)} \bar{\delta}_a^{(g')}\right] - \lambda = 0 \quad \forall\ g' \in \mathcal{G}, \tag{8}$$

$$\sum_{g \in \mathcal{G}} w_a^{(g)} = 1. \tag{9}$$

If the bias error, $\bar{\mu}_a^{(g)}$, is uncorrelated with the random error, $\bar{\varepsilon}_a^{(g)}$, then the coefficients of the weights in Equation 8 can be expressed as follows:

$$\mathbb{E}\left[\bar{\delta}_a^{(g)} \bar{\delta}_a^{(g')}\right] = \mathbb{E}\left[\bar{\mu}_a^{(g)} \bar{\mu}_a^{(g')}\right] + \frac{\sigma_\varepsilon^2}{N_a^{(g')}} \qquad \forall g \leq g' \text{ and } g, g' \in \mathcal{G} \tag{10}$$

where σ_ε^2 denotes the variance of the statistical noise in the observations.

Proof: The proof is given in appendix A. The derivation of Equation 8 involves using the Lagrangian for the problem stated in Equations 6-7 and performing some simple arithmetic on the corresponding first order optimality conditions. Equation 9 is identical to Equation 7 from the optimization formulation.

In the remainder of this analysis, our computations will be conditional on a given sequence of observed attribute vectors. In other words, all expectations and probabilities are computed with respect to the probability space, Ω^ε. We prove Equation 10 by simplifying the expression $\mathbb{E}\left[\bar{\delta}_a^{(g)} \bar{\delta}_a^{(g')}\right]$ using some properties of hierarchical aggregation. □

For the case where $g = 0$, we can use the result, $\mathbb{E}\left[\bar{\mu}_a^{(0)}\bar{\mu}_a^{(g')}\right] = 0$ (which follows from the property: $\mu_a^{(0)} = 0$), to further simplify (10) and obtain the following result:

$$\mathbb{E}\left[\bar{\delta}_a^{(0)}\bar{\delta}_a^{(g')}\right] = \frac{\sigma_\varepsilon^2}{N_a^{(g')}}. \tag{11}$$

We refer to the optimal weighting scheme as WOPT.

4.2 An Approximation Assuming Independence

It is a well-known result in statistics that if the estimates $\left\{\bar{v}_a^{(g)}, g \in \mathcal{G}\right\}$ were independent and unbiased, then the optimal weights would be given by

$$w_a^{(g)} = \frac{1}{{\sigma_a^{(g)}}^2/N_a^{(g)}}\left(\sum_{g' \in \mathcal{G}} \frac{1}{{\sigma_a^{(g')}}^2/N_a^{(g')}}\right)^{-1}. \tag{12}$$

We can obtain this result from proposition 1 as follows. If we assume that the estimates $\left\{\bar{v}_a^{(g)}, g \in \mathcal{G}\right\}$ are independent and unbiased, then the cross-terms in Equation 8 disappear, leaving behind the following modified relation:

$$w_a^{(g)}\mathbb{E}\left[\left(\bar{\delta}_a^{(g)}\right)^2\right] - \lambda = 0 \quad \forall\ g \in \mathcal{G}. \tag{13}$$

Solving Equations 13 and 9 gives us weights that are inversely proportional to the expected squared errors, $\mathbb{E}\left[\left(\bar{\delta}_a^{(g)}\right)^2\right]$. For the case of independent, unbiased estimates, $\mathbb{E}\left[\left(\bar{\delta}_a^{(g)}\right)^2\right]$ is identical to the variance, ${\sigma_a^{(g)}}^2/N_a^{(g)}$.

Solving the system of equations in Proposition 1 can be computationally expensive since in practice, there may be hundreds of thousands of models. For practical solutions, it will be useful to have an expression along the lines of Equation 12 for computing the weights, even though neither of the conditions (independence and absence of bias) holds true for estimates that arise from aggregation due to structural errors introduced in the process of aggregation. In order to adapt the simpler formula in (13) to the aggregation setting while acknowledging the bias, we first define:

$$\begin{aligned}\mu_a^{(g)} &= \text{Expected bias in the estimate, } \bar{v}_a^{(g)} \\ &= \mathbb{E}\left[\bar{v}_a^{(g)} - \nu_a\right].\end{aligned}$$

For biased estimates, the total squared error can be expressed as the sum of bias and variance components, provided the bias and variance are independent of each other (Hastie et al., 2001, p. 24):

$$\mathbb{E}\left[\left(\bar{\delta}_a^{(g)}\right)^2\right] = \frac{{\sigma_a^{(g)}}^2}{N_a^{(g)}} + {\mu_a^{(g)}}^2. \tag{14}$$

We use this relation to modify the weights as follows:

$$w_a^{(g)} = \frac{1}{\frac{{\sigma_a^{(g)}}^2}{N_a^{(g)}} + {\mu_a^{(g)}}^2} \left(\sum_{g' \in \mathcal{G}} \frac{1}{\frac{{\sigma_a^{(g')}}^2}{N_a^{(g')}} + {\mu_a^{(g')}}^2} \right)^{-1} \quad \forall\ g \in \mathcal{G}. \tag{15}$$

We call this weighting scheme, WIND.

4.3 Weighting by Inverse Mean Squared Errors

In the more realistic setting where the exact values of the parameters involved in the computation of weights as in Equation 15 are unknown, we propose using the plug-in principle (see, for example, Efron and Tibshirani 1993, chapter 4) where we use statistical estimates of the bias and variance to produce approximations of the weights. We first compute estimates of the bias and the variance using

$$\begin{aligned} {s_a^{(g)}}^2 &= \text{The sample variance of the observations corresponding to the estimate } \bar{v}_a^{(g)} \\ &= \frac{1}{N_a^{(g)} - 1} \sum_{n \in \mathcal{N}_a^{(g)}} \left(\hat{v}^n - \bar{v}_a^{(g)} \right)^2. \\ \tilde{\mu}_a^{(g)} &= \text{An estimate of the bias in the estimated value } (\bar{v}_a^{(g)}) \text{ from the true value} \\ &= \bar{v}_a^{(g)} - \bar{v}_a^{(0)}. \end{aligned}$$

The approximate weights on the estimates at different levels of aggregation are inversely proportional to the estimates of their mean squared deviations (obtained as the sum of the variances and the biases) from the true value:

$$w_a^{(g)} = \frac{1}{\frac{{s_a^{(g)}}^2}{N_a^{(g)}} + {\tilde{\mu}_a^{(g)}}^2} \left(\sum_{g' \in \mathcal{G}} \frac{1}{\frac{{s_a^{(g')}}^2}{N_a^{(g')}} + {\tilde{\mu}_a^{(g')}}^2} \right)^{-1} \quad \forall\ g \in \mathcal{G}. \tag{16}$$

We refer to this formula as weighting by inverse mean squared errors (WIMSE). In the event that $N_a^{(g)}$ is too small or zero (which can happen in the early iterations and/or at the more disaggregate levels), it is difficult to form meaningful estimates of the variance and bias. In such a situation, we set the corresponding weight to zero.

Equation 16 is very easy to calculate even for large scale applications where we may observe hundreds of thousands of attributes. However, it produces the best results only when the estimates of values at different levels of aggregation are independent, an assumption that we cannot expect to hold true. In the next section, we present theoretical and experimental evidence supporting the claim that the error introduced from this assumption is negligible.

It is important to note that the use of the plug-in principle, which in this setting means using statistical estimates of parameters (the bias and variance), may result in some unexpected behavior when the number of observations is small. For example, the estimate of the total squared error in Equation 14 would be expected to decrease with each additional observation. When we use estimates of the bias and variance, this is no longer guaranteed, especially when $N_a^{(g)}$ is small. However, our empirical evidence is that it seems to behave as expected in an aggregate sense.

5. The Case for Assuming Independence

In this section, we justify our decision to ignore the dependence between the estimates from hierarchical aggregation, while combining them to form an improved estimate. We discuss the special case where we combine estimates from only two levels of aggregation, which enables us to obtain simple expressions for computing the various parameters. We assume that the statistical noise is independent of the attribute vector sampled and also that we know the probability distributions of the sampling of the attribute vectors and their values. These assumptions enable us to solve the optimality equations to obtain a solution explicitly. In Section 5.1, we analytically compare the two sets of equations (with and without assuming independence) for computing optimal weights. We provide an experimental comparison of the two methods, demonstrating the similarity in results, in section 5.2.

5.1 Analytical Comparison

For the two-level problem, we can obtain the optimal weights (WOPT) by solving the following system of equations:

$$\begin{aligned}
\mathbb{E}\left[\overline{\delta}_a^{(0)^2}\right] w_a^{(0)} + \mathbb{E}\left[\overline{\delta}_a^{(0)}\overline{\delta}_a^{(1)}\right] w_a^{(1)} - \lambda &= 0, \\
\mathbb{E}\left[\overline{\delta}_a^{(0)}\overline{\delta}_a^{(1)}\right] w_a^{(0)} + \mathbb{E}\left[\overline{\delta}_a^{(1)^2}\right] w_a^{(1)} - \lambda &= 0, \\
w_a^{(0)} + w_a^{(1)} &= 1, \\
w_a^{(0)}, w_a^{(1)} &\geq 0.
\end{aligned}$$

Since we are concerned with computing the weights for a particular attribute vector, we drop the index a in the following analysis. We obtain the value of $w^{(0)}$ as,

$$w^{(0)} = \frac{\mathbb{E}\left[\overline{\delta}^{(1)^2}\right] - \mathbb{E}\left[\overline{\delta}^{(0)}\overline{\delta}^{(1)}\right]}{\mathbb{E}\left[\overline{\delta}^{(0)^2}\right] + \mathbb{E}\left[\overline{\delta}^{(1)^2}\right] - 2\mathbb{E}\left[\overline{\delta}^{(0)}\overline{\delta}^{(1)}\right]}. \tag{17}$$

By assumption, the estimate at the disaggregate level is unbiased, that is, $\mu^{(0)} = 0$. We let $\mu^2 = \mathbb{E}\left[\overline{\mu}^{(1)^2}\right]$ denote the expected value of the square of the bias term at the aggregate level. Using Equations 10 and 11, we may write,

$$\begin{aligned}
\mathbb{E}\left[\overline{\delta}^{(0)}\overline{\delta}^{(1)}\right] &= \frac{\sigma_\varepsilon^2}{N^{(1)}}, \\
\mathbb{E}\left[\overline{\delta}^{(0)^2}\right] &= \frac{\sigma_\varepsilon^2}{N^{(0)}}, \\
\mathbb{E}\left[\overline{\delta}^{(1)^2}\right] &= \mathbb{E}\left[\overline{\mu}^{(1)^2}\right] + \mathbb{E}\left[\overline{\varepsilon}^{(1)^2}\right] \\
&= \mu^2 + \frac{\sigma_\varepsilon^2}{N^{(1)}}.
\end{aligned}$$

These results enable us to rewrite Equation 17 for computing the weights on the disaggregate estimate using the WOPT scheme (which we denote as w^{opt}) as follows:

$$w^{opt} = \frac{1}{1+\left(\frac{1}{N^{(0)}}-\frac{1}{N^{(1)}}\right)\frac{\sigma_\varepsilon^2}{\mu^2}}. \quad (18)$$

The competing scheme, WIND, assumes independence of the estimates. The weights at the disaggregate level are obtained using the formula:

$$w^{ind} = \frac{1+\frac{1}{N^{(1)}}\frac{\sigma_\varepsilon^2}{\mu^2}}{1+\left(\frac{1}{N^{(0)}}+\frac{1}{N^{(1)}}\right)\frac{\sigma_\varepsilon^2}{\mu^2}}. \quad (19)$$

We denote by $\tilde{v}^{opt}$ and $\tilde{v}^{ind}$ the estimates computed using the two weighting schemes.

$$\begin{aligned}\tilde{v}^{opt} &= w^{opt}\bar{v}^{(0)}+(1-w^{opt})\bar{v}^{(1)},\\ \tilde{v}^{ind} &= w^{ind}\bar{v}^{(0)}+(1-w^{ind})\bar{v}^{(1)}.\end{aligned}$$

We can write the difference between the estimates of the value obtained with and without the independence assumption as $\Delta = \tilde{v}^{opt}-\tilde{v}^{ind} = \Delta_w \cdot \Delta_v$, where $\Delta_w = w^{opt}-w^{ind}$ and $\Delta_v = \bar{v}^{(0)}-\bar{v}^{(1)}$. The following proposition establishes that Δ is small under certain conditions.

Proposition 2
(i) $\lim_{\mu\to 0}\mathbb{E}[\Delta]=0$,
(ii) $\lim_{\mu\to\infty}\Delta=0$,
(iii) $\lim_{\sigma^2\to 0}\Delta=0$.

Proof:
(*i*) As $\mu\to 0$, $w^{opt}=0$ and $w^{ind}=N^{(0)}/\left(N^{(0)}+N^{(1)}\right)$. w^{ind} attains a maximum value of $1/2$ when $N^{(0)}=N^{(1)}$, but that would imply that $\bar{v}^{(0)}=\bar{v}^{(1)}\Rightarrow\Delta_v=0$. At the other extreme, if $N^{(0)}=0$, then $w^{ind}=0\Rightarrow\Delta_w=0$. For intermediate values of $N^{(0)}$, it is no longer true that the random variable Δ_v will always be zero (for statistical reasons), but we can show that its expectation will be zero using

$$\begin{aligned}\mathbb{E}[\Delta] &= \mathbb{E}\{\mathbb{E}[\Delta|\mathcal{N}]\},\\ \mathbb{E}[\Delta|\mathcal{N}] &= \mathbb{E}\left[\Delta_v\frac{N^{(0)}}{N^{(0)}+N^{(1)}}|\mathcal{N}\right]\\ &= \mathbb{E}[\Delta_v]\frac{N^{(0)}}{N^{(0)}+N^{(1)}}\\ &= 0.\end{aligned}$$

Since $\mu^2=0$, $\mathbb{E}[\Delta_v]=0$ and Equation 20 follows.
(*ii*) As $\mu\to\infty$, $w^{ind}\to w^{opt}\to 1$, which can be easily obtained by applying the appropriate limits in Equations 18 and 19. This is intuitive since with very high bias, the best strategy is to put all the weight on the most disaggregate level. As a result, $\Delta_w\to 0$.
(*iii*) As the variance goes to zero, $w^{(ind)}\to w^{(opt)}$ that again implies $\Delta_w\to 0$. □

Thus, the error from the independence assumption is small when the bias is high or low, or when the variance is low. The error will be highest for moderate values of the bias and higher values of the variance. Given that the errors vanish for the extreme cases, it is perhaps not surprising that the errors are never very large. We provide experimental evidence to support this conclusion in the next section.

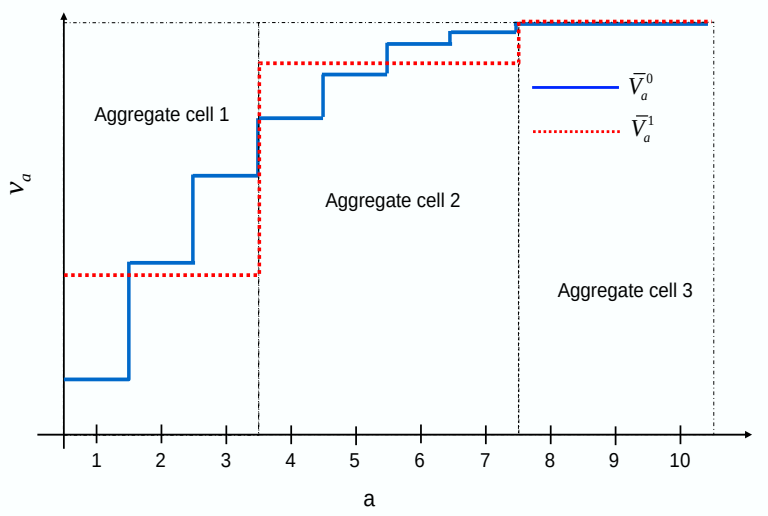

Figure 3: A piecewise constant function with its aggregate approximation. Estimates of values of each attribute vector are computed at both the aggregate and disaggregate levels. A weighted averaging is done to improve the estimates.

5.2 Experimental Results

In this section, we analyze the estimation of functions characterized by known parameters (which effectively requires that we know the actual function) in order to demonstrate the effectiveness of the optimal weighting strategy, as well as to serve as a benchmark for the strategy which assumes independent estimates at different levels of aggregation. We observe that the weights given by either method (Equations 18 and 19) are functions of the bias in the value at the aggregate level, the variance of the statistical noise in the observation of the values and the number of observations at either level. In order to compare the values of the weights from the competing strategies, we create scenarios with different combinations of the parameters that would produce significant changes in the weights. We then analyze how the variations in the weights given by WOPT and WIND affect the actual function estimates computed using the two schemes.

We consider a piecewise constant monotone function and its aggregate version as shown in Figure 3. We note that there are distinct regions in the domain where the bias is high, intermediate and zero - we expect the relative weights to be very different in these three regions. Figure 4 gives the weights (to be applied to the disaggregate level) produced by the optimal formula, WOPT, and the formula assuming independence, WIND, for each attribute a. The weights are obtained by sampling since the corresponding Equations (18 and 19) require the number of observations at the two levels of aggregation, $N^{(0)}$ and $N^{(1)}$. As we would expect, the optimal weights at the disaggregate level are zero when there is no structural error, in contrast to WIND. When the structural error is highest, the weights produced by the two methods are very similar. Note, however (consistent with our understanding from the previous section) that the weights are also quite different for the cells $a = 2$ and $a = 5$ where the aggregate and disaggregate functions are most similar (which means the bias is small). It is also the case that the weight to be given to the disaggregate level is also smallest when the bias is smallest.

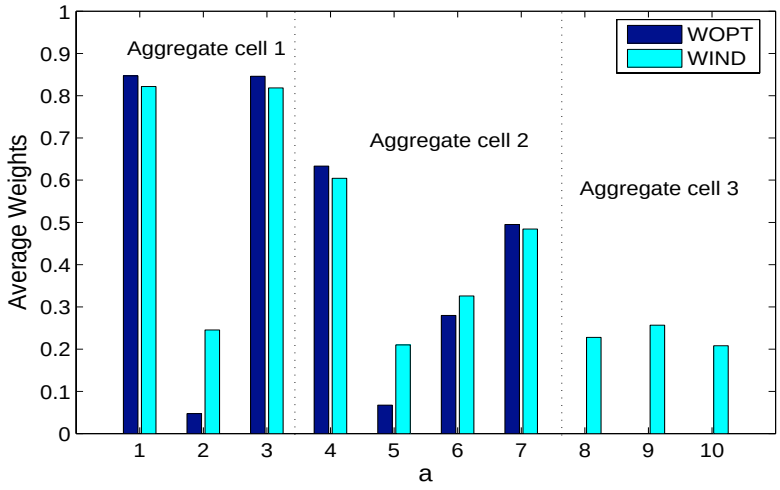

Figure 4: Comparison of the weights over the function domain

We have illustrated the difference in the weights produced by the two strategies, but less obvious is the difference in the estimates of the underlying function. In order to compare the two schemes, we developed a measure of the degree to which a weighting strategy reduced the variance of an estimate. We define the following:

$$\begin{aligned}
\tilde{v}_a^s &= \text{The value of the attribute vector } a \text{ as estimated by strategy } s.\\
\varepsilon^s &= \text{The sum of squared errors as estimated by strategy } s.\\
&= \sum_{a\in\mathcal{A}} (\tilde{v}_a^s - v_a)^2\\
\varepsilon^G &= \text{The sum of squared errors using the static aggregation strategy which treats the function as a constant over its domain.}\\
\theta^s &= \text{The performance measure for strategy } s.\\
&= 1 - \frac{\varepsilon^s}{\varepsilon^G}.
\end{aligned}$$

θ^s measures the degree of variability explained by a particular weighting strategy relative to using a single constant which can be thought of as a default strategy where all observations are aggregated together. θ^s is analogous to an R^2 measure commonly used in statistics.

A major factor in the performance of a weighting strategy is the relative size of the structural variation compared to the statistical noise. For this purpose, we define an index, ρ, that measures the ratio of the noise to the bias.

Figure 5 compares the performances of the two weighting strategies for three levels of noise. We observe that the performance of WOPT and WIND are almost identical even though there were situations where the weights given by the two schemes were significantly different. The similarity in the function estimates from the two strategies is explained by the analysis in Section 5.1.

We tested the relative performance of the two methods for other function classes. We summarize the results in figure 6 where we plot the performance measure as a function of the average number of observations per disaggregate cell. We observe that there is very little statistical difference between

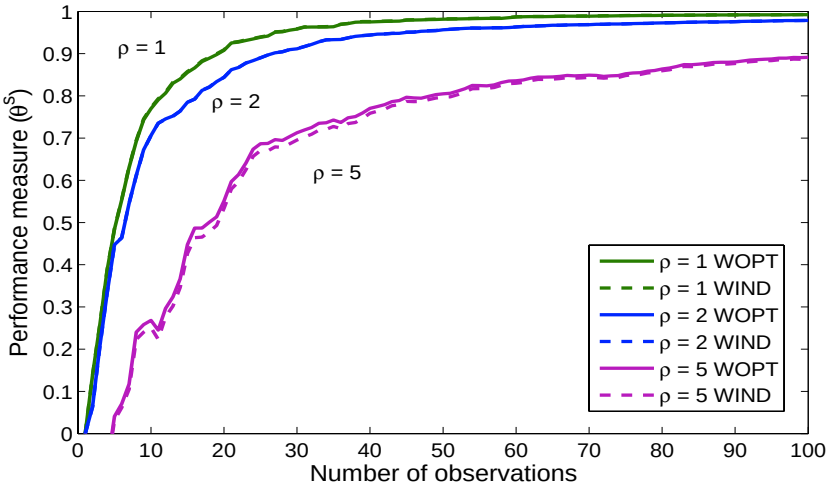

Figure 5: Comparison of the performance, as measured by θ^s, of WOPT and WIND in estimating the piecewise constant function

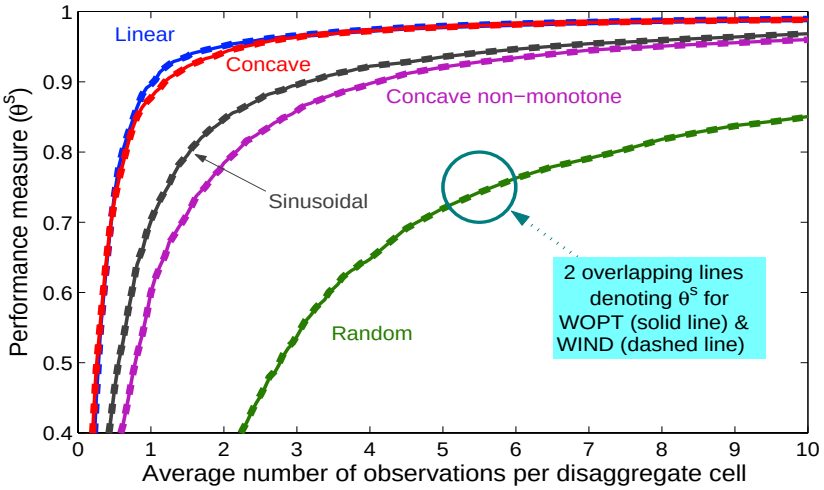

Figure 6: Comparison of WOPT and WIND for various function types using expected values of weights. The graph shows the average performance measure (θ^s) over 1000 samples for a moderate value of $\rho = 2$. WOPT is represented using solid lines and WIND, with dashed lines - the two are virtually indistinguishable.

the performance of the two methods. From this analysis, we conclude that WIND, which combines estimates assuming independence, will generally be a close approximation of WOPT. Of particular interest for our problem setting is that WIND is much easier to implement.

6. Experiments in an ADP Application

We implemented the hierarchical weighting strategy in the approximate dynamic procedure for solving the nomadic trucker problem described in Section 2. In Section 6.1, we describe the specifics of the problem instances that we consider. We also state the competing strategies that we compare in the experiments that follow. We then proceed to show the effectiveness of our hierarchical weighting scheme using two sets of experiments. In Section 6.2, we report on experiments where the discount factor is set to zero. In this case, the observations of values are unbiased, since they do not involve the estimates of values of future states. In Section 6.3, we present the results of experiments with positive discount factors. We have made available a collection of data sets used in these experiments on the following webpage - `http://castlelab.princeton.edu/`. Finally, in Section 6.4, we provide experimental results from applying our techniques on an industrial strength problem.

6.1 Experimental Design

We consider a problem where we specify the state of the truck using three attributes, namely, the current location, the day of week and the number of days away from home. The problem is rich enough to offer interesting opportunities for hierarchical aggregation, but small enough that we can solve the problem to obtain the exact solution.

The decisions are to be made over a finite time horizon of 21 time periods. The location attribute can be represented at two degrees of resolution - regions (eastern Pennsylvania, northern New Jersey) or geographical areas (Northeast, Midwest and so on). There are 50 locations at the region level which can be aggregated to 10 geographical areas.

The major contributor to the stochastic nature of the nomadic trucker problem is the uncertainty in the availability of loads in any particular location to be moved to other locations. The probability that a load is available to be moved from one location to another is dependent on the origin-destination pair. Another factor that influences the load availability is the day of week. Loads are more likely to appear during the beginning of the week (Mondays) and towards the end (Fridays). We use a probability distribution whereby the load availability dips during the middle of the week and is lower over the weekends. We introduce further uncertainty into the problem by allowing the one-period contributions to be moderately noisy.

The final attribute that we consider is the number of days that the driver is away from home. There is a penalty that we impose on moves that keep the driver away from his home domicile, which is a quadratic function of the number of days away from home. In order to keep the state space manageable (so we can obtain optimal solutions), we cap the number of days away from home at 12.

In Table 2, we list the aggregations that we use for the problem and the number of attribute states at each level of aggregation. For example, at aggregation level 1, the location attribute is aggregated from 50 regions to 10 geographical areas. We aggregate out the day-of-week attribute and retain the days-away-from-home attribute. Adding in the factor for 21 time periods, we have a total of 2541 possible states. The apparent discrepancy in the size of the state space at levels 0 and 1 arises because the days-away-from-home attribute is always set to 0 for the location corresponding to the home of the driver, while for all the other locations it can be any number from 1 to 12.

In order to compute the true values associated with each attribute vector, we use a standard backward dynamic programming algorithm. Our focus is on the problem of statistical estimation of the true values of the various states. In order to form estimates of these values we incorporate

g	Time	Location	Days-away-from-home	Day-of-week	$\lvert\mathcal{A}\rvert$
0	*	Region	*	*	86583
1	*	Area	*	-	2541
2	*	Area	-	-	210
3	*	-	-	-	21

Table 2: Aggregations for the multiattribute nomadic trucker problem. A '$*$' corresponding to a particular attribute indicates that the attribute is included in the attribute vector, and a '$-$' indicates that it is aggregated out.

our aggregation strategies in the approximate dynamic programming algorithm outlined in Figure 1. The value function estimate in Equation 1 is obtained as a weighted sum of the value estimates at various levels of aggregation:

$$\bar{v}_{a'}^{n-1} = \sum_{g\in\mathcal{G}} w_{a'}^{(g),n-1}\bar{v}_{a'}^{(g),n-1} \qquad \text{where } a' = a^M(a,d)\ \forall d \in \mathcal{D}_a$$

where $w_{a'}^{(g),n-1}$ denotes the weight, at iteration $(n-1)$, on the estimate of the value of attribute vector a' at the gth level of aggregation.

The methods that we compare use the following sets of weights:

1. Static Aggregation:

$$w_{a'}^{(g),n-1} = \begin{cases} 1 & \text{if } g \text{ is the fixed level of aggregation,} \\ 0 & \text{otherwise.} \end{cases}$$

2. Dynamic Aggregation (MINV):

$$w_{a'}^{(g),n-1} = \begin{cases} 1 & \text{if } g = \arg\min_{g'\in\mathcal{G}} \left(s_{a'}^{(g'),n-1}\right)^2 \\ 0 & \text{otherwise.} \end{cases}$$

3. WIMSE: $w_{a'}^{(g),n-1}$ is computed using Equation 16.

Equation 4 is replaced by a series of equations for updating the value function estimates at all the levels of aggregation corresponding to the currently visited attribute vector:

$$\bar{v}_a^{(g),n} = (1-\alpha)\bar{v}_a^{(g),n-1} + \alpha\hat{v}_a^n, \qquad a \in \mathcal{A}, g \in \mathcal{G}. \tag{20}$$

In the early iterations, especially for the more disaggregate levels, we often encounter the situation where the number of observations is too small (zero in certain cases) to form a meaningful estimate of a value. In such instances, we ignore the estimate at that level of aggregation. While forming a weighted sum of estimates, this usually results in all the weights being placed on the more aggregate levels.

For methods 2 and 3, we point out that the chosen level of aggregation and the weights on the estimates at different levels are dynamic in nature, in that they change with each iteration. This is brought out in the sections that follow.

The performance measure that we use for these experiments is based on the deviation of the value function approximations from the optimal value functions which can be obtained using a traditional backward dynamic programming algorithm such as value iteration. We first define

$$\begin{aligned} p_a &= \text{The steady state probability of being in state (equivalent to, in this situation, attribute vector) } a. \\ N_a &= \text{The number of observations of or visits to state } a. \\ \nu_a &= \text{The true value associated with state } a. \\ \tilde{v}_a^s &= \text{The value function approximation for state } a \text{ estimate computed using strategy } s. \end{aligned}$$

Using these we may define the following performance measures:

$$\begin{aligned} E_1^s &= \text{Error measure based on steady state probabilities, that is, a stationary distribution} \\ &= \frac{\sum_{a\in\mathcal{A}} p_a(\tilde{v}_a^s - \nu_a)}{\sum_{a\in\mathcal{A}} p_a \nu_a} \times 100\%. \qquad (21) \\ E_2^s &= \text{Error measure based on the number of visits to each state} \\ &= \frac{\sum_{a\in\mathcal{A}} N_a(\tilde{v}_a^s - \nu_a)}{\sum_{a\in\mathcal{A}} N_a \nu_a} \times 100\%. \qquad (22) \end{aligned}$$

6.2 Experiments on Myopic Data Sets

We first analyze the ability of our proposed method to make estimates from a purely statistical perspective. For this purpose, we maintain a zero discount factor, which means that the downstream values of the states are ignored while making the decisions at any time period. Instead the decisions are based on the one-period rewards alone. Using a discount factor of zero eliminates the bias that is introduced in the ADP procedure, which implies that the errors in the estimates are purely due to the noise in the observations. We compare the different estimation techniques in Table 3 where we tabulate the E_2^s values (as computed using Equation 22) for several problem instances. The static aggregation strategies for $g = 0, 1$ & 2 are denoted as *Disaggregate*, *Aggregate1* and *Aggregate2* respectively. We observe that WIMSE demonstrates lower errors than the other techniques.

6.3 Experiments on Non-myopic Data Sets

In this section, we discuss results obtained by using a positive discount factor. As such, the estimates of the future values have an impact on the current decisions. Figure 7 illustrates the variation in the weights on the estimates from different levels of aggregation, as a function of the number of observations, computed using the WIMSE weighting scheme. As expected, in the early iterations we place the highest weight on the most aggregate level since this offers the greatest statistical reliability. As the algorithm progresses, higher weights are put on the more disaggregate levels, with ultimately the highest weight on the most disaggregate level. It is interesting (and noteworthy) that the weights on the higher levels of aggregation drop quickly at first, but then stabilize, dropping

Problem #	Disaggregate		Aggregate1		MINV		WIMSE

6	5.52	*0.09*	17.50	*0.09*	7.26	*0.10*	**5.10**	*0.10*

Table 3: Comparison of techniques for different problem instances (Disaggregate: $g = 0$, Aggregate1: $g = 1$). The performance measure used for each of the methods is the percentage deviation from optimality. Figures in italics denote the standard deviations of the terms to the left.

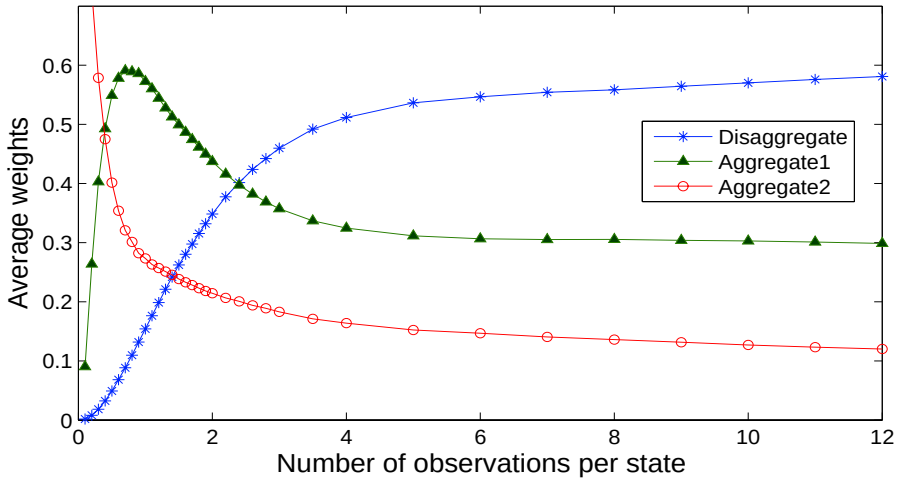

Figure 7: Average weights using hierarchical aggregation. (Disaggregate: $g = 0$, Aggregate1: $g = 1$, Aggregate2: $g = 2$).

very slowly. This behavior primarily reflects attributes with very low bias where the weight on the aggregate level will always remain fairly high.

In Figure 8, we compare the various techniques based on E_1^s values, that is, the percentage errors in the estimates from the optimal values weighted by the steady state probabilities under an optimal policy (see Equation 21). The steady state probabilities can be obtained in the process of computing the optimal values. This error measure enables us to determine how close the policy produced by the value function estimates is to an optimal policy. We see that the hierarchical weighting scheme outperforms all the static aggregation strategies as well as the dynamic aggregation strategy which picks the "best" level of aggregation, producing the least errors in the estimates.

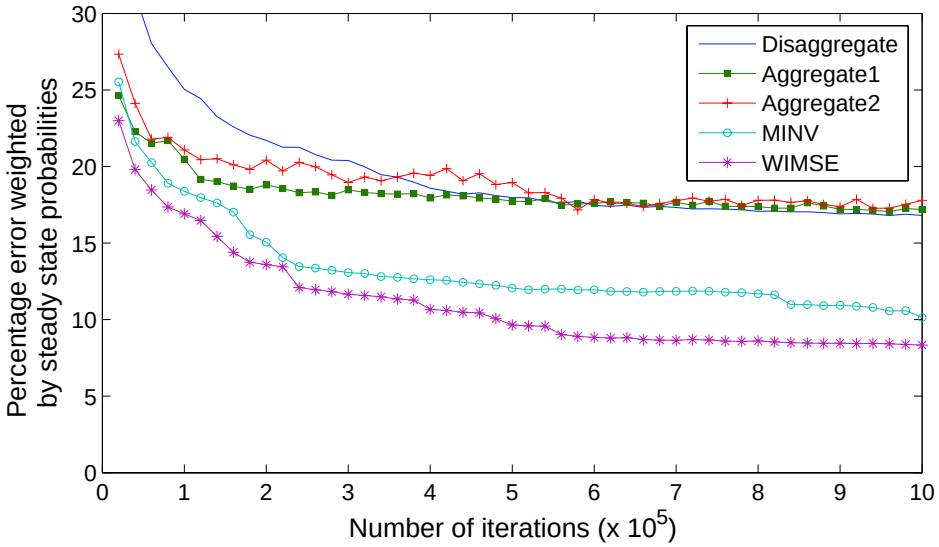

Figure 8: E_1^s values as a function of the number of observations.

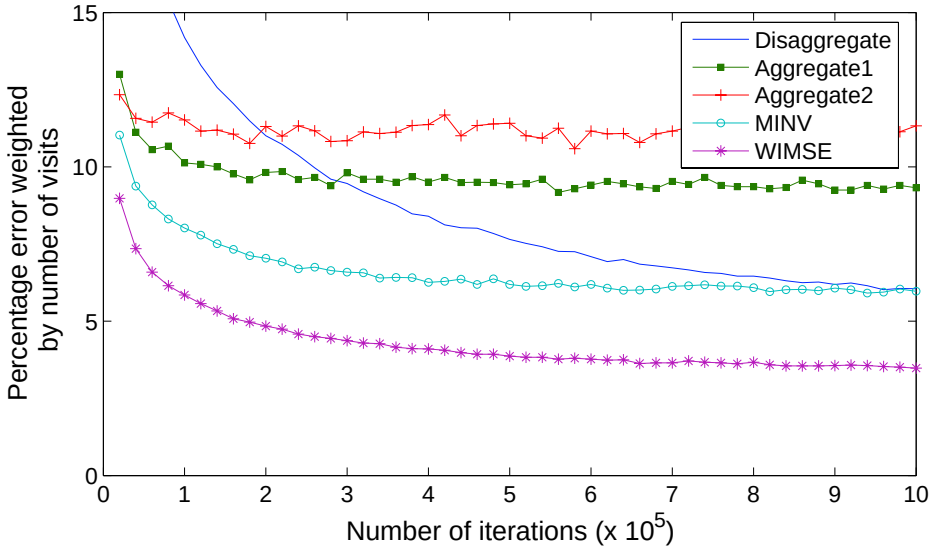

Figure 9: E_2^s values as a function of the number of observations.

Figure 9 shows the relative performance of the various schemes with respect to the errors weighted by the number of visits to the various states (E_2^s values). This error measure gives an idea of how well a particular strategy is able to estimate correctly the optimal value of the various states with higher weights on the errors in the estimates of states that are visited more frequently.

Table 4: Comparison of techniques for different instances of the nomadic trucker problem. Two higher levels of aggregation are also used in the problem, but omitted from the tables, as they give inferior results. Figures in italics denote the standard deviations of the terms to the left.

Here again, WIMSE is found to consistently outperform the remaining techniques, producing error values that are much lower.

We now compare the various techniques for several problem instances. The major parameters that are varied to obtain the different problem sets are the discount factor, the probability distribution of the load availability at the various locations and the level of uncertainty in the contributions resulting from choosing a particular decision. We used discount factors of 0.80, 0.90 and 0.95, three different load probability distributions and two levels of uncertainty in the rewards. The E_2^s values for these problem instances are tabulated in Table 4. Here again, WIMSE outperforms all the other schemes consistently, irrespective of the number of iterations.

6.4 Experiments with a Fleet of Trucks

The techniques in this paper were designed to be applied to approximate dynamic programming algorithms for optimizing a fleet of trucks. To illustrate, we provide a very brief model of a multiattribute resource allocation problem that can be applied to the management of large fleets of trucks, freight cars, locomotives, military air cargo jets or business jets (we have industrial experience with

all of these problems). Let

$$\begin{aligned}
R_a &= \text{The number of resources with attribute } a.\\
R &= (R_a)_{a\in\mathcal{A}}\\
\mathcal{D} &= \text{The set of different decision types that can be used to act on a resource (e.g., moving from one location to another, repairing a vehicle).}\\
x_{ad} &= \text{The number of times we act on a resource with attribute } a \text{ using a decision of type } d\in\mathcal{D}.\\
x &= (x_{ad})_{a\in\mathcal{A},d\in\mathcal{D}}\\
c_{ad} &= \text{The contribution generated by } x_{ad}.
\end{aligned}$$

For problems with moderately complex attribute vectors, we have found that we can obtain high quality solutions using dynamic programming approximations by solving (at iteration n) approximations of the form,

$$\tilde{V}^n(R^n) = \max_x \left(\sum_{a\in\mathcal{A}} \sum_{d\in\mathcal{D}} c_{ad}x_{ad} + \sum_{a'\in\mathcal{A}} \bar{v}^{n-1}_{a'} R^x_{a'}(x) \right) \tag{23}$$

subject to,

$$\sum_{d\in\mathcal{D}} x_{ad} = R^n_a \quad \forall\, a\in\mathcal{A}, \tag{24}$$

$$R^x_{a'} = \sum_{a\in\mathcal{A}} \sum_{d\in\mathcal{D}} \delta_{a'} x_{ad}, \tag{25}$$

$$x_{ad} \geq 0. \tag{26}$$

This is a fairly basic model, but it is enough to illustrate the application (for a more complete description, see Spivey and Powell 2004). Problem 23 - 26 is a linear program, and returns a dual variable that we denote $\hat{v}^n_a$ for the resource constraint in Equation 24. In a real application, the attribute space $\mathcal{A}$ is large enough that we do not generate Equation 24 for each $a\in\mathcal{A}$. Instead, we might generate the equation only if $R^n_a > 0$ (for example). We can then update our value function approximation using

$$\bar{v}^n_a = (1-\alpha_n)\bar{v}^{n-1}_a + \alpha_n \hat{v}^n_a.$$

The problem we encounter, just as in the earlier sections, is that real problems might have attribute spaces with several million elements, and yet we can only run a few hundred iterations of the algorithm. Many of the attributes are never sampled, while others will have only a few observations. A small handful may receive dozens of observations. As a result, the statistical reliability of the approximations $\bar{v}^n_a$ can be quite low. The standard technique is to estimate the values at some aggregate level that trades off between the statistical reliability and cost of bias introduced by aggregation. The right level of aggregation depends not only on the specific attribute (some are sampled more often than others) but also on the number of iterations we have run the algorithm.

We tested our multilevel weighting strategy using this model to simulate the operations of a major truckload motor carrier. A detailed description of this problem can be found in Simao et al. (2008). The most disaggregate attribute vector used for the value function captured the location

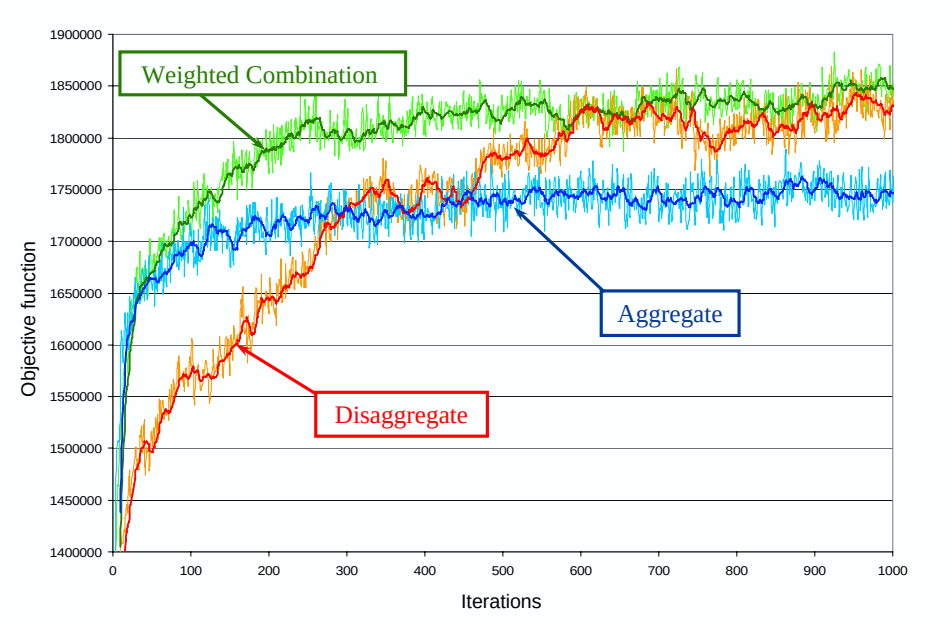

Figure 10: Comparison of using a single level of aggregation (aggregate and disaggregate) against a weighted aggregation strategy for optimizing a fleet of trucks.

of the driver (out of 100 regions), the driver's home domicile (out of 100 regions), and whether the driver was a single driver employed by the company, a contract driver, or a team (two drivers working together). At the most disaggregate level, the attribute space consisted of 30,000 elements. We considered an aggregate level which captured only the location of the driver (100 elements) and a hierarchical strategy that used a weighted estimate across four levels of aggregation.

The results of the experiment are shown in Figure 10. For this problem, a single iteration of the ADP algorithm can take 20 minutes. Even if we had confidence that the solution quality would never be better, improving the rate of convergence is extremely important. Since it is required to run this model continually to perform policy analyses, it would be extremely advantageous if we could reduce the number of iterations needed for convergence from 1000 to 200. As expected, if we use only an aggregate attribute vector, we obtain fast convergence but it levels off quickly. Using the most disaggregate representation produces slow convergence but it eventually reaches a better solution. By contrast, using a weighted combination of estimates at different levels of aggregation produced the fastest convergence and the best results overall. We point out that faster convergence to a better solution does not necessarily imply gains in running time. Even though the weighted combination strategy has a greater number of computations per iteration compared to static aggregation schemes, we have observed that the increase in running time for additional computations is not significant.

7. Conclusion

There is a vast range of problems that can be described as multiattribute resource allocation problems that can be modeled as stochastic dynamic programs. All of these problems pose the statistical challenge of estimating the value of a resource as a function of a potentially complex vector of attributes. Requiring no more than a set of aggregation functions which are typically quite easy to design, we have proposed an adaptive weighting strategy that produces an estimate of the value of a resource with a particular attribute. The weighting system is quite easy to compute, and is implementable for very large scale problems with attribute spaces that are arbitrarily large, since the computational complexity is a function of how many attributes you actually visit. The weights adjust naturally as the number of observations change. Thus, it performs well in the early iterations when there are very few observations. As more observations are made of particular attributes, the weight given to disaggregate estimates increases, producing higher quality solutions.

Our most surprising result was the finding that a weighting system that assumed independence of the estimates at each level of aggregation worked so well. This assumption is clearly not accurate. However, our analysis showed that it had little or no effect on the accuracy of a prediction. If the difference between a disaggregate estimate and the corresponding aggregate estimate was large, the weights produced by our approximation closely matched the weights that would have been produced had we properly accounted for the correlation. If the difference between the disaggregate and aggregate estimates was small, the weights could be quite different, but in this case it did not matter. The result is a weighting system that is easy to compute, scales well to very large scale applications and provides very accurate estimates.

An interesting possibility for future work would be to analytically solve for the optimal weights to combine estimates when there are more than two levels of aggregation. Further, the heuristic techniques that we have proposed could be applied to a broader range of estimation problems, not restricted to applications in approximate dynamic programming.

Appendix A. Proof of Proposition 1:

We first prove (8). The Lagrangian for the problem formulated in (6)-(7) is

$$\begin{aligned} L(w,\lambda) &= \mathbb{E}\left[\frac{1}{2}\left(\sum_{g\in\mathcal{G}} w_a^{(g)}\cdot\bar{v}_a^{(g)} - \nu_a\right)^2\right] + \lambda\left(1-\sum_{g\in\mathcal{G}} w_a^{(g)}\right) \\ &= \mathbb{E}\left[\frac{1}{2}\left(\sum_{g\in\mathcal{G}} w_a^{(g)}\left(\bar{v}_a^{(g)} - \nu_a\right)\right)^2\right] + \lambda\left(1-\sum_{g\in\mathcal{G}} w_a^{(g)}\right). \end{aligned}$$

The first order optimality conditions are easily shown to be

$$\begin{aligned}\mathbb{E}\left[\sum_{g\in\mathcal{G}} w_a^{(g)}\left(\overline{v}_a^{(g)}-\nu_a\right)\left(\overline{v}_a^{(g')}-\nu_a\right)\right]-\lambda &= 0 \quad \forall\ g'\in\mathcal{G}, \\ \sum_{g\in\mathcal{G}} w_a^{(g)}-1 &= 0.\end{aligned} \tag{27}$$

To simplify Equation 27, we note that,
